It is quite true that in competitive trials at the Royal Agricultural Society's shows the fuel consumption of the best portable engines working under the most favourable conditions for a short time is slightly under 2 lb. per indicated h.p. per hour, but this result can only be obtained by the most careful nursing of the fire by highly-paid skilled attendants who salt the fire, so to speak, with a slight sprinkling of coal at very frequent intervals. In any case we may safely say that with gas power the fuel consumption under ordinary working conditions is at least 50 per cent. less than with non-condensing steam engines of equal power. With gas there is the further advantage that it can be conveyed to any part of the works without appreciable condensation, that separate engines can be used for different lines of shafting, and that any department working overtime can have its engine supplied with gas from a single generator. With steam, however, there is much condensation if it be carried far, and much loss of fuel if a large boiler has to be fired to keep a small amount of shafting at work.

I have so far confined my remarks chiefly to the application of improved generator gas to motive power, and there is no doubt that the recent departure in this branch of mechanical science is one of great importance. I am, however, glad to add that a considerable advance has also been made in the use of this gas for heating of various kinds.

At the Gloucester County Asylum it has been in daily use for a variety of purposes for about five years. All the kitchen work for the staff and inmates is done with it, and there is no ordinary fire in the kitchen. About 300 quartern loaves are baked with the gas every day at a cost of about one shilling only for fuel. The gas is also used for two 12 h.p. (nominal) Otto engines, which pump water, and drive a dynamo for electric lighting. The average cost of the gas is about 2d. per 1,000 c. ft., including wages, repairs, and all incidental expenses, or about 8d. for the equivalent of 1,000 c. ft. of ordinary lighting gas. The anthracite costs about 13s. per ton.

This gas is used on a large scale at the cocoa works of Messrs. Van Houten & Son, of Messrs. Cadbury Brothers, and of Messrs. Russ-Suchard & Co. Careful trials at the first-named works showed that the cost was under 1¾d. per 1000 c. ft., or only 6½d. for the equivalent of 1000 c. ft. of the town lighting gas, with which comparative tests were made. The anthracite costs 16s. per ton.

Messrs. Onderwater & Co., of Dordrecht, use the gas for heating the drying chambers in their large starch works. Messrs. Guittet, of Herblay, have for some years used it for making varnish, and they not only effect a considerable economy, but they avoid risk of fire from the boiling over of the oil and gums, and this of itself is an important consideration in varnish works.

The gas is also used by the Société Nestlé for soldering their condensed milk tins, and more recently it has been adopted by Messrs. Huntley, Bourne, and Stevens, of Reading, not only for soldering biscuit tins, but for heating a large number of ovens in which japanned and varnished goods are baked.

Messrs. Hillman, Herbert, and Cooper use it at their Coventry works, and in Germany, for brazing with blowpipes the joints of bycicles and tricycles as well as for enamelling.

On the Continent several firms use the gas for singeing silk yarns and textile fabrics. It is also used by several linen manufacturers in the North of Ireland for stentering, which was formerly done with hot air.

This gas is also used for melting type metal, for heating hat forms, and for other work in a hat manufactory. It has also been adopted for glass-blowing in an electric-lamp factory, and for many other industrial purposes. I have, however, mentioned enough to show that gas of this kind can be and has been produced and applied successfully, and there is every reason to believe that its use will extend, especially as the gas-making apparatus is easy to work. I am not at liberty to state the annual saving effected by several firms who use the gas, but it is very considerable. The cost of the gas somewhat depends on that of the fuel and on the scale of working, but, speaking generally, the equivalent of 1,000 c. ft. of ordinary lighting gas costs from 6d. to 1s. Compared with solid fuel, gas has certainly many advantages—it is under complete control, the heat derived from it can be kept constant or varied at will, it is comparatively easy to insure complete combustion with but little chimney draught, it is more economical, and there is an entire absence of smoke. When solid fuel is used, it is necessary to introduce more than twice the quantity of air theoretically required for combustion, in order to drive away the products of combustion and to insure a sufficiency of oxygen being brought into contact with the surfaces of the fuel. This large supply of air can only be drawn in by a strong chimney draught or other artificial means, and this causes a very rapid withdrawal of heat from the fire. Further than this there is invariably some escape of smoke and partially burnt carbon in the form of carbonic oxide.

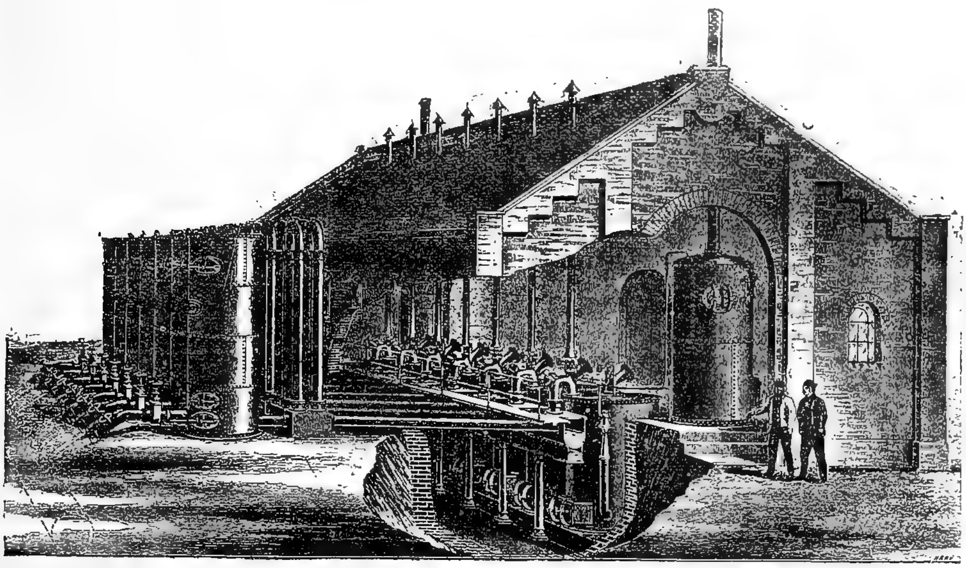

Fig. 3.—The Dowson Gas Plant on a Large Scale, as used at the Cocoa Works of Messrs. Van Houten and Son, Holland.

It is admitted that there is a demand for fuel gas, but for many purposes the ordinary lighting gas is too expensive, and the mere fact that it is made for lighting renders it so expensive. The percentage of illuminating constituents in coal gas is indeed very small —20 candle-power gas containing about 6½ per cent., and 16 candle-power gas, as in London, containing only about 4 per cent. The remaining 93½ or 96 per cent. is composed of non-luminous heating gases, but the addition of this small proportion of illuminants adds greatly to the trouble and cost of producing the gas, and any great reduction of its present cost is improbable. It is therefore rational to suppose that for fuel purposes the lighting constituents should be dispensed with.

Assuming that we have a good and cheap fuel gas there remains the question of how to apply it advantageously to whatever has to be heated, and here I regret to say difficulties often present themselves. It is one thing to have a combustible gas, but quite another to find suitable apparatus to be heated with it. Take for instance the case of a circulating boiler for heating a building—there is not one suitable for gas. There are a few very ingenious little boilers for heating a small quantity of water, but as it would be too costly to heat a large one with town gas there has hitherto been no inducement for boiler-makers to trouble about a large size. In fact, the pioneer of gaseous fuel not only has to provide the gas, but in most cases he has also to devise the means of using it for the different purposes required. I have often been asked if generator or water gas can be used economically for heating ordinary steam boilers, and I have always felt obliged to answer in the negative. I have seen examples of nearly all the water gas plants used in the United States and elsewhere, and I am aware that several attempts have been made to heat boilers with gas of this kind, but so far as my knowledge goes none of them have been successful from an economical point of view. In the first place, if the flames come in contact with the comparatively cool surface of the boiler, there is such a rapid withdrawal of heat that some of the gas does not attain the temperature necessary for its combustion. In the next place there is no overlooking the fact that there must be a considerable loss of heat when the incandescent mass of fuel is enclosed in a gas generator, away from the boiler, instead of being on a grate within, or immediately under the boiler. I venture to think that the true solution of this important question is to be found in the production of gas within the boiler itself, and not in a separate apparatus. The mass of incandescent fuel would then assist by conduction and radiation in heating the boiler.

Reviewing the subject generally, I think it will be admitted that if the progress made has not been rapid, it has at least been sure, and, judging by experience gained in several countries, I find that more attention is given to gaseous fuel every year. It is a subject, too, that is now much better understood technically than it was only a few years ago, and my belief is that every year will see gas more largely used. Speaking more particularly of my own contribution to the subject, it is only right that I should acknowledge my indebtedness for the encouragement I met with when I read my first paper on the subject in 1881. It has often occurred to me since that my own experience in this respect may be taken as a fair illustration of one of the practical advantages of the British Association meetings to a beginner, whose success must depend to a great extent on the help he derives from useful criticism and advice.

THE VOLCANIC ERUPTION IN JAPAN.

THROUGH the courtesy of the editor of the *Pall Mall Gazette* we are enabled to give our readers an account of this catastrophe, together with some illustrations of its effects. The correspondent of that paper writes:—

On the morning of the 16th instant the appalling news reached Tokyo that an enormous volcano had exploded somewhere in the north of Japan, killing and wounding a thousand people. Japan is the earthquake country of the world, but familiarity with cataclysms, as experience has shown, breeds anything but contempt, the moral effect of them being cumulative rather than diminishing; and this news was received with something like consternation, as possibly foreshadowing a general renascence of volcanic activity. The outbreak had occurred in a group of three mountains, in a remote part of the interior, forming part of the great volcanic ridge running north and south through the country, the chief of them being Bandai-san, situated on the shore of Lake Inawashiro, in the province of Iwashiro, in the perfecture of Ken of Fukushima, about two hundred miles north of Tokyo and midway between sea and sea. Besides the difficulty of obtaining accurate information, such an event is among the very rarest experiences of life, and a party was hastily formed to visit the scenes of the catastrophe. We left at daylight the next morning, and before we came back we had seen things to dwarf the most extravagant visions of a disordered imagination, and the mere memory of which is enough to render the solid earth unreal beneath one's feet. To attempt to describe them is to try to draw upon the heavens with one's pen.

One of the excellent lines of railway in Japan runs from Ueno, on the outskirts of Tokyo, nearly due north for 224 miles, passing through the province of Fukushima. Nine hours in the narrow-gauge cars, which are midway between the English and American models in their construction, brought us to the little town of Motomiya, which was the limit of the itinerary we had been able to determine upon before leaving Tokyo. From here we set out next morning for a ride of about thirty miles in jinrikishas to the village of Inawashiro, from which Bandai-san could be reached on foot or on horseback.

From the village of Iwanimura, which we reached at eight o'clock, every mile took us uphill and the landscape rapidly became more broken and rugged, until in two hours' time, when we ran into the village of Takatama, the country resembled the rolling foothills of the Rocky Mountains, except that instead of being bare and brown it was covered to the hill-tops with brilliant verdure. Here we received our first information of the eruption. A terrible noise, the people said, had reached them, lasting nearly an hour, and they had all deserted the village and fled, expecting to be overwhelmed. But the noise was all, and by and by they returned. At Takatama we were nearly half way to Inawashiro. Here the peasants were engaged in the culture of silk; hundreds of flat mat-baskets filled with bushels of cocoons lay about the houses, and through every door we caught a glimpse of men and women reeling the silk thread upon primitive wooden spinning wheels.

The road had now become very bad and hilly. Soon our men stopped at the foot of a broken ascent and pointing upwards told us that there was a short cut for us, while they must go round by the road. The climb was several hundred yards at an angle of forty-five degrees, by the side of a cascade which poured out of a round hole a few yards from the top. When we reached the top we found that this was fed from an irrigating canal four or five miles long from Lake Inawashiro, excellently built and bridged with stone and provided with admirable modern sluice-gates. That the remote parts of the country should thus contain public works of first-class engineering reflects great credit on the Japanese authorities. At our next halting-place, the village of Yamagatta, on the shore of Lake Inawashiro, the dark group around Bandai-san lowered more distinctly in sight to our right; and an obliging Japanese official, already on his way back from the scene, drew plan after plan of the catastrophe for us with his pen and little box of water-colours, as deftly and rapidly as only a Japanese can. At four o'clock we left him and pushed on round the lake, over a road so bad that it was constantly necessary to walk, until at last it degenerated into a mere path among the narrow paddy-fields.

On reaching Inawashiro at last, at the farther end ot the lane, we found that accommodation, not palatial perhaps, as the village is a small and poor one, but much the best to be had, was provided for us.

THE EDGE OF THE PRECIPICE.

The village of Inawashiro, from which we started next morning, is situated at the base of the volcano opposite to that on which the violence of the eruption expended itself, and therefore it escaped injury. It was up this uninjured side of the mountain that we proposed to ascend, and for the first five miles our road was smooth and shaded, leading us through pleasant ascents and between cultivated fields. Then we struck off into the short green scrub, and three miles of this, along a narrow track used by the peasants when cutting fodder for their horses, brought us to the beginning of the ascent proper. The climb now became really fatiguing; it was so steep that an alpenstock was almost necessary, and occasionally hands had to come to the rescue of feet; the path wound in and out round trees and over torrents and stones; recent rains had made it slippery with mud, and all the while a tropical sun was beating straight down upon our heads.

THE BRINK OF THE CRATER.

For an hour and a half, too, there were no more signs of a volcano than there are in Kent or the Catskills; then suddenly our leaders stopped short. We looked about us; there was a smell of sulphur in the air; the leaves at our side were coated with impalpable grey ashes; and there, within a few steps, was a small crater twenty feet wide, a conical hole blown out as though a hundred pound shell had exploded underground. The first burst had of course exhausted the slight volcanic energy at this point, and the bottom of the craterkin was entirely closed. Curiously enough, too, the explosion had been in a lateral direction, trees and shrubs having been blown away, and those left half buried in mud, while a fine tree directly over head was not only uninjured, but not even bespattered. It was only a small affair, but it was our first sight of the actual operation of the volcanic forces of nature, the most mysterious and dreadful forces that man knows, and a thrill ran through us as we stood around the mud hole.

Then we resumed our climb and half a mile more brought us to the midst of the volcanic activity. In every direction were crater-like holes of different sizes; the trees had been twisted off, and split and buried and hurled about; five or six inches of sticky grey mud covered everything; we sank ankle-deep in it at every step, and every now and then, as we still climbed, one of the party would struggle back as he found himself sinking deeper, and shout a warning to the rest to avoid the dangerous spot. Pools of dark yellow sulphurous water, small lakes some of them, had been formed wherever the soil was flat enough for water to rest, and of all the bright turf and foliage which had beautified the spot a few days before, not a single blade or square inch of green was left. It would be impossible—so, at least, we thought then—to imagine a more complete picture of utter desolation than this grey and stinking wilderness, all the more terrible that the form of landscape was vaguely preserved in it, just as a mutilated corpse is the more horrible because it cannot mask entirely the graciousness of the living body. Silently and laboriously, panting and perspiring, we plod upwards, watching every heavy step. We are in single file, a guide leading, and I am third in the line. Surely we cannot get much higher, for the mountain seems to end abruptly just above us. The guide is on the top, the man behind him struggles up, seeking a place for his feet. Then, as he raises his head, his body being half above the edge, he stops short like a man shot, and slowly and in an awe-stricken tone the words fall from his lips—"Good God!" Those of us below shout to him to pass on, and in irresistible excitement and curiosity we scramble up anyhow.

We found ourselves standing upon the ragged edge of what was left of the mountain of Bandai-san, after two-thirds of it, including of course the summit, had been literally blown away and spread over the face of the country. Or, to employ the terminology of geometry, the original cone of the mountain had been truncated at an acute angle to its axis, and we were standing upon the flattened apex of the resulting cone. It must be borne in mind, of course, that we had of necessity approached the focus of the eruption from behind, the volcanic energy having exerted itself laterally and not vertically. From our very feet a precipitous mud slope fell away for half a mile or more till it reached the level: at our right, still below us, rose a mud wall a mile long, also sloping down to the level, and behind it was evidently the crater, for great clouds and gusts of steam were pouring over it; beneath us on our left was a little table-land of mud, on which a few pools had formed. But before us, for five miles in a straight line, and on each side nearly as far, was a sea of congealed mud, broken up into ripples and waves and great billows, and bearing upon its bosom, like monstrous ships becalmed upon the fantastic ocean of some cyclopean nightmare, a thousand huge boulders, weighing many hundred of tons apiece. The sunlight was reflected in weird tints from the pools and lakes; one larger lake was all that was left of a river buried at a blow; where the mud had been coated with ashes it was of a dull grey tint, elsewhere in spots it was dark red; on one side of this awful expanse, a couple of miles away from us, a stretch of bright green meadows sparkled in the sun; on the other a dark pine forest showed how the sea of mud had rolled up to its foot and actually stopped there, almost touching the trunks of the trees; and straight in front of us, five miles away, we could just discern an exit into a long green valley behind which again rose the mountains, range upon range.

(To be continued.)

MUSEUMS AND THEIR ARRANGEMENT.

OUR contemporary, *Humboldt*, gives a very interesting summary of a memoir on this subject by F. W. Haacke. Leaving on one side collections of artificial products, he distinguishes four orders of true museums, in each of which he proposes a separation of the collections for scientific research from those intended for popular instruction. The popular department would consist of two main divisions. The first of these divisions would show the composition of the individual animal, of subordinate elements, cells, tissues, organs, and systems of organs. Where natural preparations are not to be had, their place must be supplied by drawings and models. Here also come collections illustrative of anatomy and ontogeny. Then would follow the faunæ of a meadow, a forest, a pool, the inmates of an oyster-bank, a bed of sea-weed, or a coral reef.

The second main division is made up of the systematic geographical and palæontological collections. The systematic collection gives a general view of the forms of the animal world in genera and families. The geographical collection should show the characteristic fauna of each main region, as described in Wallace's "Geographical Distribution of Animals." The palæontological division would show the fauna of each successive geological formation.

We may here pause and ask how many museums are there in the world which place at the disposal even of the professed naturalist, a system of collections such as Haacke hopes to display to the general public?

Haacke rightly insists that presents which are not in harmony with the purpose of the museum should be declined, as they take up room, of which there is always a deficiency, and involve useless work. A friend of ours, in visiting a provincial museum, was once most unpleasantly struck at seeing in a glass-case a pair of breeches which had been worn by a foreign nobleman who at one time resided in the district!

The four orders of museums are such as respectively embrace the products of the world, of an empire, a province, or a parish.

General Notes.

Sanitary Precautions in France.—The Consultative Committee of Public Health in France (*Cosmos*) has interdicted the use of benzoic acid as well as that of salicylic acid as an antiseptic addition to articles of food and drink. The committee has also decided against alloys of lead for capsuling bottles.

Volcanic Eruptions.—Advices from the Philippine Islands, *via* Hongkong and Yokohama, received at Queenstown on Saturday morning, state that over 300 lives were lost in those islands by the eruption of an old volcano, named Mayon, at the latter end of July. Several hundreds of houses were also destroyed by the lava and ashes, and the natives were in a state of panic. Volcanoes in the islands of the Bissayar group were also in a violent state of eruption, and it is thought there has been a terrible loss of life. The news was brought to Queenstown from New York by the *Umbria*.

Eruption of Stromboli.—Captain Hammond, of the steamship *Duchess of Sunderland*, reports that on the 12th inst., while on a voyage to Venice, he noticed that the volcano Stromboli was in a state of eruption. Ordinarily nothing but thin vapour is observed to proceed from the mountain, but on this occasion a huge flame eclipsed the stars. At an altitude of 7 deg. the upper portion of the flame burst into countless glowing particles. The deck of the steamer was covered with dust, and the steamer was enveloped in dusty cloud for a distance of ten miles.

Ascent of Mount Elburz.—On the 25th ult. the ascent of Mount Elburz was successfully made from the eastern side by Baron Ungern Sternberg. In notifying the event to the Tiflis Geographical Society, the Baron wrote:—"We set out at 11, and crossed the glaciers Iriktchat, Atrium, and Djelkaoughenkes, hitherto deemed impassable. At an altitude of 15,200 feet I discovered an enormous crater. We passed three nights on the mountain at the different heights of 9,000, 14,760, and 17,840 feet. At the last height we passed through a terrific snowstorm. Breathing was not attended with any great difficulty. The health of my men has been good. I descended by the southern side between Azaou and the Terek."

Discovery of Nuggets in Australia.—The *Melbourne Argus* states that a nugget, weighing 386 ozs., and estimated to yield 375 ozs. of pure gold, was, on July 23rd, discovered in the workings of the Burnt Creek Company, Dunolly. This is the largest nugget found since July, 1887, when one weighing 617 ozs. was unearthed in the Midas claim. Two months previously a nugget 169 ozs. in weight was discovered in the ground of the same Company. These are the three largest nuggets found in the colony since August, 1880, when one weighing 330 ozs. was found in Shicer's Gully, Wedderburn. A report was also received by the Secretary for Mines (Mr. C. W. Langtree) that a party of miners at Wedderburn, at 6 ins. below the surface, had dug up a nugget 44 ozs. in weight.

The Krakatoa Eruption.—The report of the Committee of the Royal Society appointed to inquire into the history of the great Krakatoa eruption is now in the press. It will contain an account of the volcanic phenomena of the eruption, and an essay on the nature and distribution of the ejected materials, by Professor Judd; papers on the air waves and seismic sea waves caused by the eruption, which, it will be remembered, was the most tremendous instance known in modern times. The general public will be most interested, however, in the report of the evidence collected from all quarters of the globe on the unusual optical phenomena of the atmosphere observed in 1883-86, including twilight effects, sky-haze, coloured suns, and coronal appearances, supposed to have been due to the presence of Krakatoa volcanic dust floating in the upper regions of the air.

Japanese Lacquer for Iron Ships.—The Japanese Admiralty has finally decided upon coating the bottoms of all their ships with a material closely akin to the lacquer to which we are so much accustomed as a specialty of Japanese furniture work. Although the preparation differs from that somewhat commonly known as Japanese lacquer, the base of it is the same, viz., gum lac, as it is commonly termed. Experiments, which have been long continued by the Imperial Naval Department, have resulted in affording proof that the new coating material remains fully efficient for three years, and the report on the subject demonstrates that, although the first cost of the material is three times the amount of that hitherto employed, the number of dockings required will be reduced by its use to the proportion of one to six. A vessel of the Russian Pacific fleet has already been coated with the new preparation, which, the authorities say, completely withstands the fouling influences so common in tropical waters. It occupied the native inventor for many years to overcome the tendency of the lac to harden and crack, but having successfully accomplished this, the finely polished surface of the mixture resists in an almost perfect degree the liability of barnacles or weeds to grow, while presumably the same high polish must materially reduce the skin friction which is so important an element affecting the speed of iron ships. The dealers in gum lac express the fear lest the demand likely to follow on this novel application of it may rapidly exhaust existing sources of supply.—*Scientific American*.

The International Meteorological Committee.—This committee held a meeting at Zurich, in the Polytechnikum, from the 3rd to the 5th of this month. The most important point on which action was taken was the subject of future meetings to be held instead of Meteorological Congresses organised by diplomatic means. The following resolution was adopted:—"The committee, in view of the circumstance that the assembling of an international meeting, of the same character as the congresses of Vienna and Rome, presents great difficulties, considers that the commission it received at Rome is exhausted, and that it ought to dissolve itself. At the same time, in order to continue the relations between the different meteorological organisations, which have been productive of such good results during a series of years, the committee appoints a small bureau, with the duty of using its best endeavours to bring about, at some convenient time, an international meeting of representatives of the different meteorological services." By a subsequent resolution the bureau was made to consist of the President and Secretary of the committee (Professor Wild and Mr. Scott). Among other matters on which action was taken may be mentioned Cloud

Classification. It was decided that the proposals of Messrs. Hildebrandsson and Abercromby were not ripe enough to be recommended for general adoption. Meteorological Information from Travellers.—On the motion of Dr. Hann, certain rules were laid down, to be recommended to all geographical societies, etc., as to the conditions which must be observed in order to render published records of meteorological observations of any real service to meteorology. These relate to instruments and their corrections, exposure, methods of calculations, etc.

Electrical Phenomenon.—A curious electrical phenomenon observed from the Danish steamer *Constantin* in the North Sea in February last, and its effect upon the vessel's compass, has been the subject of research by a Danish physicist, Herr Neergaard, from which we gather the following:—On February 10th, at 5.30 a.m., when 160 geographical miles off the Tyne, and steering E. ½ N., the weather being cloudy and variable with alternate calms and strong gusts of wind, the officers on watch observed two great clouds, whence flashes of lightning proceeded from time to time, approach each other, one coming from the N.E. and the other from S.W. Presently the clouds commingled, when a terrible clap of thunder rent the air, and a shock was felt on board the vessel so severe that all those on their legs below and on deck were thrown down, whilst the captain rushed on deck thinking that a collision had occurred. Simultaneously the vessel seemed to float in a sea of red fire and enveloped in red flames, whilst all protruding objects on board became tipped with a brilliant light. In a couple of minutes the red sheen disappeared, but for a long while afterward a strong smell of sulphur was experienced on board. The vessel was at the time steering straight on the clouds in question, and must have received the terrible electrical discharge full on the stem. However, all went well till the Scaw was reached, when it was found that through the phenomenon the ship's compass showed a deviation of 1 deg., but when approaching Copenhagen on the following day it was discovered that the deviation had really been altered from 6·5 degs. west to 3 degs. east. It is needless to point out the serious consequences such a deviation would undoubtedly have entailed at night.

The Public Health.—The Registrar-General's return for the week ending September 15th shows that the deaths registered during that period in 28 great towns of England and Wales corresponded to an annual rate of 17·7 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The 6 healthiest places were Oldham, Wolverhampton, Leicester, Hull, Sunderland, and Bristol. In London, 2,488 births and 1,331 deaths were registered. Allowance made for increase of population, the births were 217, and the deaths 77, below the average numbers in the corresponding weeks of the last 10 years. The annual death-rate per 1,000 from all causes, which had been 17·5, 16 4, and 16·0 in the three preceding weeks, rose again last week to 16·2. During the 11 weeks ending on Saturday last the death-rate averaged 16·2 per 1,000, and was 3·8 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,331 deaths included 27 from measles, 24 from scarlet fever, 18 from diphtheria, 31 from whooping-cough, 12 from enteric fever, 1 from ill-defined form of continued fever, 122 from diarrhœa and dysentery, and 1 from choleraic diarrhœa; thus 236 deaths were referred to these diseases, being 19 below the corrected average weekly number. No death from small-pox was registered, the corrected average being 6; no small-pox patients were under treatment in the Metropolitan Asylum Hospitals, and only 1 in the Highgate Smallpox Hospital, on Saturday last. In Greater London, 3,285 births and 1,671 deaths were registered, corresponding to annual rates of 31·0 and 15·8 per 1,000 of the estimated population. In the Outer Ring 34 deaths from diarrhœa, seven from diphtheria, and five from "fever" were registered. Of the fatal cases of diarrhœa, 8 occurred in West Ham, and 3 in Richmond sub-districts. The 7 deaths from diphtheria included 2 in Croydon sub-district.

The Faro of Maracaibo.—Something like an intelligible explanation of the singular phenomenon which has been known since the conquest of South America as the Faro of Maracaibo is volunteered by Consul Plumacher in a recent report from that interesting quarter of the globe. The phenomenon consists of constant lightning without thunder, which has been observed from time to time by travellers, southwards from the bar at the entrance of the lake. Several theories have been put forward to explain the strange occurrence, and Codazzi, in his geography, supposes it to be caused by the vapours arising from the hot water swamps, situated about a league to the east of the mouth of the Escalante river, at the southern extremity of the lake. Consul Plumacher, however, ascribes the Faro to the immense amount of inflammable gas given off by the flows and deposits of petroleum. Writing on the information of some explorers who have visited the place in search of *balsam copaibo*, and who call it the *Infernito*, or little hell, the consul furnishes a description of this unknown but exceedingly rich region. A very large portion of the department of Colon, situated between the rivers Santa Anna, Zulia, and the Sierra of the Columbian frontier, is an uninhabited forest, very rich in asphalte and petroleum. Near the Rio de Oro, at the foot of the Sierra, there is a very curious phenomenon, consisting of a horizontal cave, which constantly ejects, in the form of large globules, a thick bitumen. These globules explode at the mouth of the cave with a noise sufficient to be heard at a considerable distance, and the bitumen, forming a slow current, falls finally into a large deposit of the same substance near the river bank. At a distance of little more than four miles from the confluence of the rivers Tara and Sardinete there is a mound of sand, from twenty-five to thirty feet in height, with an area of about 8,000 square feet. On its surface are a multitude of cylindrical holes of different sizes, which eject streams of hot water and petroleum with great violence, causing a noise equal to that produced by two or three steamers blowing off simultaneously. For a long distance from the site of this phenomenon the ground is covered or impregnated with petroleum, and it is stated that from one only of these streams of petroleum a receptacle of the capacity of four gallons was filled in one minute. For one hour this would give a flow of 240 gallons, or 5,760 gallons in twenty-four hours. It is from this discharge that the gas, which Consul Plumacher considers to be the origin of the Faro of Maracaibo, issues.

SURFACE TENSION.

(*Continued from p.* 314.)

HITHERTO we have operated only on masses of liquid relatively considerable, and having only one free surface. We may now mention new instances of tension furnished by small masses having two surfaces in contact with the air and capable of producing effects of a much more striking character.

Fifth Experiment.—We take a litre of water in which have been dissolved twenty-five grammes of curd-soap and the same weight of sugar-candy. We plunge into it a wire frame, and then withdraw it. We find it occupied by a flat plate which seems to be without weight, so little is it bent. As it becomes attenuated, the contractile force of the two surfaces predominates more and more. Let us place upon this plate a closed outline of cotton or silk thread. It may take any form, because there is a liquid film both within and without. But as soon as we burst the interior film the thread becomes perfectly circular (fig. 5). This is the effect of the combined tensions of the two surfaces of the remaining film. The thread takes the form for which the surface which it bounds is as great as the length of the thread permits, that is, a circle.

Sixth Experiment.—My assistant, Professor Schoentjes, has endeavoured to modify this experiment, which I published in 1866. He takes not a simple thread, but a system composed of solid rectilinear portions, and portions of arbitrary form; according to Steiner's theorem, the maximum surface bounded by such an outline is found when all the portions of arbitrary forms are arcs of one and the same circumference of which the solid rectilinear portions constitute so many chords.

Prof. Schoentjes has realised such systems by means of cocoon threads passed into the small free channels of portions of the stems of fine graminaceous plants. Each time Steiner's theorem has been perfectly verified when one of these systems has been placed upon a plane liquid film, and the inner portion has then been burst. (fig. 5.)

The foregoing experiments have been made each with a single liquid. But it may be foreseen that if we bring in contact two liquids of different tensions there will be produced centripetal or centrifugal movements, according to the value of these tensions.

If the two liquids mix like water and alcohol, the tension of the surface of contact is null. Hence if we place upon water a drop of alcohol (2·5) or of ether (1·88), we observe a violent movement of extension, because the tension of water (7·5) greatly exceeds that of alcohol (2·5), or that of ether (1·88). After this spreading out the liquid retreats towards the point where it has been deposited. It is because the evaporation of the alcohol or the ether has cooled the subjacent liquid, which has thus a stronger tension than that of the more distant parts.

When the two liquids brought into contact do not mix, as, for instance, oil and water, the surface common to these liquids has also a tension which cannot be neglected.

If we place a drop of oil of turpentine (2·90), of oil of lavender (3·0?), etc., upon pure water contained in a large vessel, we observe at once a rapid diffusion of the drop, which is transformed into a very thin film, often presenting the most beautiful colours. This diffusion is due to the fact that the tension of pure water (7·5) is greater than the sum of the tensions of the oil and of the surface common to the two liquids.

As this rapid extension is accompanied by a fall of the temperature of the original drop, the film does not retain its form, but is subdivided into an infinity of very minute portions, forming sometimes small curvilinear polygons, and recalling the aspect of fine lace; this is what Mr. Tomlinson has called a "cohesion-figure." With oil of lavender the figure is soon broken up into a multitude of spots scarcely visible.

The application of one drop or of two drops of oil upon water is generally sufficient to render the extension of a new drop impossible. This is because the surface tension has become equal or inferior to the sum of the tensions of the oil and of the surface common to the two liquids.

Since 1869 I studied this kind of phenomena very carefully, though Signor Marangoni, of Florence, had,

FIG. 5.

unknown to me, already given the explanation. If, upon the surface of pure water, we deposit a small fragment of a solid body which is more or less soluble, the equilibrium of the surface of the water is destroyed, and if the act of solution takes place unequally on different sides of the fragment the latter presents abrupt movements of translation and of rotation.

Let us place, for instance, upon distilled water a flexible, closed outline (of thread), 25 or 30 centimetres in length, so that it touches the water on all its lower side without being submerged at any point. Let us then drop upon the surface of the water within the enclosure one or more small fragments of camphor. Immediately the fragments begin to rotate briskly, and to change their place, and the thread will arrange itself in a perfect circle. The interior liquid sometimes passes over the flexible outline at one or more points, when the entire circular film moves on the surface of the liquid. All these phenomena are due to the unequal distribution of the camphorated water, the tension of which is 4·5 milligrammes.

As regards the diffusion of oil upon water, I may be permitted here to mention an important application which I pointed out in 1882. Let us remember that per millimetre of length the surface of water experiences a tension of 7·5 milligrammes. Let us imagine a surface of water of one square millimetre, and ask what work must be expended in order to double this surface of one square millimetre. We have to overcome a series of small forces the sum of which is 7·5 milligrammes, and to cause all the points of application of these elementary forces to describe a track equal to one millimetre. But as the work is exactly equivalent to the product of the intensity of the force of the track traversed upon the right line where the force exists we have to effect here a work of 7·5 milligrammes-millimetres. This work expended will be found as available energy in the new square millimetre of free surface; it is this energy of 7·5 milligrammes-millimetres which I have called the potential energy of pure water. We must not forget that this energy resides in a layer of not more than $\frac{1}{20,000}$ millimetre in thickness. We thus comprehend than in the surface layer of the ocean there is stored up a mechanical power, of which nothing can give an exact idea.

I suppose now that of two surface layers, equal and in juxtaposition, the one glides over the other by the action of the wind. The layer which is completely covered, will have lost its free surface, and with it its characteristic potential energy. If the sliding is effected slowly, this energy will be replaced by an equivalent quantity of heat. But if the phenomenon takes place rapidly the lost potential energy gives rise to an increase of speed. If, therefore, the wind communicates to certain layers of the sea a greater velocity than it does to the neighbouring layers, the latter are covered by the former which in turn cover others more remote, and so on. This is why each wave in the course of formation is composed of portions whose velocities are greatest towards the top. When the wind is violent the acceleration of velocity produces upon each wave a crest which becomes more and more prominent, and which finally *breaks*.

Hence it follows that any cause which prevents the sliding of superficial layers of the waters of the sea one over the other, will constitute an obstacle to the gradual increase of the *vis viva* of the liquid masses.

But just such a cause is found in oil which covers the surface of the sea over a sufficient extent; in virtue of its low specific gravity it always rises to the surface and renders the sliding of one layer over the other impossible. This explains the seemingly mysterious efficacy of oils capable of being spread out in films of an incredible thinness (1-100,000 to 1-200,000 of a millimetre). As soon as this sliding of the layers is prevented the formation of the breakers so dreaded by ships is rendered impossible.

Further, this action of oils transforms crested waves into an even swell, as was pointed out even by Aristoteles, Pliny, and Plutarch.

The author, Professor Van der Mensbrugghe concludes his memoir with regretting that the use of oil at sea is not studied in Belgium.

EXPLORATION IN MOROCCO.

FROM communications received from Mr. Thomson, dated from the city of Morocco, July 22nd, it appears that by a series of surprises and cleverly-planned excursions he has been able to enter the mountain fastnesses of Morocco and do more than any previous traveller has done. From Demnat he made two extremely interesting trips into the lower ranges, visiting some remarkable caves and equally remarkable ruins, and one of the most wonderful natural bridge-aqueducts in the world. Geologically and geographically these trips are alike important. This was followed by a dart across the main axis of the Atlas to the district of Tiluit, which lies in the basin of the Draa. As the tribes further west on the southern slope were in revolt, Mr. Thomson was compelled to return to the northern plains. Starting once more, he crossed the mountains by a pass a little south of Jebel Tizah, ascended by Hooker, and reached Gindafy safely. He was able to make a trip up a wonderful cañon, which he declares rivals those of America for depth and grandeur, and ascended a mountain, where he and his party were confined to their tents until it suited them to go back to their starting point. Here Mr. Thomson's companion, Mr. Crichton Browne, was stung by a scorpion, and they were compelled to return by a new route.

From his previous starting point Mr. Thomson scored another great triumph. He crossed the mountains once more, and ascended with no small danger and difficulty the highest peak of the Atlas range north of Amsiviz, a height of 12,500—the highest peak by 1,500 ft. ever attained.

In a few days after the date of his letter Mr. Thomson intended to resume work. He proposed to make for the Urika river and penetrate the mountains up its course, then work his way round to Mogador, which he expects to reach about the end of August. He may then make one or two short trips into the interior and down to Agadir. The return route to Tangier will probably be from Mogador to the city of Morocco, thence to Mazagan on the coast, and on to Casablanca and Rabat. Then he will leave the sea again and go to Mequinez and Fez, reaching Tangier about the end of the year.

NOTES ON ESSENTIAL OILS.

HOP oil, distilled from Bavarian hops, has now displaced that prepared from lupulin, which it excels in richness and delicacy of odour, due to the absence of butyric and valerianic acids. It is a mistaken notion that this oil has narcotic properties.

Marjoram oil, from Spain, recently introduced into commerce, differs essentially from the oil distilled from German marjoram. It is recognized by its freedom from colour.

Pepper oil, used extensively in fortifying spices, is obtained as a by-product in the manufacture of piperonal (heliotropin).

Rose oil and rose water have been recently produced in limited quantities experimentally in Germany, near Leipsic. It is said that there are now under cultivation for this purpose 15 acres of land, and the results have been quite satisfactory. The German oil is superior to any imported. It congeals at 20° (68° F.), showing the presence of a larger proportion of the fragrant stearoptene than is contained in the best Turkish oil.

Betel leaves yield an essential oil (0·5 per cent.) of a brown colour, an agreeable, tea-like odour, and a burning taste. Its specific gravity is 1·020 at 15° C. It boils at 250° to 260° C., and consists of a phenol agreeing in properties and reactions with eugenol and an indifferent hydrocarbon. The leaves are used in India in catarrhal and pulmonary affections, and it is probable that they owe whatever therapeutic virtue they have to the essential oil.

Natural History.

THE PROTOPTERI AT THE MUSEUM OF NATURAL HISTORY, PARIS.

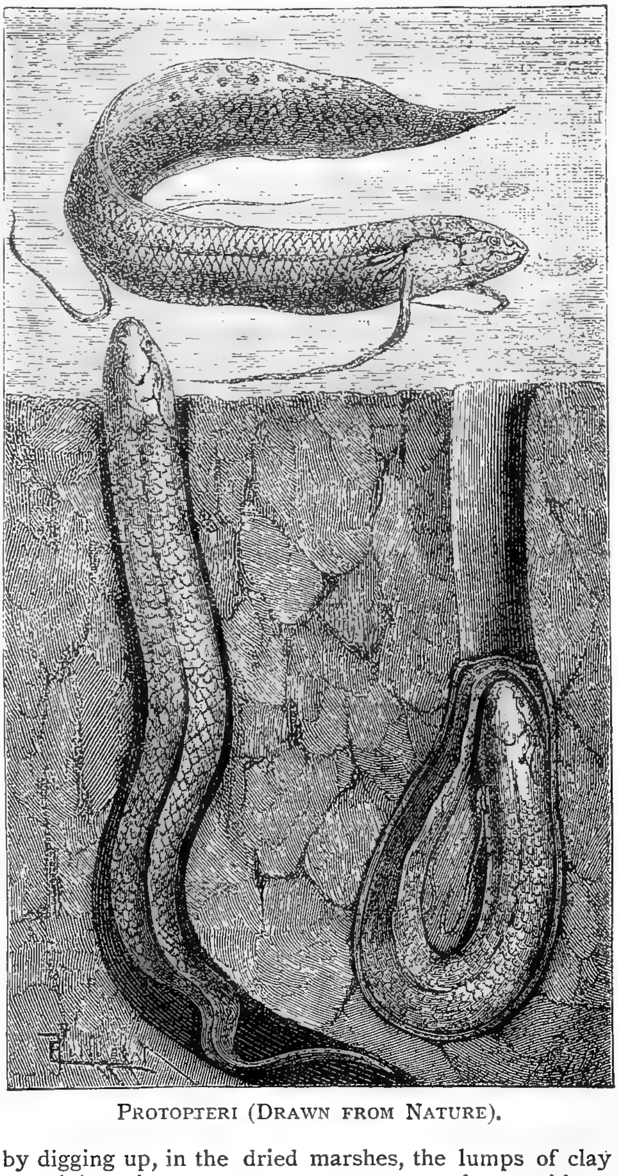
THANKS to the efforts of Professor Heckel, of the Faculty of Sciences at Marseilles (who must not be confounded with Professor Haeckel of Jena), the menagerie of the Museum of Natural History has just received a most curious fish, the *Protopterus annectens* (Owen), a creature the singularity of whose habits and the ambiguity of whose organisation have attracted the attention of zoologists for more than half a century.

The aspect of these worm-like creatures reminds us, to a certain extent, of that of an eel. They are covered with very distinct scales, and instead of symmetrical limbs they possess merely a sort of filaments fringed upon one of their margins. Of these filaments they make use rather awkwardly, sometimes when they float in the water letting them droop on each side of the body and sometimes giving them an undulatory motion apparently at hazard. According to our present knowledge there exists one only species of this genus, but it is widely distributed throughout tropical Africa from the Senegal to the coast of Mozambique and from the Upper Nile to the Ogoone. Those in the Museum are from the Gambia.

The habits of this fish have not yet been studied in full detail, though what we know is sufficient to excite curiosity. They inhabit the margins of great rivers, and especially the marshes formed by the periodical inundations in the rainy season. At this time the *Protopteri* lead an active life, swimming along the muddy bottom and feeding on small aquatic animals, or biting off, with their strong and scissors-like jaws, pieces of flesh from larger prey which they may seize. But the conditions of existence are soon greatly modified. The dry season sets in and the heat of the sun dries up the marshes. The animal knows very well how to accommodate itself to the novel situation. Knowing that the water will soon be deficient it excavates in the mud a cylindrical hole of a depth proportionate to its size, so that when coiled up laterally and the tail placed over its snout the latter may still be from ten to twenty centimetres from the entrance of the hole (fig. 1). There appears at the same time over the surface of its body a mucous exudation which hardens and forms a solid case, not easily penetrable in fact, a true cocoon. In this the *Protopterus* patiently awaits the return of better days.

The arrangement of the cocoon seems to indicate that it does not result from a simple cutaneous secretion, in which case it ought to produce a covering, having more or less exactly the regularly ovoid, elongated form taken by the fish. On the contrary, it represents a kind of bottle with a hemispherical end below, whilst the opposite extremity, turned towards the mouth of the hole, is covered with a circular lid, marked of from the rest of the cocoon by a very well-defined line of junction. This structure may perhaps be explained by a direct action of the fish, which elaborates its covering intentionally in a definite form, analogous to the procedure of certain insects. Still, it seems more probable that the result is purely mechanical. The mucous secretion forms at first a homogeneous case which adheres strongly to the mud wherever it comes in direct contact. Still, the upper extremity remains free. We comprehend that at the moment of desiccation the sides and the bottom will be kept in their place by this natural adherence whilst the free part will stretch, as does parchment if applied whilst moist to the mouth of a vessel, and will finally form a flat portion as if superadded to the case.

The *Protopterus* when once enclosed may remain dry for a longer or shorter time in a sort of lethargic sleep, comparable to hybernation, until it is set at liberty by the return of the rainy season. It is then very easy



PROTOPTERI (DRAWN FROM NATURE).

by digging up, in the dried marshes, the lumps of clay containing these cocoons to transport them without trouble and without any injury to the animal. Those which are now to be seen at the museum, after remaining six months at the Isle MacCarthy, have still remained dormant for five weeks on their journey to Marseilles and Paris.

This property, singular for a fish, of being able to pass so long a time away from its normal element, was, we might say, explicable even before we knew its abnormal habits. The first type known of the group is the

Lepidosiren, a very near ally of the *Protopterus*, from which it is distinguished by the absence of fringes on its natatory filaments. It inhabits the great rivers of South America, where it was discovered in 1837 by Natterer. Its simultaneous possession of gills and lungs was readily discovered, and the question arose whether this strange vertebrate was to be referred to the Batrachians or the fishes. Natterer, Bischoff, Milne-Edwards, Vogt, and Duvernay placed this animal in the former group, whilst Owen, Muller, Agassiz, and Peters referred it to the second.

Although this latter view is now generally accepted, we must admit that these ambiguous beings form between the two classes an intimate connecting link, well adapted to show us how artificial are our systematic classifications. It is easy to understand how, by means of this double breathing apparatus (whence the name of *Dipnoi* is given to the group) the *Protopterus*, as it may happen to require, may either use its gills or breathe air, being thus amphibious in the absolute sense of the word.

To induce these animals to resume their active life, we plunged the lumps of clay into water. The result was favourable; the next morning the survivors, about half of the lot, had abandoned their cells and were swimming freely in the aquarium.

One of them makes an exception. Since its immersion, three weeks ago, it refuses to quit entirely its tube. It is, however, full of life, for its head appears almost always at the aperture, but at the least alarm it hides itself with great rapidity.

Although this one alone has thus remained in this position, M. Leon Vaillant, from whose memoir in *La Nature* the above facts are borrowed, is led to believe that it shows us the normal habits of these animals. When they are observed swimming by means of the undulatory movements of their bodies they proceed with difficulty, and their long filamentous fins seem more embarrassing than useful. On the ground they make use of these organs to feel at surrounding bodies, lumps of clay, stones, etc., among which they glide along with a certain agility, after the manner of serpents or eels. On the other hand, being better adapted for attack than defence, in our aquariums they are often mutilated by their companions, who snatch away portions of their tail, skin, etc.—losses which are quickly reproduced. Perhaps the one which remains inside its tube is the most judicious, and may, like certain lower animals, lurk in its cell and snatch at any passing body.

The size which the *Protopteri* reach in their native rivers is considerable. M. de Brazza has found them above a yard in length and of the thickness of a man's arm. The largest of those in the menagerie does not exceed half-a-yard.

Whether analogous facts may be observed in the other Dipnoi is uncertain, especially whether they can use their double respiration and encase themselves. With the Lepidosiren the anatomical structure and the outer appearance speak in favour of this supposition, though we have no positive proof. With the *Ceratodus* of Queensland the matter is less probable as its lungs are very imperfect.

A New Parasite.—Professor Baelz (*La Nature*), of the University of Tokio, has detected, in the liver of some of the native Japanese, parasitic worms resembling the "flukes" so often found in the livers of sheep. This new species has received the name *Distoma Japonicum*. Its life-history has not yet been studied, but its geographical distribution is most remarkable. It is endemic in the centre of Japan in two very limited regions, where it is a real public calamity. These two regions have a swampy soil, and the inhabitants, who are attacked in the proportion of 20 to 50 per cent., drink an impure and very saline water. In the remainder of Japan this parasite is very rare in man, but it has been found in the liver of cats at Tokio.

Cuckoo Hatching Her Eggs.—The notion that the cuckoo is incapable of incubating, and that she of necessity lays her eggs in the nests of other birds, is incorrect. Herr Müller, forest-superintendent, of Hohenschied, in Germany, makes the following communication on this subject in the *Gartenlaube*:—On May 16th he found in the north-eastern portion of his district a cuckoo sitting on three eggs. Of these one was actually hatched. The bird proved a most attentive mother, feeding her young with small green caterpillars. Herr Müller is known as a careful and accurate observer.

The Origin of the Hottentots.—With reference to the Hottentots now on view at the Jardin d'Acclimatation M. Zaborowski (*La Justice*) maintains that this race is a cross between the Caffre and the Buschman. M. Topinard remarks that the Hottentot men have more of the Caffre character, whilst in the women the Buschman type prevails. The Buschmen pronounce six consonants with a peculiar "click," which no adult European can acquire; the Hottentots click four consonants and the Caffres only three.

A Vaccination Against Cholera.—M. Pasteur has just read to the Academy of Sciences a communication from Dr. Gamaleia, of Odessa, in which the author expresses his confidence that he has discovered a "vaccine" for Asiatic cholera. Having rendered the cholera bacillus intensely morbific by a passage through guinea-pigs, he finds that inoculation with an ordinary non-virulent culture of cholera renders the subject capable of resisting the intensified modification above-mentioned. He finds that this immunity is acquired without danger and without exception.

Action of the Ultra-violet Rays upon the Growth of Plants.—This subject, according to *Humboldt*, has recently been studied by Sachs, who cultivated nasturtiums (*Tropæolum majus*) behind glass vessels filled with a solution of sulphate of quinine, which cuts off the ultra-violet rays. The plants developed their leaves imperfectly, and did not flower. Other plants, grown as a check behind similar vessels, filled with water, grew, and flowered perfectly. Hence it appears that the solar spectrum has three regions differing in their physiological action: the yellow rays, which decompose carbonic acid, and effect assimilation; the blue and violet rays, which effect the mechanical processes of vegetation, in as far as these depend on light; and, lastly, the ultra-violet rays, which effect in the green leaves the formation of those principles which are necessary for the formation of flowers.

Humble Bees in New Zealand.—According to J. W. Dunning (*Transactions of the Entomological Society*), in 1885 about 100 humble bees were sent to New Zealand in two lots, and set free at Lyttleton. By the next summer they had penetrated as far as Timaru, West Coast Road, and Stenmark, and increased to an astonishing degree. The farmers find that their red clover is now exceedingly rich in seed.

Weight of Brain in Small Birds.—In the following following species the weight of the brain in proportion to the body is greatest. In *Regulus calendula* (ruby-crossed kinglet) it is one-seventeenth of the body; in *Parus atricapillus* (chickadee) one-seventeenth, and in *Setophaga ruticilla* (American red-start) one thirteenth.

Insect-eating Plants. — According to Prof. W. P. Wilson (*American Naturalist*), the appliances for the capture of insects are much more efficient in *Sarracenia variolaria* than in the more common *S. purpurea*. He considers that in the latter species the insect-feeding habit is disappearing.

Cure for the Bite of Vipers.—According to the Rev. Henri Dussart, of Saint Omer, a small glass of the juice of the burdock (*Arctium lappa*) taken inwardly effects a cure even in apparently desperate cases.—*Cosmos.*

Extirpation of the Vicuna.—The American Consul Baker (*Humboldt*), in a report to his Government, estimates the number of vicuñas destroyed yearly at a quarter of a million, and fears their early extermination unless protective measures are promptly adopted.

THE KAGU.—II.

(*Continued from page* 316.)

Little is known of the breeding habits of these birds, as up to 1885 not a single nest had ever been found by any reliable authority (although the natives, of course, have theories of their own upon the subject). The Kagus make apparently but little use of their wings, invariably roosting on the ground, with their heads either sunk between their shoulders or tucked under their wings, and although very expert in climbing up the wires of their cage when in captivity, they manifest but little interest in the higher vegetation of their native land, contenting themselves with the stumps and lower branches of the trees, and when alarmed, simply hiding in the brushwood. According to some later English settlers in New Caledonia, the Kagu is a nocturnal bird, a fact which its earlier biographers omitted to chronicle, though they all noticed that it was invariably more lively towards evening. It frequents the banks of rivers, small marshes and ponds, and especially the sea-shore, and it seems to have a great predilection for wet weather and heavy dews. It feeds on snails, worms, etc., seeking its food in all sorts of holes and corners, instead of patiently waiting, like its cousin the Heron, to seize its prey when in motion. It breaks the snail shells on a stone in much the same way as our English thrush. It never touches seeds, vegeables, or bread, even when in captivity, but will eat meat, if cut up small, and will devour worms to an amazing extent. M. Joubert used to employ natives to collect worms for his Kagu, and found that it easily disposed of about a quart per diem. The Kagu is very shy when wild, but once caught, is easily tamed and domesticated, especially if caught young, and it will adapt itself with surprising quickness to the habits of a poultry-yard. At Port de France, New Caledonia, there lived for some time a very tame pair of these birds, which were quite well-known and highly-respected inhabitants of the town. If a dog ever ventured to interfere with them, they would at once raise their crests, and vigorously flap their wings and otherwise show signs of anger until they had driven the intruder away, and they invariably followed workmen with digging implements, showing a quick appreciation of the laws of cause and effect, as demonstrated in the relations between spades and worms. As domestic pets, these birds should be held in high esteem; they are active and agile to a degree, and their pantomimic antics are so absurd that they could not fail to amuse any one at all interested in bird-life. The Kagu has a sort of Mark-Tapley-like faculty of accommodating itself to adverse circumstances, which is worthy of all praise. It presumably prefers liberty, but once captured, instead of idly bemoaming its fate, it briskly sets to work to make the best of a bad bargain, generally inaugurating life under these new aspects, if in company with other birds, by a rousing chase of its companions. It would be unjust to the bird (which, by the way, must be M. Ferdinand Joubert's "Kagu Bush" so-called, since he stigmatises the other member of the family as distinctly pugnacious)—it would be unjust, we repeat, to hastily dub this cheery little being as quarrelsome. He is merely mischievous, and extremely fond of teasing, but all in a good-natured way which seldom provokes the serious anger of even the object of his attacks. To rush with crest erect and wings outspread, at some peaceably-minded fowl, and chase her wildly round the yard, spurring her all the while with little twinges of her tail, seems to afford a Kagu the greatest possible pleasure, while at other times he will play with a piece of paper or dead leaf like the veriest kitten. Sometimes he will thrust his bill into the ground, spread his wings, and kick his yellow legs convulsively in the air, as though in the last agonies of a fit, and when some one, attracted by the unusual sight, hastens to his assistance, he promptly regains his equilibrum, and bowing gravely to the sympathetic spectators, walks off with stately mien and dignified gait as if in silent protest of the whole proceeding. A Kagu finding his breakfast is a decidedly entertaining sight. With his crest down, his wings smooth and sleek, he paces demurely along until he sights a likely spot, where, with becoming solemnity, he proceeds to gently tap the ground until a worm, probably alarmed lest the tapping should herald the approach of a mole, emerges at the surface to escape his underground enemy. Then, hey presto! the crest is jerked up, wings shaken out, and with evident approval the worm is swiftly swallowed. A few little jerks of satisfaction, a general shake of crest and feathers into their former sleekness, and with Puritan-like gravity Mr. Kagu steps daintily off to fresh fields and pastures new. Occasionally these comical birds will lay aside all their antics, and will parade soberly up and down their enclosure, bowing to their companions as they pass with a grace and dignity worthy of Sir Charles Grandeson, and with an air which seems to challenge admiration and defy criticism. All things considered, it it a matter of deep regret that a bird of such "infinite parts" should have been so ruthlessly sacrificed to the gourmands of its native land that it threatens to join the Dodo and the Epiornis in the unhappily steadily-increasing ranks of the extinct species.

DOMESTICITY IN ANIMALS.

THE existence of domestic animals suggests to us some curious questions, to some of which naturalists have not hitherto been able to furnish a rational answer. We may be asked why man has succeeded in taming certain species and not others? Why had the natives of the western hemisphere, when discovered by the Spaniards, practically speaking, no domestic animals at all, whilst nations of the eastern continent, not further advanced in civilization, had enjoyed the services of beasts of burden from the most remote antiquity?

Swainson and his followers cut the knot by asserting that animals of the rasorial type had been Divinely pre-ordained for domestication. These, therefore, man had succeeded in taming, whilst with all other species he has failed.

But if Swainson's "rasorial type" have been especially adapted for domestication, why do so many of them hold aloof? Take as an instance the common pheasant. This bird belongs to the same family as the barn-door fowl. The delicacy of its flesh has tempted man to reduce it to complete domestication, so that it might be bred in the poultry-yard. But no: on the approach of a stranger it shows none of the confidence of the domestic fowl, but flees for shelter to the nearest thicket.

Why did none of the aborigines of America domesticate the turkey? In Europe, as with the white settlers beyond the Atlantic, it has proved quite capable of tameness. Were not the ancient Mexicans civilised enough to have made the attempt?

Why was the American bison (erroneously called buffalo) never brought into subjection by the Red Indians? To them it would have been of great service as a beast of burden as well as for food. Mr. Swainson, to make his escape, pronounces the "ox the typical example of the genus bos, the bison the sub-typical." He adds that "no two animals can be more opposite in their moral character: the one is the most useful, docile, and tamable of the brute creation, the other wild, revengeful, and showing an innate detestation of man."

This declaration is at issue with facts. The bison shows no disposition to attack man unless molested. He is far less dangerous than the half-wild cattle of Texas, of the Falkland Islands, and of the Peramos of the Andes. To an unarmed man in an open country there are few animals more dangerous than the common bull. Further, the bison has been found to be readily capable of domestication. (J. A. Allen: *History of the American Bison*, p. 585). There is little inducement to multiply the tame breed, as the cows are not good milkers, but in the absence of ordinary cattle it would have been of value. It remains therefore a problem why the Red Indians did not have herds of tame bison just as the Tartars of the Asiatic steppes had their oxen.

Of the carnivorous animals which enter into domestication, the dog and the cat, Swainson pronounces the former to be the "rasorial type" of the carnivorous circle. But he vouchsafes no explanation of the tameness of the cat. This animal according to his theory should be hostile to mankind, yet no creature shows a greater craving for human sympathy. This is the more remarkable as it is not a social species, and shows very little liking for the companionship of its own kind. It is to be noted that several nearly allied forms, including the wild cat of Britain, seem hitherto quite untamable.

In like manner it may be noticed that certain wild Canedæ such as *C. dukhuensis and C. primævus*, have as good a right as the domestic dog to be considered as "rasorial types" of the carnivora. Yet they show little attachment to man and no dependence can be placed upon them, although they have been occasionally employed in hunting.

A very different attempt at finding some general principle is shown in the assertion that all domestic animals are naturally gregarious. To this rule the cat and the mungus are the only exceptions. But we cannot affirm conversely that all gregarious animals have entered into domestication. The wolf, the zebra, the baboon, the hyæna, and various other forms might serve for examples.

A very curious observation is that all the truly domesticated species, both of mammals and birds, are polygamous or at least promiscuous in their amours. We have here the only difference in habits between the ordinary inmates of the farm-yard and the pheasants. The common cock, the turkey, and the guinea-fowl are feathered Mormonites, whilst the pheasant adheres to one mate. The same is the case with the mammalia. The ox, sheep, goat, horse, ass are all polygamous, whilst the dog and the cat form no permanent connections, the nurture and defence of the young devolving upon the female alone. On the other hand, the fox, which lives in pairs, has not become domesticated.

But this attempted rule also breaks down on close scrutiny. The pigeon and the parrot are monogamous; yet the former lives contentedly in a state of tameness. Parrots if kindly treated and not startled by sudden and abrupt movements, must rank among the most docile and affectionate of creatures and have even been known to die of grief if separated from their owners. This is the more striking, as in their case domestication is the result of a single life-time.

Having thus set aside all these attempts at finding a general principle in the tamability of animals, we submit that the truth is much simpler than any of them. Any species, thought desirable, can be tamed if the attempt be made judiciously and perseveringly and if the animal does not break down in the process. It is curious that this view was put forward by St. James and was doubtless the opinion current in his time. In most cases, however, many generations must pass before the original wild nature is completely and permanently subverted.

It is a not unimportant fact that in ancient Egypt one species of antelope, or perhaps more than one, was kept in herds. Thus we see that the group of tame animals is not alike at all times.

There are at least three different degrees in the friendly relations into which the lower animals enter with man. In the lowest grade we find creatures which seek his near neighbourhood, not for plunder, as do rats, mice, and sparrows, but for safety. Such are the stork, the swallow, and the martin. Many more harmless and useful species of birds would enter into this class if nesting, ratting, shooting, and trapping were put under due restraint.

In the second class come creatures which are the property of men and which display a certain kind of docility, but which do not enter into companionship with man. Here we have all kinds of cattle and poultry. The horse, if kindly treated, may pass into the third grade.

In this highest class the animal is not merely the chattel, but the companion and friend of its owner. Here we find only the dog, the cat, the mungus, the parrot, and a few song-birds.

It is a curious fact that no ruminant animal can be admitted into this class; pet lambs, kids, fawns, etc., always grow vicious as they reach maturity, and have to be consigned to the butcher.

Reviews.

English Worthies. Edited by Andrew Lang.—Charles Darwin, by Grant Allen. London: Longmans, Green and Co.

Some time must still elapse before Darwin will have received finally and definitely his position in the history of science. If evolution among minds which from training are capable of judging rightly, be hailed as victorious along the whole line, Darwinism proper, which refers the origin of species to "natural selection," is less unreservedly accepted than was the case twenty years ago. Even the intellectual calibre and the moral character of the great biologist are still a subject of dispute. In strange contrast to the estimates formed by Huxley, Romanes, and the author of the work before us, we find the censures of S. Butler and Oswald Dawson, who fiercely accuse him of insincerity, hypocrisy, and of appropriating without acknowledgment the ideas of others.

It is sad that such differences cannot be for ever decided. Mr. Grant Allen is well qualified to write the scientific biography of his master. He represents orthodox Darwinism, and represents it most ably. So fully is he master of the art of charming to slumber the watchful dragons of British Philistinism, that to him is very largely due the acceptance which the doctrine of development now finds among the educated public. His general appreciation of Darwin's relation to his forerunners and his contemporaries is throughout masterly, often brilliant. We cannot, however, in all cases accept his views as here put forward. Thus he writes:—"From time immemorial, in modern Christendom at least, it had been the general opinion of learned and simple alike, that every species of plant or animal owed its present form and its original existence to a distinct act of special creation." That such an opinion prevailed in the last century we fully admit. That it had been from time immemorial generally accepted, we dispute. Mechanical creation is not to be found in the Church fathers, and seems to have taken its rise with Milton, Ray, and Raphael.

To certain remarks on Lamarck we must also take exception. Says our author:—"A bold, acute, and vigorous thinker, with something of the vivid Celtic poetic imagination, Lamarck went to the very root of the matter, etc." Now, if Mr. Grant Allen will examine, he will find that the opposition to evolution and to Darwin's reforms has been headed by men of Celtic nationality!

We notice with regret that Oken is here under-valued. Had Mr. Allen ever heard Oken lecture, or conversed with him, he would have found something other than "fanciful parodies of the Lamarckian hypothesis."

We notice the author speaking with scant respect of biological specialists. The butterfly-catchers and plant-hunters of the world can only be convinced by long and patient accumulations of facts. . . . It was easy enough to gain the ready adhesion of non-biological but kindred (?) minds like Leslie Stephen's and John Morley's; these might all, perhaps, have been readily convinced by far less heavy and crushing artillery than that so triumphantly marshalled in the "Origin of Species." But why? Because the biological specialists knew hundreds of difficulties which to men of the Leslie Stephen and John Morley type were unknown, and therefore non-existent! All the same Mr. Grant Allen admits that it is with the biological specialists that the practical acceptance or rejection of such a theory must ultimately rest. Perhaps, also, he forgets that the opposition to the new natural history was due not to working biologists, but to divines, ethicists, novelists, and other outsiders.

In the outset of Chapter VI. we find Alfred Russell Wallace spoken of as "a young *Welsh* biologist." Was this in anything beyond the accident of birth?

Much of what the author says on the "Malthusian principle" we must reject, as not in accordance with facts.

Very captivating is Mr. Grant Allen's summary of the fate of former philosophies which had ignored development. "Dogmatic Comte was left forthwith to his little band of devoted adherents; shadowy Hegel was relegated with a bow to the cool shades of the common rooms of Oxford; Buckle was exploded like an inflated windbag; even Mill himself was felt instinctively to be lacking in full appreciation of the dynamic and kinetic element in universal nature."

There are here points many on which issue might be joined; others, still more numerous, which might be brought into approving notice. But lack of space forbids, just as, perhaps, it has prevented the author from unfolding the causes of the general rejection of evolution in France, not as elsewhere by divines or ethicists, but by bureaucratic *savants*.

The Journal of the Franklin Institute. Vol. cxxvi., Nos. 751 and 752.

The most interesting paper in these two numbers is that on "Sanitary Science in the Home," by Mrs. R. H. Richards. The author concedes that "sanitary science"—she might better have said "sanitary art"—may be traced back for 2,000 years, to the hygienic formula of Hippocrates, "Pure air, pure water, and a pure soil." But it seems very probable that the hygienic precepts to be found in the Pentateuch and in the sacred books of the Buddhists are fragments of a knowledge of the laws of health fully on a level with our own, and greatly in advance of our present practice.

Mrs. Richards insists on sanitary reforms as being to a great extent an attempt to counteract the evils resulting from the existence and the increase of great cities. Whilst recognising the general correctness of this view, we must not forget that intensely, desperately unsanitary conditions may and actually do prevail in small villages and in scattered dwellings, be they baronial halls or labourers' cottages. The author, however, seems to us to misinterpret the crowding of population into urban districts. She quotes from a story by George W. Calle this remarkable passage: "They had done that dreadful thing which everybody deprecates and everybody likes to do—left the country and come to live in the city." Now, this view, as far as Britain is concerned, is a mistake. With us everybody does not "like" to come to live in the city. The stream flowing townwards consists of the poor who cannot find employment in the rural districts, or who fancy that in London they may earn higher wages. At the same time there is a stream of the wealthy flowing outwards, leaving the town and going to live in the country. We distinctly recognise city life as a *pis aller.* Our civilisation, in so far as it is a reality, would not be thrown back fifty years, as Mrs. Richards thinks, if the population were dispersed. But this is a subject not coming directly within our purview, and upon which, consequently, we do not wish to enlarge.

Heed should be given to a passage quoted from Dr. Wight, "The unsanitary conditions of school-buildings slacken the speed of educational progress more than one-third." Here is much truth, yet unsanitary conditions are not confined to school-buildings alone, but extend to educational systems which in pupil or teacher exact brain-work under the stress of anxiety.

The burden of Mrs. Richards's song, and a very praiseworthy one, is that the public must be individually trained in sanitary lore, and that they must be prepared to sacrifice whatsoever stands in the way. Till this is done legislation must remain a dead letter. Lastly, we must remember that the task of sanitary reform is not so much to increase the quantity as to raise the quality of human life. The "masses" of our great cities are an essentially morbid product, developed under unnatural conditions.

CUSTOMS OF SAVAGE RACES.

Lecture Delivered by Sir John Lubbock, M.P., F.R.S., to the Working-Classes of Bath.

(Continued from p. 319.)

THE lowest savages, indeed, appear to be entirely devoid of any belief in a future life. A friend of Mr. Lang's once tried to explain to an Australian the idea of a soul, but in vain he tried to describe a living entity, without a body, without arms or legs, or a mouth to eat. The native could not believe he was serious, and when he did realise it the more serious the teacher was the more ludicrous it appeared to the black, but when once grasped it is accepted with unwavering faith. The Ancient Britons are said to have lent money readily on promise of repayment in the next world. Not long ago a Hindoo thought he had been cheated out of 40 rupees, upon which, with his mother's full consent, he cut off her head in order that her spirit might torment the man who had robbed them. But a belief in the survival of the spirit is by no means the same as one in the immortality of the soul. In some parts of Polynesia it is supposed that the common people are mortal, and that the chiefs only go to the land of spirits; others think that while men have souls, this is not the case with women. Some negro tribes believe that their father and mother are still alive (for do they not visit them in their dreams?) but of their grandfather they say sadly, "*Amekwisha,*"—"it is finished." The firm faith of the New Zealanders in the existence of another world beyond the grave made it a serious thing to kill an enemy, for what was the result? Embittered by his defeat the dead man went to the land of spirits, prepared his revenge, and when his old enemy died took him at a terrible disadvantage. On the other hand, if a man was eaten as well as killed, there was an end of him—at least, of his separate existence. His spirit, strength, and courage were absorbed into, and appropriated by, the victor. Hence, in war, the conquerors were most anxious to eat any chiefs who had fallen in battle.

It is not an uncommon belief that as a man dies so he will rise again, and that this applies to the body as well as the mind. Moreover, the way to the land of spirits was long, dangerous, and beset with demons. Many perished on the way, and no one who was not in possession of all his faculties could hope to arrive in safety. So convinced were the Feejians of this, that as soon as a man felt the least sign of old age he was anxious to start on his long journey. Mr. Hunt tells us that one day a young man in whom he took much interest came to him and invited him to attend his mother's funeral, which was to take place the next morning. Mr. Hunt accepted the invitation and went. As he walked along in the procession he was surprised to see no corpse, and asked the young man where his mother was, when he pointed to a woman who was walking along just in front, to use Mr. Hunt's words, "as gay and lively as any of those present. When they arrived at the grave she took an affectionate farewell of her children and friends, and then submitted to be strangled." So general, indeed, was this custom in the islands that in many villages there were literally no old people, all having been put to death; and if we are shocked at the error which led to such fearful results, we may at least see much to admire in the firm faith with which they acted upon their religious belief.

In a great many cases there are supposed to be deities of Disease, of Misfortunes, and of Crimes. These wicked spirits naturally encourage evil rather than good. In one part of India, when small-pox was prevalent, there was a temple to the goddess of that terrible disease. An energetic friend of mine, who was sent as magistrate there, in spite of some opposition had all the people vaccinated. The disease ceased, much to the astonishment of the natives. But the Priests of the Goddess of Small-pox were not disconcerted. One morning they came as a deputation to my friend. They said, "We have made a mistake. We have worshipped the wrong Deity. You are evidently the true God of Small-pox," and they petitioned him to give them some emblem or representation of himself which they might enshrine in their temple. In fact, that mysterious problem of the origin of Evil which has exercised so many of the highest intellects, the savage solves by his creation of evil deities. We who are fortunate enough to live in this comparatively enlightened century hardly realise how our ancestors suffered from their belief in the existence of mysterious and malevolent beings; but among savages we find life still overshadowed and embittered by those awful apprehensions. From such evil beings sorcerers and witches derived their hellish powers. No one was safe. No one knew where danger lurked. Actions, apparently the most trifling, might be fraught with serious risk; objects apparently most innocuous might be fatal. In some cases an image was made to represent the persons whom it was wished to murder, and it was supposed that the destruction of the image involved the death of the victim; in others it was supposed enough to obtain a hair, or even a piece of dress, the destruction of which would involve that of its owner. In others, even the knowledge of a person's name was sufficient to place them in the power of the sorcerer. Hence we find that in many races a person's true name was kept a profound secret. As man, however, gradually became better acquainted with the world in which we live, his religious conceptions were raised, he was able to form a higher ideal of the divine nature, not only as respects power but with reference to morality also. The assistance which science has thus rendered religion has not, I think, been sufficiently appreciated. This truth by no means holds good with reference to the lower races only. Our own ancestors in the dark ages, long after they were nominally Christians, clung to superstitions which the light of science gradually enabled them to shake off. Gradually, however, the progress of knowledge freed us from this terrible dread. We do not, I think, generally realise how much our ancestors suffered from the overshadowing horror of this fearful superstition, and how much in this respect the advance of science has raised and purified, not indeed Christianity itself, but our appreciation of it. But however this may be, as regards the lower races, I think we see that as men have risen in civilisation, their religions have risen with them: they have gradually acquired higher and purer conceptions of divine power. Nevertheless, though there is much in the religion of savages which is erroneous and even grotesque, it is not less worthy of respect as an attempt to arrive at the truth and to fulfil a duty.

Some of you whom I have the honour of addressing this evening will, I have no doubt, have the opportunity of observing savages in their native abodes. I trust I may express the hope that if so, you will avail yourselves of every chance of adding to our knowledge of this interesting branch of science—a science interesting to the philosopher; still more to the Englishman, belonging as we do to an empire which comprises many races of men, and people in every stage of civilisation; and one which is most encouraging in its results, since it appears to prove that, though there have been exceptional periods of degradation and decay, the history of mankind has on the whole been one of progress, and that we may fairly look forward to the future with confidence and with hope.

INTERNATIONAL GEOLOGICAL CONGRESS.

THE Reporter (Mr. J. E. Marr) of the British Sub-Committee on the Classification and Nomenclature of the Cambrian and Silurian Rocks, states in his report that "in the case of the Cambrian and Silurian, there is a pretty general agreement as to the position of the boundaries of the various series which make up the systems; but, on the other hand, it is hopeless to attempt any grouping of the series into these two systems which shall give satisfaction to all parties." After reviewing the opinions of the various authorities, he gives the following table embodying their views:—

Sedgwick	Murchison	Lyell and Hicks.	Lapworth.	Geological Survey.
Silurian	(1) Upper Silurian	Upper Silurian	Silurian	Upper Silurian
(2) Upper Cambrian	Lower Silurian	Lower Silurian	Ordovician	Lower Silurian.
(3) Middle Cambrian	Primordial Silurian	Cambrian.	Cambrian	
Lower Cambrian	Cambrian			Cambrian

(1) Murchison and Geological Survey include Lower Landovery in their Lower Silurian. (2) Upper Cambrian, nearly=Cambro-Silurian of some authors. (3) Includes Arenig, which is placed by Lapworth in his Ordovician, and by Lyell and Hicks in their Lower Silurian.

This subject gave rise to interesting and animated discussion, which took place on Tuesday the 18th September, at 10.30.

As all the reports were taken as read, the Chairman of the Committee (Professor Capellini) called upon Dr. Hicks to open the question, and the latter gave a short sketch of the origin and history of the difficulty declaring himself to be, as a pupil of Mr. Salter, and equally attached to the Geological Survey and to Cambridge, simply an independent seeker after truth. He laid stress on the point that there were three distinct faunas, the lowest being the one that he had so large a share in discussing, while the middle, the part about which the whole of the disagreements has arisen, is that containing the primordial fauna of Barrande. The division line between these is the top of the Tremadoc with its Olenus fauna, the Palæontological break being largest here. The Cambridge school, on account of the physical unconformity at the Llandovery beds, make their great division in the latter. Dr. Hicks proposed that Professor Lapworth's suggestion of Ordovician for the middle series should be adopted, as solving the difficulty and giving their own way to both the Geological Survey and the Cambridge School.

Mr. Marr, who began by expressing his regret at the absence of Professor Hughes and its cause, followed the same line of thought as Dr. Hicks, and supported the adoption of the term Ordovician. He, however, though that the Cambrian-Silurian rocks formed a whole so coherent and with such a common facies that a designation for the whole group would be of great advantage and proposed the name Barrandian in that sense.

Professor Lapworth, in an emphatic address, accentuated the views of the preceding speakers, describing, with the aid of a large section of the geological formations, the relative importance of each of the three great periods, and pointing out that as the Mesozoic was divisible into the two great Jurassic and Cretaceous groups, so the Palæozoic had two main divisions, the *proterozoic* (Cambrian, Ordovician, and Silurian) and the *deuterozoic* (Devonian, Carboniferous, and Permian). Against Murchison's classification he urged that Murchison's stratigraphical work was full of errors, and that where the latter had mapped a regular succession, he (Professor Lapworth) had traced an unconformity over a hundred miles, and that a large part of the Upper Caradoc had been completely swept away. As to the Taconic he had heard only two days ago that its fauna was quite below the Cambrian, and it was thus outside the question. In conclusion, he affirmed his belief that his own term (Ordovician) must inevitably be adopted, and that no result the Congress might arrive at would in any way affect its ultimate acceptance.

Mr. Walcott, palæontologist, United States Geological Survey, in giving the results of his work in America, stated that the true Taconic fauna of Emmens, or Olenellus fauna, containing 42 genera and 112 species, occurs below the Paradoxides fauna both in America and Europe. He supported the classification and nomenclature of Professor Lapworth.

Dr. Sterry Hunt, of Montreal, also supported Professor Lapworth's terminology, and said the Taconian was below Barrand's primordial fauna, and the Cambrian corresponded to the Urschiefer. He opposed Mr. Marr's suggestion of Barrandian as a mere personal name, and on that ground objectionable.

Professor Torell, Stockholm, did not accept the name

Ordovician, but kept to Murchison's classification, and desired to include in the Cambrian the Olenellus beds.

Professor Gosselet, of Lille, objected to the newer classification, because the fauna of the so-called Ordovician is so nearly related to the Upper Silurian. Professor Lapworth's protero and deuterozoic seemed to him also unwise, on account of the great development of the Devonian out of England, as in the Ardennes.

Professors Dewalque and Kayser spoke in the same sense.

Dr. A. Geikie, Director-General of the Geological Survey, referring to his long connection with Sir Roderick Murchison and the general acceptance of the views of the latter, stated that while he was quite willing to change his opinions on due cause being shown, he did not find a sufficient reason in this case. He expressed regret that Professor McK. Hughes, the present head of the Sedgwickian school, had been obliged to leave the Congress, and thought the question could not be settled in his absence. As to the term Ordovician, he considered it absolute nonsense, and thought the classification of Murchison sufficiently clear and well known.

Professor Blake, of Nottingham, who followed, was the first English member who used the French language, the previous English speakers' remarks, however, being, on the proposition of Professor de Lapparent, summarised in French in a most lucid and admirable manner by Professor C. Barrois, of Lille. While supporting Professor Lapworth's views, Mr. Blake would add a fourth fauna, that containing Olenellus, to which he would apply the name Monian.

Professor de Lapparent, of Paris, urged the desirability of deciding whether the Cambrian should only include fossiliferous strata or should extend down to the crystalline schists.

Mr. Delgado referred to the classification in three divisions adopted in the Portuguese map.

Mr. Hull objected to the term Ordovician, on the ground that there was no serious reason for its introduction, and because the Lower Silurian of Murchison had priority, besides being adopted all over the Continent.

Professor Barrois pointed out that the term Silurian, as used on the Continent, did not lend itself to synonymy, as it corresponded to both the Ordovician and Upper Silurian.

Mr. Gilbert, of Washington, U.S.A., desired to hear the opinions from all parts of the world. It was well, he thought, not to settle the terminology by reference to one locality only, and, if possible, only after extended investigation, as in each locality the limits of the beds were different.

As there seemed no prospect of a general agreement, the Chairman decided not to put it to the vote.

After referring to the death, since the Berlin meeting, of M. Fontannes, he made a proposition, which Dr. Sterry Hunt seconded, to send a telegram, in the name of the Congress, to Boella, the birthplace of Quintina Sella, the geologist, where a monument to the latter was to be unveiled on the following day.

On Wednesday the basis of the discussion on Crystalline Schists was supplied by eight monographs by authors of well-proved ability. Dr. Sterry Hunt communicated a paper on the crystalline schists, setting out with a summary of the theories on their origin. He pointed out that the geologists of our day are divided into two classes, as long as they admit for these rocks an igneous (Plutonic) origin, or an aqueous or so-called Neptunian origin. Among the Plutonists there are still two schools, the one regarding the foliaceous structure of these schists as due to the lamination of an igneous mass submitted to a strong pressure. For this school the crystalline schists as well as the granites, the trachytes and the basalts, are eruptive rocks. This manner of explaining the origin of the crystalline schists may be called the exoplutonic or volcanic. For the other Plutonian school, these same crystalline schists are the products of the consolidation of the igneous matter of the globe beneath a crust formed by surface-cooling; the schistous structure being the result either of currents established in the mass still liquid and heterogeneous, or of a segregation in the mass during crystallisation. To this second igneous school may be given the name Endoplutonic.

The Neptunists on their part are divided into several schools. Werner and his disciples believed that the crystalline rocks, both granitic and schistous, have been deposited successively from a universal ocean, which they conceive as a chaotic liquid holding in solution the elements of all the primitive rocks. This supposed derivation by a slow crystallisation from a primordial chaos may be named the chaotic hypothesis. Into this purely Neptunian hypothesis the notion of a fiery centre does not enter, but certain Platonists who admit this notion have devised a *thermochaotic* hypothesis, propounded by Poulett Scrope in 1825, and subsequently maintained by Daubrée.

Another Neptunian school was that of Hutton, who supposed that the crystalline rocks are derived from the consolidation and crystallisation, by the action of internal heat, of the sediments deposited by the water at the bottom of the sea, these sediments being the detritus, either of the endoplutonic or the exoplutonic rocks. This view, which the author calls the metamorphic hypothesis, has the defect of not taking account of the chemical changes which the bulk of the silicates undergo during the degradation of the crystalline rocks and their transformation into sands and clays.

Dr. Sterry Hunt, among these hypotheses, gave the preference to that of Werner. He did not, indeed, venture, in the present state of our chemical knowledge, to suppose all these bodies simultaneously present in solution, even at the elevated temperature which the thermochaotic hypothesis supposed. But he sought to conciliate with the known facts the notion that a great part of the primary rocks, both granitic and schistous, had passed through the state of an aqueous solution. To this hypothesis he gave the name *crenitic*. A full discussion of this view may be found in the author's work "Mineral Physiology and Physiography."

Professor Albert Hein discussed the classification of the crystalline schists. He concluded that the texture of the crystalline schists of the Alps had been variously modified by dynamo-metamorphosis.

Professor Lory examined the constitution and the structure of the mountain masses of crystalline schists of the Western Alps. He pointed out that a substitution of chloritic schists by protogine in the mountain mass of Pelvoux, as in that of Mont Blanc, presents itself precisely along the intra-alpine limit of the Mont Blanc zone, a limit marked by a grand fault, which may be followed for more than sixty leagues from Fallouise to Airdo. Between the two sides of this great fault are observed the striking contrasts of the rudimentary trias of the zone of

Mont Blanc, with the enormous development of the quartzites of Tarantaise and the Valais.

Professor J. Lehmann contributed a critique on certain recent researches and speculations on crystalline schistous rocks.

Dr. A. Michel Levy discussed the origin ot the primitive crystalline formation.

Dr. A. C. Lawson, of the Geological Survey of Canada, considered the Archæan geology of the region north-west of Lake Superior.

G. F. Becker, of the U.S. Geological Survey, treated of the crystalline schists of the coast ranges of California. He observed that the crystalline schists of the coast ranges are mingled with crystalline rocks which cover thousands of square miles. A great portion of these rocks were laid down as sedimentary during the Neocomian. Soon afterwards they were upheaved with extreme violence, and were subjected to the action of magnesian solutions, probably approaching to temperatures above the average, and perhaps approaching the boiling point.

Professor Lory, in opening the discussion, spoke on the crystalline schists of the Western Alps. He pointed out that they were composed of a regular series of *assises* of constant mineralogical characters. Their structure was independent of dislocations. One crucial observation for any one seeking to explain their mode of origin was furnished by the existence of crystallised silicates in the secondary and tertiary formations of the Alps; garnets, mica, tourmaline, in the schists of the Trias; and crystals of albite in the Eocene limestones. They were thus formed in the crystalline silicious rocks of every epoch. The presence of these crystals had no connection with the intensity of the mechanical movements, for they were even found in horizontal beds. The crystals were formed in each geological epoch shortly after the period of sedimentation, and their development was connected with the mode and formation of the rocks themselves, and depended upon the original conditions of the deposit. He agreed with the theory of the hydrothermal origin of the crystalline schists.

Mr. Mattirolo gave some interesting details about a metamorphic Permian rock widely distributed in the Western Alps and Apennines. It presented a gneissic-porphyritic structure, and he had classified it under the name of Besimandite.

Mr. M'Farlane declared himself a Plutonist, and read to the Congress his opinions on the origin of the crystalline schists.

Professor Issel insisted on the analogies which his observations presented with those of M. Lory. The schists and nummulitic limestones with crystallised silicates owed their origin to hydrothermal action. This most assured fact put us in sight of a rational explanation of the formation of the crystalline schists.

Professor Heim remarked that many questions presented themselves to any one beginning the study of crystalline schists. They had been subjected to general metamorphism, to modifications by contact, and by mechanical contortions. It was, therefore, an advantage to seek the key of the problem in the study of the transformed sedimentary rocks. In the two cases, in fact, common characters of structure might be observed—cleavages, entirely linear, surfaces, contortions, etc. These sedimentary formations, mechanically contorted into synclinal curves, contained crystallised silicates. They were analogous to those which were developed by metamorphism of contact; but they could not in this case be attributed to that cause. The extent of the mechanical phenomena was the predominant fact in the Alps, and it complicated the study of the subject. In the parts of the earth less affected by mechanical contortions one might hope to find an explanation of the origin of the schists.

Dr. Sterry Hunt declared himself to be a disciple of Werner. He believed that the old granites as well as the basic gneisses were of aqueous origin and were chemically deposited. This action had continued since the most remote period, and was going on at the present day with diminished intensity.

Dr. Hicks said that the crystalline schists, when they occurred over a great area, were, he believed, invariably of the pre-Cambrian age. He believed that the massive gneisses were originally igneous rocks which had undergone much change. The mica and chloritic schists he believed to have been formed mainly from volcanic ashes and muds. He admitted that rocks of volcanic origin could change at any period of the world's history into crystalline schists under favourable conditions, such as pressure, mechanical movement, and percolations of liquid. The detrital rocks would show certain important changes, but only partially simulated the older rocks. The porcellanites, quartzites, and clay slates were detrital rocks. Sediments repeatedly deposited gradually lost their power of complete changes, hence the crystalline schists were mainly of pre-Cambrian. The Pebidian rocks in Wales yielded most instructive evidence in support of the above views.

M. de Lapparent, who now occupied the chair in the place of Dr. Geikie, explained very summarily his personal views on the primitive formation. The formation had a distinct existence, it was independent of the following periods, and the explanation of its origin should be found in the combination of chemical, mechanical, and calorific actions carried on to their *maximum*.

Professor O. Torell explained that he had distinguished in Sweden two granites, one eruptive and the other ancient, passing into gneiss.

Mr. M'Pherson called attention to the regularity presented by the succession of three great groups of crystalline schists in Spain—1, granitoid gneiss at the base; 2, micaceous gneiss with limestone; and, 3, mica schists.

M. de Lapparent, in closing the discussion, referred to the facts collected in the published memoirs of the English Committee.

On Thursday the question discussed was, whether for the period immediately preceding the present, the term Quaternary should be used as of equal value with Secondary, Tertiary, etc., or the period should be called Pleistocene, and considered as merely a part of the Tertiary. The term Quaternary has found much more favour on the Continent than in Great Britain, where the Lyellian name, Pleistocene, is almost universally adopted. As might have been expected, the foreign geologists mostly were in favour of Quaternary. This, however, was not universal, Professor Renevier, of Lausanne, who began the discussion, adhering to the term Pleistocene as a division of the Tertiary. This opinion he held, because no important organic type marked the period except the appearance of man, and this fact would not be considered as fully established. The glacial period also is not characteristic of the period, because it began in the Pliocene, or perhaps before.

Professor de Lapparent thought that the very important event of man's appearance justified the separation of the period from the Tertiary.

M. Gaudry, the great French vertebrate palæontologist of Paris, also would separate the Quaternary from the Tertiary, the former being the present epoch in its fauna. As the Primary era was that of invertebrates, then that of fishes, the Secondary of cold-blooded reptiles, the Tertiary ot warm-blooded mammalia and birds, so the Quaternary is the epoch of the domination of man.

Professor Sacco, of Turin, in support also of the Quaternary, adduced the argument that a great movement of the earth's crust and a change of climate had taken place between the Pliocene and Quaternary.

Dr. Blanford agreed with M. Renevier in rejecting the term Quaternary, and joining the latter to the Tertiary. The introduction of the personal element, the appearance of man, into the question was to be regretted. He pointed out that in Asia the Tertiary was naturally divided into two great series, an inferior marine of 2,500 feet of eocene and miocene, and a superior terrestrial or freshwater series of deposits of 10,000 feet thickness from the Pliocene to the present day.

Professor Gosselet, of Lille, as an additional argument in favour of Quaternary, instanced the great development of fluviatile conditions and erosion of great valleys.

Professor Renevier objected to the importance attached to the appearance of man alone; besides, man probably appeared in the pliocene and perhaps before. No new organic type characterised the Quaternary.

Dr. John Evans was in favour of possessing a term to indicate the human period, without giving it an absolute value as compared with other epochs.

Professor de Lapparent added to his former remarks the following geological reasons for Quaternary:—The foraminiferal and nummulitic accumulations characteristic of the Tertiary; the great explosive volcanic phenomena of the Quaternary following the fissure eruptions of the Tertiary; and, finally the extraordinary development of glacial conditions in the Quaternary.

Professor Pilar, of Agram, supported the use of Quaternary as equivalent to anthropozoic, and of the same importance as cænozoic, mesozoic, and palæozoic.

The President, Professor Prestwich, agreed with Professors Gaudry and Lapparent in adopting the special term Quaternary. What is of importance in history, he said, is not the long periods of time but great events, and the appearance of man was one of these. In addition to this, there were the production of cosmic phenomena and an important change of climate. He adopted for this quaternary period the term Pleistocene, and considered it as beginning with the base of the forest-bed, the epoch of the appearance of the last fauna, and the introduction of the present climate. It will thus be seen that Professor Prestwich uses Lyell's term Pleistocene, but separates it from the Tertiary.

On Friday the Chairman, in opening the proceedings, informed the Congress that an invitation, endorsed by all the American geologists attending the Congress, had been received from the City of Philadelphia for the holding of the next Congress (that of 1891) at Philadelphia.

The invitation was accepted by acclamation.

M. Hanchecorne then submitted to the Congress the first proof of a section of the international geological map of Europe, the preparation of which was decided upon at the Bologna Congress. The map is drawn on the scale of 1 to 1,500,000 from the most recent topographical documents furnished by the different nations. The geographical part of the work was done between the meetings of the Bologna and Berlin Congresses. The geological divisions traced on the sheet submitted to the Congress by M. Hanchecorne were adopted conformably to the decisions arrived at by previous Congresses. By the principle adopted with regard to the colouring, each great group is represented by one particular colour, and the different subdivisions by various shades of the same colour. The deeper colours have been chosen for the most ancient formations, a single exception being made in the case of the coal measures, which, according to long established custom, are coloured black. For the volcanic rocks it has been found necessary to vary the tints adopted according to the differences of age and of chemical composition (acid or basic). The sheet submitted, which was only a proof, and which was open for further improvements, bore twenty-four different shades of colours for the sedimentary rocks, three for the Archæan formations, and nine for the volcanic rocks.

Professor Prestwich, in the name of the Congress, presented his thanks and congratulations to the committee which had had the map in charge for the remarkable piece of work which they had submitted.

The discussion on the crystalline schists was then resumed.

Dr. Hull, on behalf of Mr. Kilroe, of the Geological Survey, presented some rocks from county Donegal remarkable for their double schistosity. The mica flakes were disposed in two main directions, in relation with two distinct periods of metamorphism. Dr. Hull, speaking for himself, considered, as a fundamental question in the study of metamorphism, the distinction to be established between the results of mechanical agencies and hydrothermal agencies. The former had determined the foldings, cleavages, etc., and the latter the formation of new mineral combinations. Mechanical movements had assisted those combinations, but they had not produced them.

Dr. Sterry Hunt enumerated the three principal hypotheses proposed for the explanation of the origin of the gneissic rocks. One predominant fact was the distinction of different stages of crystalline schists and of their constant regular succession from the fundamental gneiss to the uppermost crystalline schists.

M. Gosselet believed that the metamorphic rocks of the Ardennes ought to be attributed to mechanical agencies; they could not be connected with the phenomena of contact. He differed from the opinions expressed by M. Lory. If, in the Ardennes, the more markedly broken and folded rocks were less crystalline than those which were slightly curved or horizontal, it was because, in the first case, pressure had produced a mechanical operation, and, in the second case, the mechanical operation had been converted into heat. Crystallised minerals, therefore, owed their origin to the action of overheated water contained in the rock.

Mr. Blake, in describing the crystalline schism of Anglesey, insisted on the action of pressure. The effects of pressure could not be misunderstood, and it was even possible to distinguish the effects of static pressure (schistosity) from the effects of dynamic pressure (false schistosity) when these two effects were successive.

Mr. Claypole referred to the different rocks of the Alps which contained crystals and organic forms.

M. Renevier drew attention to the determinations of fossils made by different *savants* in certain crystalline rocks of the Alps, of Norway, and of the Ural. He opposed the theory that supposed all the crystalline schists to be of Archæan age. They were generally pre-Cambrian, but in some regions of a more recent age, as in the Swiss Alps.

Dr. Sterry Hunt rejected the idea attributed to him, according to which the crystalline schists were without exception of the pre-Cambrian age. The formation of minerals and even of silicates had been carried on in all periods, but with a diminishing force. These crystallisations took place at all times under the action of mineralising waters—perhaps at the bottom of the old seas, perhaps in the neighbourhood of, or in contact with, the volcanic rocks. The pressure to which certain geologists attributed so important an influence on the phenomena would not be able to produce heat by itself. For that the movement must have been checked. The experiences of Spring had furnished the most evident proof that the most powerful pressures had not produced heat. It was the chemical affinities which gave birth to the minerals.

Professor Heim declared that the trunks of trees stated to be found in the gneiss of Switzerland were not found in the real gneiss but in the intercalated beds and in sericitic pseudo-gneissic rocks. In the same way the belemnites were found in the schistose rocks, containing albite, garnet, chlorite, and mica.

Colonel Delgado called the attention of the Congress to the graptolitic schists with chiastolite exhibited by him, and the modifications of which were due to the proximity of granite.

M. de Lapparent drew attention to the classical locality of the chiastolite schists with fossils—namely, Lobau in Brittany. From a general point of view he insisted on the power of pressure to develop heat, but if, as pressure, it was really incapable of this, it produced a movement instead when its effect was not checked by the absolute resistance of the wall. This movement, when it was not identical for all the elements, caused a friction, and the change engendered heat. However this might be, all metamorphic, mechanical, and chemical effects were limited in extent, and it was this which distinguished their results from that universal crystalline formation which lay at the base of all the formations.

Professor Lapworth called attention to the special point of view, based exclusively on facts, which had always been adopted by the English geologists. When present causes were sufficient there was no need to have recourse to other agencies. This was the school of Lyell, of Hutton, and of Darwin. The known evolution of organic nature at the Cambrian epoch bore witness to the fact that numerous periods had preceded. The sedimentary and eruptive rocks formed in those distant times were necessarily the most modified. In fact, the rocks of the most recent periods continued their process of transformation according as one descended in point of time and in depth of the formation. His personal researches in the north-west Highlands had shown him that the crystalline schists formed an inferior division to the palæozoic formations. He explained the sweeping modifications to which they had been subjected in accordance with the principles of Heim and of Lehmann—such as mechanical actions, volcanic injections, and others.

Professor Heim believed that the heat might be produced by shocks and successive movements analogous to those observed in the earthquakes of the present time. But the dislocations *en masse* of the contorted regions had not had this effect.

M. de Lapparent equally attributed a production of heat to the sliding of the particles, mineralogically different, over one another.

Mr. Callaway presented the result of his researches concerning the origin of the crystalline rocks of the north-west of England.

On Saturday M. Hanchecorne announced that he had received the geological map of Great Britain, for use in the preparation of the European map.

Professor K. von Zittel then gave the names of the gentlemen appointed on the American Provisional Committee for the arrangement of the next meeting of the Congress. The gentlemen were Messrs. Dana, Frazer, Gilbert, Hall, Marsh, Newberry, Sterry Hunt, and Walcot.

Dr. Persifor Frazer said that he was requested to give some explanations in regard to the invitation which he had presented to the Congress on behalf of the citizens of Philadelphia. The year 1891, in which the Congress would again meet, was the centenary of the University of Pennsylvania in its present organization, and great preparations were being made to celebrate this event. No doubt the occasion would draw together a large number of the men of letters and science best known throughout the world; and, besides this, the International American Congress would meet at the same time in Washington, and assurances had been received from some of its members that they would attend at the Philadelphia gathering. These facts furnished some of the reasons for the invitation to the Geological Congress to meet next at Philadelphia. The invitation was remarkable in the signatures attached to it. In addition to the mayor and the principal municipal officers, the Judges of the United States and State Courts, the professors of the Universities, etc., the presidents of the railways, and many others had joined in the invitation, so that there would be no doubt as to the warmth of the reception that would be accorded to members of the congress. The presence of the principal officers of three great railways insured that the expenses of travel would be reduced to a *minimum*. Excursions would be arranged to the Rocky Mountains, and to the gold and silver regions, to Georgia and North Carolina, to the great lakes, and to Canada.

Professor von Zittel expressed the thanks of the Congress to Dr. Frazer for his announcement, and felt sure that the Congress of 1891 would be successful.

M. de Lapparent then presented the report of the committee on the subject of voting. In order to avoid the inconvenience which might arise from the great numerical superiority of the members belonging to the country in which the Congress is held, the committee recommended that the votes should be decided in the following manner:—The votes of native members and the votes of the foreign members should be taken separately. If the votes of the two divisions were accordant, the result was to be accepted; but if they differed, the subject was to be considered immature for settlement. Matters purely theoretical should not be voted upon by the Congress. These recommendations were carried unanimously. M. de Lapparent then expressed his appreciation of the courtesy and respect for the individual which had been shown by the English members of the Congress. They had been in a sufficient majority to carry any proposition; but, instead of using their power, the London Congress had been signalised by the adoption of the foregoing rules for voting.

M. Capellini announced that the council had found it necessary to continue the International Commission on Nomenclature, although certain modifications of its functions had been made.

The Commission, which included representatives of all countries, chose M. Capellini for its president, and M. Dewalque for its secretary.

Professor Prestwich then delivered his concluding address as president of the Congress. He said:—We approach the end of the Congress and we can now congratulate ourselves upon the results obtained. The first sitting was devoted to the discussion on the divisions of the Cambrian and Silurian systems, and although no vote has been taken, the opinions expressed have demonstrated that all are in accord for retaining the three groups or zones of Barroude and Murchison. But the necessity is not seen of making, as some members proposed, the intermediate zone a separate system. Thus the *status quo* of the Upper and Lower Silurian for the beds as far as the Tremadoc, and of the Cambrian for the group below, will not be affected. Two sittings have been devoted to the discussion on the origin of the crystalline schists by hydrothermal chemical action or by movements, for each of which causes powerful arguments have been advanced. The Congress had received and printed in advance memoirs by eminent geologists, which will be valuable documents in the solution of this important problem. Another sitting took cognizance of the connection between the Tertiary and the Quaternary, the result of which is that, although opinions are divided, the majority of members approve of retaining the term Quaternary. Although in these cases votes have not been taken, the discussions had a great interest in the demonstration of the ideas which predominated among the most distinguished geologists. According to the resolutions adopted by the committee on voting, it will be easier in the future sessions to arrive at more positive conclusions. The reports which the Committee of Nomenclature has received from the national committees, and which are printed, are of great importance and will serve as bases for a more settled classification. The unavoidable absence of Professor Hughes is much to be regretted, since he took so active a part as President of the English Committee. It is to be regretted also that the great palæontological work of all the known fossils is about to be abandoned for the present, by reason of the great expenses which it involves. One of the most important objects of the Congress has been brought to a conclusion—the unification of colours and shadings in maps, and the Committee on the Geological Map of Europe announce to us that the publication of this fine map will not be delayed.

After the usual vote of thanks the proceedings of the Congress terminated.

STRANGE PHYSIOLOGICAL DEFECT.—It appears that some persons have a defect in the sense of smell, analogous to colour-blindness. An instance is known of such a person who cannot distinguish the scent of violets from that of garlic, though his recognition of other smells seems normal.

TECHNICAL EDUCATION NOTES.

AGRICULTURAL LECTURES.—The annual course of lectures on agriculture will be given at the City of London College, Moorfields, on Tuesday evenings, at 7 p.m., beginning on October 2nd, by Mr. Bernard Dyer, consulting chemist to the Essex, Leicester, and Devon Agricultural Societies. The lectures will treat of soils, plant life, manures, tillage operations, live stock, dairying, food, etc. The course will be in connection with the Government Science and Art Department, and will end in May. In addition to the college and other prizes, the Saddlers' Guild offers, as in former years, a prize of £5 5s. to the student who passes the best examination in chemistry and agriculture.

TECHNICAL EDUCATION IN THE POSTAL TELEGRAPH DEPARTMENT.—The thirteenth session of the Telegraphists' School of Science, which was established in the Central Telegraph Office in 1876, is about to commence, and a good and useful programme is announced, embracing classes in telegraphy, magnetism and electricity, mathematics, chemistry, workshop and laboratory practice, and a new and special course of instruction in relay and cable manipulation, the *raison d'etre* of this last class being the approaching transfer of the Submarine Telegraph Company's system to the Post-Office. The principal of the school is Mr. W. Slingo, who is assisted by three of his old pupils. The school is now a recognised portion of the Central Telegraph Office, and has for some time received considerable support from the Department, as indeed it should, seeing that it derives very material profit from the work carried on. Last year's classes were unusually successful, taking at the examinations of the Science and Art Department and the City and Guilds Institute eighty-one certificates, as compared with forty-one in the preceding year. In the Telegraphy examinations twenty-two certificates were gained by the school out of the seventy awarded throughout the kingdom. A valuable prize, consisting of a bronze medal and £3, was also gained. During the past five years thirty-three medals and £85 have been awarded as prizes throughout the kingdom; and of these, six medals and £24 have been gained by this school. In electrical instrument-making, the honours prize (consisting of a bronze medal and £5) was also gained by the school. Altogether more than 350 members of the staff of the Central Telegraph Office have passed through the school, and have gained upwards of 500 certificates.

CITY AND GUILDS OF LONDON INSTITUTE.—The classes at the Technical College, Finsbury, for the session 1889 will begin on Monday, October 1st. They are divided into five departments—viz. (1) Mathematics and Mechanical Engineering; (2) Electrical Engineering and Applied Physics; (3) Industrial and Technical Chemistry; (4) Applied Art; (5) Special Trade Classes. The classes are conducted both in the daytime and in the evening. The entrance examination for day students took place on Wednesday, September 26th, at 10 o'clock a.m. Scholarships of £30 a year each, and the Holl Scholarships of £20 a year, all tenable for two years, were awarded (in accordance with the several schemes) on the results of the entrance examination.

SCHOOL BOARD EVENING CLASSES.—We are asked to state that the seventh session of the evening classes for male and female pupils, conducted by the School Board for London, began on Monday evening, the 24th inst. As many as 16,320 persons received instruction in the classes last session. They are held in every district of the metropolis, and meet, as a rule, on three evenings a week, between the hours of 7.30 and 9.30. The subjects of instruction are reading, writing, dictation, spelling, arithmetic, book-keeping, drawing, grammar composition, geography, history, singing, algebra, mensuration, domestic economy, physiology, sound, light and heat, mechanics, magnetism, and electricity, etc. Special classes for instruction in French, shorthand, science and art (in connection with the Science and Art Department) are also opened where there are enough pupils. Where possible the Recreative Evening Schools Association, whose President is her Royal Highness the Princess Louise, illustrate the lessons by the magic lantern, and introduce such recreative and practical subjects as musical drill, wood-carving, modelling, etc. The work of the classes is made as interesting and attractive as possible, so that the pupils may spend pleasant as well as profitable evenings. The fee is, as a rule, 3d. per week or 2s. a quarter, or 3s. 6d. for the two quarters; and the payment of this fee entitles a pupil to attend the classes on the three evenings a week and receive instruction in any of the subjects, except those taught in special classes, where small extra fees are charged. Well-qualified teachers are engaged. Prizes and certificates are awarded by the Board.

Abstracts of Papers, Lectures, etc.

LIVERPOOL SCIENCE CLUB.—On the 14th inst. the members of this club visited the Ship Canal Works at Eastham, and through the courtesy of the contractors were taken over the ground in an open waggon drawn by a locomotive. The work of the steam navvies in the soft clay and sand, near Eastham, was very interesting, but before reaching Ellesmere Port the entire character of the work was changed by the appearance of the soft red Trias sandstone of the district. Gunpowder and other explosives took the place of the steam diggers, and the vast piles of rock on the banks showed the source of the stone for building the walls of the canal. The recently uncovered "Roman Road" was pointed out, and many other interesting sights, and the expedition was one of the most enjoyable of the season.

ANDERSONIAN NATURALISTS' SOCIETY. — The usual monthly meeting of this society was held on the 13th inst. in Anderson's College—Mr. J. Donochy, one of the vice-presidents, in the chair. The secretary read the reports of the society's excursions to the Whangie and the Falls of Clyde. At the former specimens of the bladder fern (*Cystopteris fragilis*) were found on the sides of the celebrated fissure, to view which the excursion had been undertaken. From the excursion to the Falls of Clyde fresh specimens of all the notable plants encountered were exhibited. Mr. W. A. Stevenson, junior, exhibited a collection of mosses from the Greater Cumbrae, arranged and named by the late Roger Hennedy, formerly lecturer in Botany in Anderson's College. Mr. R. Turner, vice-president, then read a paper on the "Cadzow Herd of White Cattle."

THE LEEDS NATURALISTS' CLUB AND SCIENTIFIC ASSOCIATION.—At the meeting on the 3rd inst., when Mr. G. Hainsworth presided, Mr. W. Clapham exhibited and explained the construction and mode of using several ingenious microscopical appliances he had made. He showed that in place of the more costly "spot lens" a very efficient substitute may be made from an artificial fish eye, which may be mounted in a tube to fit under the stage of the microscope. A very handy section-cutter or microtome was shown and explained. This consisted of the usual brass disc with a hole in the centre communicating with a short tube beneath, in which the object to be sectionised is placed, and up which it is pushed by a screw arrangement. Mr. Clapham showed that by means of a very simple yet perfectly efficient indicator, it was possible to produce sections of any required degree of tenuity down to the five-hundredth of an inch. Another section-cutter, made on the principle of the Cambridge rocking microtome, awakened considerable interest in the members, not only beause of its very evident "home-made" construction, but also, and chiefly, that by such rough means it is possible to cut sections of properly prepared substances so thin as less than the three-thousandth of an inch. Altogether a very pleasant and profitable hour was spent in the examination and discussion of Mr. Clapham's ingenious contrivances. The remainder of the evening was devoted to a number of interesting plants recently collected at and near Seascale, Cumberland, by Mrs. Stringer. Mr. W. Kirkby called attention to some special features of some of the plants, noticing particularly the sawwort (*Serratula tinctoria*), of which he gave the following note from Smith's "British Flora":—"This plant gives a yellow colour to wool, for which purpose Linnæus says it is much used in Sweden. Haller records, on the authority of some foreign writers, that the above colour, fixed by means of alum, is both beautiful and permanent, and with the addition of blue, makes a better green than either *Reseda luteola* or *Genista tinctoria* for dyeing wool or silk."

PHYSICAL SOCIETY OF GLASGOW UNIVERSITY.—The opening meeting for this session of the above society was held last Friday in the Natural Philosophy Class-room, when Mr. Maclean, M.A., president, delivered an address on "Electric Hypotheses." The lecturer discussed at some length the two-fluid theory, first propounded in 1733 by Du Faye, but improved and extended by Symmer in 1759; the one-fluid theory, first put forward by Dr., afterwards Sir William Watson, of England, and Dr. Benjamin Franklin, of Philadelphia; also the ingenious theory of Æpinus, of Germany, and Cavendish, of England. A summary of Faraday's views concerning the distribution of electric forces, as well as a brief *resumé* of the modern views of electricity, concluded the address.

RAMIE.—The subject of the utilisation of the China grass plant, also known under the names of rhea or ramie, has occupied attention for the last 50 years. It is a valuable textile plant, easy of cultivation, and presenting a vast and appropriate field for enterprise for planters in most tropical countries. The only obstacle to the development of an extensive trade in this product has been the want of suitable means for decorticating the plant. The Indian Government in 1869 offered the large sum of £5,000 for the best machine for extracting the fibre of ramie in a green state. No machine has fully answered the purpose, and hence at the present time, in view of the wonderful properties of ramie fibre, the subject is regarded as of the highest importance. It is followed both in this country and in the colonies with the keenest interest. As affecting India the question is of national significance, for the plant could be cultivated over vast areas and, with suitable machinery, be made to yield enormous profits. The French Ministry of Agriculture has taken up the subject, and at trials to be held at Paris on the 25th inst. it offered prizes of the value of 6,000 f. for any process or machine that would extract ramie fibre in commercial quantities. Mr. D. Morris, F.L.S., Assistant Director of the Royal Gardens, Kew, was appointed to represent this country at the trials, and to prepare a summary of the results for the information of persons interested in the subject in India and the colonies.

SALES.

The Charge for Advertisements in this Column is Sixpence for the first sixteen words, and Sixpence for every succeeding eight words.

Advertisements for this Column should be received by first post on Tuesday to insure insertion in the following number.

For sale, Brotherhood 3-cylinder Engine, 6 in. by 7 in., £7. (London).—Address, S., 45, Clarendon Road, Southsea.

For sale, double Launch Engine, by Plenty, 5½ in. by 5 in. £20.—S., 45, Clarendon Road, Southsea.

Greenhouse Stoves, portable, require no chimney, no fixing, cheap, and effective.—PETERS, BARTSCH, AND CO., Derby.

A number of Microscope Objectives, Opera and Field Glasses, Thermometers, for sale cheap.—List on application to A. DANCER, 3, Monton Street, Greenheys, Manchester.

Set 50, coloured Photographic Lantern Slides of London, 6d. each, sample 9d.—5, Hanover Buildings, Southampton.

Field Glass, by Steward, Strand, nearly new, cost 90s., bargain, 35s.—HOLMES, 13, Hollis Street, Leeds.

Proctor's "Star Atlas," and "Universe of Stars," 8s. free.—R. ROWLEY, 45, Camden Street, Derby.

Astronomical Telescope, 3¼ by Wray, 4 powers, finder, tripod stand, 240s. Cost £25.—GOAMAN, Bridgeland, Bideford.

Amateur Mechanics supplied with Lathes, Drilling, Planing Machines, Castings, etc. Cash, or easy payments.—Britannia Company, 100, Houndsditch, London.

Britannia Co. *Bona-fide* makers of 300 varieties of lathes, and other engineers' tools. Prize medals. Makers to the British Government.

Wanted, by two experienced Mechanics, Model Work to do at home (Mechanical or Electrical). Specialities and ideas worked out to drawings, scale, or size. Good workmanship guaranteed. Moderate terms.—P. R., 40, Westbury Street, S.W.

Practical Hints on Electro-Plating, etc. One stamp.—Address HENRIC, 234, Great Colmore Street, Birmingham.

Amalgamating Brushes, Scratch-brushes, Polishing Sand, Calico Mops, Rouge and Crocus Compositions, Nickel Salts and Anodes.—HENRIC, 234, Great Colmore Street, Birmingham.

Do your own Electro Plating and Gilding. System inexpensive. Particulars one stamp.—PERKS, 47, Alexandra Road, Richmond, Surrey.

Steel Name Stamps, 3d. per letter. Figures (set), 2s. 4d. Post free.—F. BALDWIN, Tuffley, Gloucester.

Meerschaum and Briar Pipes Repaired, Mounted, or Cased, ambers fitted.—W. GEORGE, 324, Essex Road, Islington, London.

Minerals, Fossils, Cretaceous, Liassic, Carboniferous, Silurian. 12 named specimens, 2s. 6d. free—CHAS. WARDINGLEY, Blackwood Crescent, Edinburgh.

Mica or Talc cut for all purposes. Mica chimneys, Mica covers, etc.—C. JOHNSON, 87, New Oxford Street, W.C.

EXCHANGES.

Exchange Notices will be inserted in this Column at the rate of Sixpence for the first twenty-four words, and Threepence for every succeeding eight words.

Advertisements for this Column should be received by first post on Tuesday to insure insertion in the following number.

Grand pair of coupled high-class model Beam Engines, bright and complete, fitted with pumps, governors, throttle valve, made regardless of cost by Lord Scarsdale's engineer, and made for work as well as show. Bargain. Half cash, half exchange.—295, St. Philip's Road, Sheffield.

New powerful Microscope, case, tongues, object-glass. Exchange for 3 in. Electric bell, new, or offers.—JOHN COLLINGE, John Street, off Cross Street, Middleton, near Manchester.

100 Geological Specimens, named. Exchange, 10s. Approval.—HOLDEN, Hoyland Nether, Barnsley.

SELECTED BOOKS.

Handbook of the Amaryllideæ. Including the Alstrœmerieæ and Agaveæ. By J. G. Baker, F.R.S., F.L.S., First Assistant in the Herbarium of the Royal Gardens, Kew. London: Bell and Co. Price 5s.

Electro-Plating. A Practical Handbook on the Deposition of Copper, Silver, Nickel, Gold, Aluminium, Brass, Platinum, etc., with descriptions of the Chemicals, Materials, Batteries, and Dynamo Machines used in the Art. By J. W. Urquhart, C.E. Second Edition. London: Crosby, Lockwood and Sons. Price 5s.

A Text-Book on Steam and Steam Engines. For the Use of Students Preparing for Competitive Examinations. By A. Jamieson, C.E., F.R.S.E., Prof. of Engineering, Glasgow Technical College. With 200 illustrations and four folding plates. Third Edition. London: Charles Griffin and Co. Price 7s. 6d.

NOTICES.

The Title Page and Index to Vol. I., now ready, price 3d.

Binding Cases for Vol. I., price 2s. each.

Cases and Binding, Vol. I., including Title Page and Index, price 3s.

Vol. I., bound in cloth, with Title Page and Index, 9s. 6d. —by post 10s.

The Back Numbers of SCIENTIFIC NEWS can be obtained from all Booksellers and Newsagents, or direct from the Publisher, 138, Fleet-street, London, E.C. Price 3d. each, or by post 3½d.

METEOROLOGICAL RETURNS

for the ten weeks ending on Monday, Sept. 17th, 1888. Specially prepared for SCIENTIFIC NEWS from official reports.

	Mean Temperature.	Rainfall.	Duration of Sunshine.
Scotland, East	53·7 degs., being 2·7 degs. below average.	6·2 ins., being 1·0 ins. below average.	300 hrs., being 58 hrs. below average
England, N.E.	55·0 ,, ,, 2·8 ,, ,, ,,	8·0 ,, ,, 1·8 ,, above ,,	260 ,, ,, 68 ,, ,, ,,
England, East	57·2 ,, ,, 3·4 ,, ,, ,,	7·3 ,, ,, 1·7 ,, ,, ,,	301 ,, ,, 83 ,, ,, ,,
Midlands ...	56·4 ,, ,, 3·6 ,, ,, ,,	6·9 ,, ,, 0·4 ,, ,, ,,	307 ,, ,, 46 ,, ,, ,,

CONTENTS.

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

In my last I discussed the series of changes which occur when a thin, filmy substance, such as a leaf or a dead butterfly falls upon a glacier of moderate slope, culminating in the complete perforation of the glacier down to its base by a *trou de cascade.*

The reader may have noted that I carefully specified a supply of *clear* water in the rill flowing into the baignoire. But the water of these glacier rills is not always clear, not usually clear, especially if it flows down the slope of the moraine ridge. On the Unteraar glacier, with its great medial backbone ridge of ice, rising as much as eighty feet above the general level, and coated with rock debris, all the rills that flow from this source carry with them more or less of the sand that results from the continuous disintegration of the rock fragments subjected to a succession of freezing nights and scorching days, such succession being one of the peculiarities of glacier climate to which many glacial phenomena are due.

One of these rills flowing during the summer daytime down the moraine slope into a baignoire and carrying with it the particles of rock deposits them at the bottom of the basin, where they accumulate. The effect of such a covering of the concavity is easily understood. It must put a stop to all further excavation of that portion of the basin which is so protected. The warmer sinking water can no longer continue scooping the bottom, though it may act on the sides. But the general surface of the glacier all around the basin is lowering daily. Supposing the baignoire to be five feet deep when this protection of the bottom begins to be efficient, and that the summer ablation proceeds at an average rate of two inches daily, what will happen at the end of thirty days?

It is evident that the deposit of sand or gravel will now become level with the surface of the surrounding ice, and its quantity will be considerable, as the deposition was continued during the thirty days. We shall thus have a pocket of sand of respectable depth imbedded in the glacier. But the sun goes on thawing the general surface, while that forming the bottom and sides of the sand pocket is protected. Thus the pocket or basin full of sand will presently be raised with its rim above the general level; it will stand upon a pedestal ring of ice. The sun, however, will not spare this pedestal, will thaw its sides and thus undermine the edges of the basin. This undermining will cause some of the sand to trickle over. This will coat the sloping sides of the pedestal and thus protect it.

It is evident that the supply of such protection to the sloping slides will slightly diminish the diameter of the basin itself; its own edge will become somewhat thawed all round. This action will be repeated daily, and as the surrounding surface of the ice continually thaws down lower and lower, the outspread of the protected base increases, and the summit basin diminishes in diameter by the thawing of its edges, until at last it contracts to a mere point, and thus a cone is formed which, as Agassiz says, appears so like a loose heap of rubbish that at first acquaintance one can scarcely resist the temptation to overthrow it with the foot or a stick, but in attempting to do so no little astonishment is excited by its firmness, which is explained on brushing off the surface sand, when a cone of clear ice, continuous with the bulk of the glacier, is revealed.

Schuttkegel (rubbish cones) is the name they have received from the mountaineers, and this is adopted by Agassiz, who refers to the fact that they were in 1840 practically unknown to science, though so interesting in their growth, and supplying, like the glacier tables, such clear demonstration of the surface thawing down of glaciers. They abound on the Zermatt and Unteraar glaciers, but are rare on other glaciers for the reasons already stated in reference to glacier tables.

They are not ordinary cones of circular (horizontal) section, but are all elliptical, the longer axis of the ellipse lying in the meridian of the place, and the southern slope of the cone steeper than the northern. The reasons for this I have already explained in connection with the glacier tables, meridian holes, and baignoires. Those that I saw varied from about one to three feet in height. Agassiz has found them ranging from a few inches in height to six and ten feet across at the base, and four to five feet high.

These are the monuments of the dead butterflies to which I first referred. Some readers may imagine that the idea of butterfly origin is rather fanciful, but such is not the case. A thin film is demanded—a leaf will do—but trees do not grow on glaciers, and the leaves that are carried there by the wind arrive at the wrong time—viz., in the autumn, when they are presently buried in the next fall of snow, and are decomposed before the next summer; but the butterfly is soaring just at the right season, and sometimes, aided by the wind, even crosses high mountain ranges alive, but more commonly alights and dies when above the snow-line or over glaciers.

In the course of our exploration we were conducted to a "crevasse" about three feet wide, on one wall of which some steps were cut in the ice. Descending these we arrived at "Fourc's Salon," or smoking-room. (Fourc was apparently the nick-name of a wag, a laughing philosopher, who took the lead in our excursion. If I am not mistaken, his proper name was M. Desor.) This salon was a cubical chamber, excavated in the ice at a considerable depth below the surface, and therefore was illuminated by the light which passed through its ultramarine roof and walls. The effect was very beautiful, resembling that of the blue grotto of Capri.

Here we had opportunity of studying the structure of glacier ice, which is visibly porous when closely examined. Water was slowly percolating downwards through these pores, and crawling in them were small shining creatures which, from lack of entomological knowledge, I was unable to identify; but I find that in my diary they are likened to the spring-tail lepisma that I had collected on the surface of pools in Battersea fields, in order to mount their scales as test objects for the microscope. I find now that this was not far from the truth, having just met with a foot-note on page 52 of "Untersuchen über der Gletscher," in which they are described as the *Podura nivalis* of Geer, or closely allied thereto. Their active existence in the midst of the ice proves that some kind of food must exist even in this unpromising habitat. I am very glad to have found this note by Agassiz, having seen no other notice of these ice-dwellers, and expecting to find myself in the position of an observer of the sea serpent, had I described them only from my own recollection of this single observation.

My present object in selecting this subject for Table Talk is to bring forward certain curiosities of glacial phenomena which have somehow been overlooked. One may read through a thick book like Geikie's "Great Ice Age," without finding a word about them. It is true that this is mainly devoted to geological agencies, but even in books on modern glacier phenomena they are scarcely noticed. Having done this, I leave the subject for the present, as my readers may have had enough of it.

Discovery of Ancient Relics at Kilmarnock.—A short time ago the workmen, in preparing the ground for the erection of a house in Tichfield Street, came upon an ancient urn, containing arrow heads, etc. Recently the president of the Glenfield Ramblers found a stone gouge near the place where an old coffin was got some seventy years ago. This gouge is made of serpentine rock, and is of fine appearance. It is 4 inches long, 3 inches wide, and curved at its cutting edges. According to authorities, it is not an Ayrshire stone. The thin edge has evidently been ground to a considerable degree of sharpness, and was probably used in gouging out the interior of an ancient canoe. It is intended that these ancient relics shall find a resting-place in the Burns' Monument Museum.

THE VOLCANIC ERUPTION IN JAPAN.

(Continued from page 334.)

A LITTLE table-land, below us on the left, marked the site of the medicinal hot springs of Shimo-no-yu, where a number of invalid visitors, forty or more in number, had been taking the waters, and now springs and visitors are buried under twenty feet of mud.

To find a spot sufficiently free from mud for us to sit down and open the tiffin-basket, we had to descend a few hundred yards. Then we returned to the same spot and climbed cautiously over the edge and down the slope, our object being to reach the top of the mud-wall I have described as being on our right, and from behind which the steam was rising from the crater itself. The mud was in great cakes and boulders, resting upon the great mass of it beneath—exactly, in fact, like a choppy sea suddenly solidified. The walking, therefore, or rather scrambling, was difficult, and the surface of the mud treacherous. By chance, when we had descended far enough in a straight line and turned off to the right to climb to the wall of the crater, two of us happened to be in advance of the rest. Slowly and cautiously we approached the edge, testing the masses of mud before us at every step. At last, side by side, and on our hands and knees, we looked over. The mud-wall upon the edge of which we stood, sank straight down out of sight into the depths of the abyss, and actually shelved in underneath us, so that we were suspended over the seething crater upon no support stronger than overhanging mud, neither solid nor tenacious. Needless to say that after a single brief look we beat a gingerly but hasty retreat. And none too soon, for there between us and the rest of the party was a long crack several inches wide. But that minute's look will never be forgotten by either of us. For a thousand feet the mud precipice rose straight up to our feet; the crater from which it sprang was probably a mile wide; from a dozen half-visible openings the steam was issuing with the noise of a distant waterfall, while the chief orifice of the crater was altogether hidden by the cloud of steam above it; and, whenever the vapour was dissipated for a moment, we could see the liquid mud at the bottom, apparently still seething in great disturbance and commotion. The colossal scale of it all, the more than Alpine precipice, the ocean of mud, the buried village, the heat, the steam, the noise, the attempt to picture in imagination the scene when the earth had been thus burst and riven and scattered and convulsed, and the solid land had melted and flowed out as the sea—all these combined to produce an impression of awe and stupefaction which nothing subsequent can ever efface, and with which no previous experiences of life afford the slightest comparison.

We were the first foreigners to make thus a rough but fairly complete examination of the scene of the eruption, and when we started for our long walk home later in the afternoon, we were in a position to say with some confidence just what had happened. These conclusions, we may say here, were confirmed and corrected by the narratives of the survivors, whom we interviewed the next day amongst the ruins of the villages at the foot of the mountain on the side opposite to that we had ascended. The main facts of the eruption are these: At the point of the manifestation of volcanic activity, the mountain range consists of three peaks, which are often spoken of together as Bandai-san, but consists properly of Bandai-san, 5,800 feet, a somewhat smaller mountain known as Sho-Bandai-san, and a third, larger again, called Nekomatadake. The eruption had taken place in the smaller central one of the three, and Sho-Bandai-san has disappeared from the face of the earth. The explosion was caused by steam; there was neither fire nor lava of any kind—it was, in fact, neither more nor less than a colossal boiler explosion. The whole top and one side of Sho-Bandai-san had been blown into the air in a lateral direction, and the earth of the mountain was converted by the escaping steam at the moment of the explosion into boiling mud, part of which was projected into the air to fall a long distance off and then take the form of an overflowing river, and part of which rushed down with inconceivable speed and resistless force, and poured over the face of the country to a depth varying from twenty to a hundred and fifty feet. Thirty square miles of country were devastated and practically buried by this eruption, a fact which places it, as I said, among the most stupendous on record.

Part of the Crater, showing Masses of Rock resting on Mud.

Importation of Scientific Books and Apparatus into the United States.—At the late meeting of the American Association for the Advancement of Science, a petition to Congress was adopted to place on the free import-list books pertaining to the physical, natural, and medical sciences and apparatus intended for the purposes of scientific research or of education.

THE ANCIENT INHABITANTS OF THE CANARY ISLANDS.

A Paper read by Mr. J. Harris Stone, M.A., before the Anthropological Section of the British Association.

About the time when printing was being introduced into England an old-time race of ancient people was rapidly and cruelly being exterminated. "The world forgetting, by the world forgot," they had lived in seclusion till then, the date of their advent being just as uncertain and ancient as their disappearance from among the races of mankind is precise and modern. In the whole history of the world there is, perhaps, no more remarkable fact than that at that late date of the Christian era when civilisation had so far advanced as to include in its scope amongst other signs of refinement, gunpowder and printing, there existed close to Europe, on islands in the Atlantic, remnants of peoples of the Stone, or may be even earlier ages. Yet such was the case. Whether or not the ancient inhabitants of the Canary Islands belonged to that extremely vague and misty period the "Stone" age, is a problem which may be left to others; but beyond all doubt as late in time as 1402 there lived in those islands a race very far removed in the upward scale from what we know as savage, a race presenting to us features of intense interest, a race till then virtually uncontaminated by external influences. These are statements which it is likely no student and traveller will deny. Traveller is thus purposely coupled with student, because for several reasons it seems advisable that besides a knowledge of their past history, the investigator should possess a personal acquaintance with each of the islands in order to intelligently and impartially treat this subject. Several grotesque and ridiculous theories and statements have seen the light about the Canaries and their ancient inhabitants, which would certainly not have been put forward had their authors ever been through the islands, and had noticed the present inhabitants, the configuration of the country, and the remains of the old inhabitants which are to be seen *in situ*. In the case of nearly all the writers on the Canary Islands, with one or two notable exceptions, a partial knowledge of the islands has proved to be misleading.

For example, Bory de St. Vincent, in a thick quarto volume, published in 1803, amongst other obvious blunders, states that the old inhabitants, whom he comprehensively and erroneously calls Guanches, buried their dead in pyramids destined to endure, like those of Egypt, for a number of centuries, and that the builders of the magnificent Egyptian structures were no more expert in architecture than were the Guanches. Now the student soon discovers that Bory de St. Vincent's large work is entirely a compilation from that of Viera, coupled with the result of *one night's stay* at Santa Cruz, in Tenerife. The pyramids, so strong, so lasting, so grand in architecture, have been visited by me. To lean against them would disarrange the loose stones of which they are composed, and they are about three or four feet in height. The epithet pyramidal might be applied to the rough and ready way in which the stones were thrown on the tombs in question, and some such rumour reaching the too credulous author doubtless accounts for his remarkable statement.

The same author also thinks that the Purpurariæ were Madeira and Porto Santo. The presence of orchil and inhabitants in Lanzarote and Fuerteventura, and their absence at that period in Madeira and Porto Santo, should have prevented Bory de St. Vincent falling into this error. Scant courtesy has always been paid to these islands by travellers.

Ogier, who could never have visited the ancient burial-places of the race, makes the following astonishing statement: "The Guanches had a temple which was long believed to be a tomb. It is a kind of stone pyramid in Gran Canaria, with respect to which we have no information of any kind. In this building, and in the shape of their temple, we can trace a similarity to the ancient pyramidal and circular constructions of Ancient Egypt and Karnac in Brittany."

Similarly Humboldt's description of Tenerife is very inaccurate and misleading. His long account is founded on a *three days' stay only* in the island, added to what he heard and had read.

Still more recently, the elaborate account of the whistling language of Gomera does credit to the inventive faculty of its German author, but it is not a contribution to our knowledge of that island.

I wish in the first place to show that this interesting people, up to the time of the conquest of the islands (1402 to 1496), incredible as it may seem, were ignorant of the use of metals.

In the collections of their remains which can be seen in the islands themselves there are no signs that metals were used. In the tombs and caves which I have visited no signs of metal remains were apparent, and history supports this conclusion.

In a narrative emanating from certain Florentine merchants (1341), and recorded by Boccaccio, we learn that the inhabitants of Canary "were shown some gold and silver money, but they were quite ignorant of the use of it, and they knew as little of any kind of spices. Rings of gold and vases of carved work, swords and sabres, were shown to them; but they seemed never to have seen such things and did not know how to use them."

Again, Azurara (1443) remarks that "their only weapons were a short club and the stones with which their country abounded; they made no account of the precious metals, but set a high value on iron which they worked with stones, and made into fishing-hooks," this was, of course, after they had obtained that metal from the conquerors, "they even used stones for shaving;" and further, that the people of Palma "fought with spears like the men of Tenerife, but pointed them with sharp horn instead of iron." Plenty of these spears are to be seen in the islands. Cadamosto, who wrote in 1455, during the conquest, says of the natives of Tenerife, "Their weapons were stones and javelins, pointed with sharpened horn instead of iron, and sometimes the wood itself hardened by fire, till it was as hard as iron." It must be remembered, however, that Cadamosto only visited Gomera and Hierro. His other information must therefore have been hearsay. The narrators of the conquest, in several passages in the course of their rather rambling narrative, clearly endorse the fact that the use of iron was unknown. When they arrived at Gran Canaria they induced some natives to come on board and exchange figs and dragons' blood for "fishing-hooks, old iron, and little knives," while with great *naivete* they continue, "The dragon's blood was well worth two hundred ducats, while what was given in exchange was hardly worth two francs." Then again, "The infidels have no armour nor any knowledge of warfare; they are not, therefore, to be dreaded like other nations." Again, of the isle of Hierro they say, "The men use long lances without iron points, for they have no iron nor any other metal;" and again, of the Canarios, "These people have no other weapons" (than stones), "and, believe me, they can throw and handle a stone much better than a Christian can." And the natives of Fuerteventura "had no armour, and were only clothed in goatskins and leather and could only retaliate with stones and wooden lances untipped with iron, although they did a good deal of mischief."

Many will join issue upon the assertion that up to the beginning of the conquest of the islands in 1402 the inhabitants had lived, to all intents and purposes, unknown to the world, and therefore unacquainted with the civilisation of the time, though the highest civilisation of that day was, it may be said, close at their doors; still, it may be maintained that the proposition is right, and that for three reasons. The recorded voyages before 1402 support this view, as do the remains of the ancient inhabitants which can be seen to-day, and also the physiognomy of the islands themselves—a factor the importance of which is considerable. Even during the conquest in 1446 we find an independent voyager who went there, Dinisianez da Gran, writing: "In fight they used no weapons but sticks and stones; their clothing upwards was skins, the lower part a covering made of palm leaves of divers colours. They took off their beards with sharp stone?"

Concerning the *very ancient* inhabitants of the Canary Islands we know nothing. They were peopled then by the souls of the blessed. The ancient poets delighted to dwell on those Elysian Fields, the resting-place of the happy departed spirits far beyond the entrance to the Mediterranean, on the banks of the river Oceanus, or on islands in its midst.

Homer says that, "there the life of mortals is easy; there is no snow, nor winter, nor much rain, but ocean is ever sending up the shrilly breathing breezes of Zepherus to refresh man." Hesiod and Pindar describe them under the name of the Fortunate Isles, but we learn next to nothing of their corporeal inhabitants. The earliest mention of the islands, not entirely partaking of the romantic halo so delightfully woven round them by Homer and other ancient authors, is in the treatise "De Mirabilis" about the year 250 B.C. The account there given, as also that by Diodorus, are no doubt taken from the historian Timæus, his authority being the Greek navigator Pytheas and the travellers' tales of Punic and other sailors. But it were only right to say that these accounts may equally apply to the Madeira group. I rather incline to the conclusion that, at any rate, the two easterly islands of the Canary group (Fuerteventura and Lanzarote) were included, because primitive sailors would come across them by coasting, the nearest island being only sixty miles distant from the west coast of Africa. For the same reason I still more strongly think that Lanzarote and Fuerteventura are alluded to in "Plutarch's Life of Sertorius." That general, Plutarch says, "crossed the Straits of Gades, and keeping to the right, landed a little above the mouth of the river Bœtis (Guadalquiver), which, running through a large track to discharge itself in the Atlantic Ocean, gives name to all that part of Spain through which it passes" (*Bœtica*, now *Andalusia*). "There he found some mariners lately arrived from the Atlantic Islands. These are two in number" (probably Lanzarote and Fuerteventura). "separated only by a narrow channel, and are at the distance of four hundred leagues from the African coast. They are called the Fortunate Islands. Rain seldom falls there, and when it does it falls moderately; but they generally have soft breezes, which scatter such rich dews that the soil is not only good for sowing and planting, but spontaneously produces the most excellent fruits, and those in such abundance, that the inhabitants have nothing more to do than to indulge themselves in the enjoyment of ease.* The air is always pleasant and salubrious, through the happy temperature of the seasons, and their insensible transition into each other; for the north and east winds which blow from our continent, in the immense track they have to pass, are dissipated and lost; while the sea winds, that is, the south and the west, bring with them from the ocean slight and gentle showers, which imperceptibly scatter plenty on their plains. So that it is generally believed, even among the barbarians, that these are the Elysian Fields, and the seats of the blessed, which Homer has described in the charms of verse."

"Sertorius hearing these wonders, conceived a strong desire to fix himself in these islands, where he might live in perfect tranquillity at a distance from the evils of tyranny and war."

This account, which bears internal evidence of relating to the Canary Islands, is the least hazy that we know of up to the date 82 B.C.

Pliny gives us a vague itinerary, drawn up by Statius Sebosus, about 40 B.C., in which, under the name of the Hesperides, five islands of the Canary Group are clearly mentioned.

Unfortunately for the Anthropological Section of the British Association, these old-world sailors, like their successors in more modern times, were not literary, and even if any of them did possess habits of scientific observation, they were not educated enough to commit their observations to writing. Hence our knowledge of the inhabitants of the islands in these times is most misty and doubtful.

King Juba II. sent out an expedition specially in

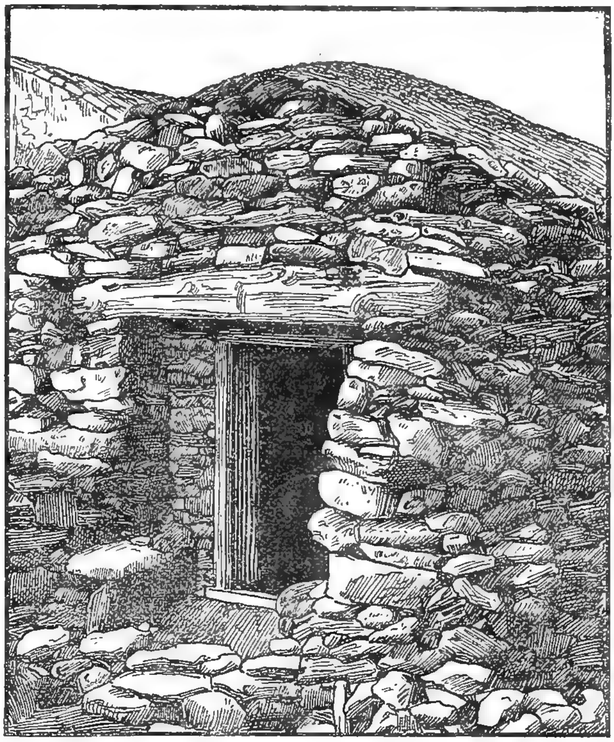

FIG. 1.—THE ONLY GUANCHE HOUSE IN THE ARCHIPELAOG, SAN BARTOLOME, TIRAJANA.

search of the Insulæ Fortunatæ, and finding the Canaries, named them from their characteristics thus: Ombrios (Palma), Junonia (Gomera), Nivaria (Tenerife), Capraria (Hierro), Canaria (Gran Canaria), while the name Purpurariæ was given to the two islands Lanzarote and Fuerteventura. From this time it might be thought we should have begun to learn something definite concerning the islands and their inhabitants. Owing to the destruction of the Roman Empire, and the pall of inertness and ignorance which settled over the civilized world, this gleam of knowledge concerning the islands faded away, and for no less than thirteen centuries they were practically lost, less being known and thought about them than in the days of Homer. In his time an interest in them was taken, even though that interest was of a romantic or semi-religious character, but now for thirteen centuries

* In a letter written in November, 1814, and published in Vol. I. of the *Pocket Magazine*, the writer, who dates from Fuerteventura, says, "There is a tradition in the island, of nearly three hundred years date, which indicates that the barren mountains were then covered with trees, like those of Tenerife and Canary."

no interest of any kind whatever was felt as to their fate. They seem to have completely faded away from men's thoughts.

The Portuguese were probably the re-discoverers. About 1341 the spirit of enterprise began once again to animate men's breasts, and the poet Boccaccio sets forth an account of a voyage made to the Canaries in that year under the direction of the King of Portugal. From this narrative we learn that the voyagers landed probably on Fuerteventura, but "they did not dare to penetrate far into the country." At Gran Canaria they saw apparently little of the inhabitants, for they say some of the natives "were covered with goats' skins coloured yellow and red, and, as far as could be seen from a distance," showing their intercourse with them was slight, the skins were fine and soft, and tolerably well sewn together with the intestines of animals. To judge from their gestures, they seemed to have a prince. Their language, however, was soft, and their pronunciation rapid and animated like Italian. The sailors went on probably to Gomera, but "ventured but a very little way into the country." They also sailed round Tenerife, but "did not dare to land."

From this important account, we plainly gather that the natives were anything but savage; that the islanders had no means of intercommunication, for they knew not the use of boats; and probably that the languages or dialects of the islands were so different that the natives of one could not understand the natives of another; still, the languages had some affinity to one another; that the sailors found the islanders anything but rich, for they "hardly covered the expenses of the voyage;" and that, finally, their intercourse with the islands when they did land was so slight and their journeys in those islands—if they left the shore, which may be doubted—so unimportant that their advent was scarcely felt. They were amongst the islanders altogether only some fifteen or sixteen weeks. It is probable that the Portuguese visited the islands on perhaps one or two occasions earlier than 1341, but no detailed accounts of the voyages have been discovered, and it may reasonably be supposed that they partook of the same superficial character as that to which allusion has been made. From this time to the commencement of the final conquest, which began in 1402 by Jean de Bethencourt, we know nothing of the ancient inhabitants of the islands. They remained as before, a simple, gentle people, unknown to the world at large, pursuing their usual avocations and having everything they wanted in their self-contained islands. Occasional expeditions from Europe, doubtless at rare intervals, reached their shores and kidnapped natives. Vessels manned by Genoese, Castilians, or Florentinos, corsairs, and adventurers in search of any kind of portable prey, whether dead or living, may have ravaged their coasts. But the natives at the approach of strangers would retire to their mountain-strongholds and fastnesses, where a handful could make an effective stand against a large number of assailants. The precipitous and rocky nature of the shores of most of the islands, the absence of natural harbours and anchorage ground, would have rendered, in those days, the coasts anything but favourable for vessels. Then again the natives never were a sea-going or sea-loving race. With most early races the sea was held to be evil and not to be trusted. They did not live much by the shores. Their great settlements were in the interior, in most inaccessible places. Hence the foreign maurauder would see little near the shore to tempt him to pursue his thieving propensity, or to again pay the islands a visit. And, besides, even the most successful adventurer obtained, in human cattle and goods, hardly sufficient to repay his outlay. Most of these spasmodic advents of civilisation must have been made at a loss. When the foreigners did meet the natives arm to arm, the latter could always give a good account of themselves; for they were lofty of stature, robust of limb, and of wonderfully healthy constitutions. Altogether it may be well imagined that the handful of men from a casual ship would think twice before engaging in hostilities with this vigorous race. The mere fact that it took the Spaniards from 1402 to 1496, and a vast amount of hard work and endurance before they were able to complete the conquest, is mutely eloquent of the courage of the natives. The configuration of the ground of the Canaries shows that it is almost everywhere admirably adapted to help the efforts of defenders knowing the country well. Even at the present day, a great portion of the islands is well nigh impassable, and the entrances to them difficult. In the narrative of the conquest we are continually reminded of this. Hierro "is very difficult of access, for it has no good port or entrance;" "the others fled and betook themselves to the mountains;" "the country is so inaccessible;" "they found it necessary to take off their shoes to pass over the slabs of marble, which were so smooth and slippery that they could only cross them on hands and feet, and even those who were behind had to hold the ends of their lances for the foremost to push their feet against, and they, when safely over, in their turn pulled the hindmost after them." This place I travelled over on a camel's back whose soft pads safely grasped the stones of the rough path now hewn, where on foot there might have been some danger of a fall over the precipice. "The forces from Seville, being unaccustomed to such rough ways, were greatly incommoded and harassed by the natives, who, being very agile, leaped from rock to rock with great ease (having been used to the exercise from their infancy), and galled the Spaniards in those narrow passes in such a manner as obliged them to retreat." And again Galindo succinctly remarks: "All the Canary Islands, except Lancerota and Fuerteventuras" (but he could not have known those islands well, or he would not thus signally except them) "are so full of deep and narrow vallies, or gullies, high rugged mountains and narrow difficult passes, that a body of men cannot march into any of them the distance of a league from the shore, before they come to places where an hundred men may very easily baffle the efforts of a thousand. This being the case, where could shipping enough be found to transport a sufficient number of troops to subdue such a people, and in a country so strongly fortified by nature?" And again, in Canaria, when the Spaniards, elated by a late victory, pursued the Canarians to the mountains, they defended themselves so well, by throwing stones and tumbling down loose fragments of rocks upon the enemy, that they obliged them to retreat, with the loss of twenty-five men killed and a great number wounded."

(To be continued.)

EARTHQUAKES.—According to a communication from Mr. W. G. Forster of Zante, there was a subsidence of the sea bed in the Gulf of Corinth, accompanying the earthquake felt in Greece on the 9th inst.

General Notes.

DRIVING BANDS OF CAMELS' HAIR.—It is said that, according to experiments made at the Polytechnic Institute of Munich, belts of camels' hair are superior to those of leather, hemp, etc.; that they work without noise, and are not affected by acids.

THE DESTRUCTION OF THE PHYLLOXERA AND THE HETERODERA SCHACTII.—M. Willot, in a communication to the Academy of Sciences, states these pests may be destroyed by solutions of common salt, though they are capable of resisting morphine, belladonna, atropine, strychnine, and curare.

A TRICYLE WITH SAILS.—The ancient Chinese invention of light carriages driven by the wind is now being successfully applied in Europe to tricycles. In open country, when the wind is favourable, the machine may be propelled even up moderate hills without any exertion on the part of the rider.

TEMPERANCE BEVERAGES.—According to the *Medical Press*, the Board of Inland Revenue have lately been examining so-called "teetotal" drinks, with some startling results. A sample of elderberry syrup contained more than 8 per cent. of proof-spirit; a "non-alcoholic" ginger cordial, more than 10 per cent.; certain "unfermented sherry" yielded 17 per cent.; and a "cowslip wine" no less than 28½ per cent.!

SOME RESULTS OF THE CANAL OF SUEZ.—Among the unforeseen consequences of the opening of the Suez Canal is a change of the climate of Lower Egypt, where rain, previously almost unknown, has become relatively frequent. Another result is less satisfactory; the sharks of the Indian Ocean have found their way into the eastern part of the Mediterranean and the Adriatic. Sea-bathing at the ports of Fiume and Pola is rendered impracticable.

THE DEPTHS OF THE SEA.—In the last report of the hydrographic service of the United States on the soundings effected by the *Albatross* in the Pacific along the coasts of Central America, mention is made of a line passing by 11° 45′ N.L. and 97° 3′ W. Long., where the water has a depth of 4,518 metres, or about the height from the sea-level to the summit of Mount Shastu, in California. Other soundings gave depths of only 90, 95, 104, and 110 metres.

NEW SCIENCE AND ART INSTITUTE.—Sir Charles Forster, M.P. for Walsall, recently opened a new science and art institute which has been built in that town. The ceremony of laying the foundation stone of the new structure formed part of the jubilation celebration last year. The total cost of the building, including furnishing and the fitting up of laboratories, is estimated at £5,500. Towards this, £4,000 was raised by subscriptions, and it was stated that with the Government grant and income derived from other sources the institute would be opened practically free from debt.

THEORETICAL ASTRONOMY.—We learn that Professor Newcomb is engaged on an important work dealing with theoretical astronomy. Its general object is the determination of the form, size, and position of the orbits of all the large planets of the solar system, from the best and most recent observations, and the preparation of entirely new and uniform tables for predicting the future positions of those objects The part of the work now far advanced comprises the four inner planets, Mercury, Venus, the Earth, and Mars, in which fourteen pairs of planets come into play. Twelve of these are completed. There remains but the action of Jupiter on Venus and Mars to be determined. All the observations at Greenwich from 1765 to 1811 have been reduced with modern data, and the work by Dr. Auwers dealing with an earlier period has also been embodied in Professor Newcombe's researches.

THE ENGLISH EXPLORING EXPEDITION IN MOROCCO.—The following telegram despatched from Mogador on September 19th, and transmitted by the Eastern Telegraph Company's cable from Tangier, has been received by the Royal and Royal Geographical Societies:—Left Morocco city August 27th. Driven back from Uricka-valley, but attained object by another route. Made an ascent of main range from Reraya, reaching nearly 13,000 feet. Skirted base of mountains to Imintanut, where we crossed by forced marches into Sous country, through tribes in revolt against Kaid. Nearly besieged in castle of Kaid of the Misgina by Howara in revolt. Succeeded in escaping safely to Agadir. Reached Mogador September 17th. May return to Hana for a few days. Afterwards go north to Fez and Mequinez. Home probably middle of December. Letters first fortnight, Consul, Rabat; afterwards Tangier. Perfect health. Successful beyond expectations.—JOSEPH THOMPSON, HAROLD CRICHTON-BROWNE.

DISCOVERY OF PREHISTORIC REMAINS NEAR BASINGSTOKE.—A shepherd, in the employ of Sir Nelson Rycroft, Bart., was pitching hurdles in a field adjoining Dummer Clump, when the bar came in contact with a large stone, which on being removed was found to have covered two very rudely-formed vessels, of which the under one was pronounced by Dr. S. Andrews, of Basingstoke, to contain human bones, which had undergone incineration. Subsequently another urn was removed of a much coarser character, bearing a band round the base of the rim ornamented with sunken dots, made apparently with a hollow stick. The whole of the vessels are hand-made, and apparently fire-baked, and the larger ones have suffered some damage from the plough, which must have repeatedly passed over them. Subsequently three other vessels, two large and one small, were found. All are of the same slightly baked clay, ornamented with bands. These are sometimes raised and ornamented with the forefinger or thumb of a woman or boy; while, in one case at least, a second band of ornament is formed by the indentations made by the tip of a finger. With one exception, all were placed in the ground bottom upwards, the bottoms themselves being in every case wanting, probably destroyed by the plough, they being only six or eight inches underground, and they were filled with earth, clay, and a few burnt bones. The only exception is the first found, which was upright, and nearly filled with burnt bones only. On it was placed a small vessel of better baked ware.

THE PUBLIC HEALTH.—The Registrar-General's return for the week ending September 22nd shows that the deaths registered during that period in 28 great towns of

England and Wales corresponded to an annual rate of 18·0 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The six healthiest places were Bristol, Huddersfield, Oldham, Brighton, Nottingham, and Wolverhampton. In London 2,463 births and 1,298 deaths were registered. Allowance made for increase of population, the births were 248 and the deaths 109 below the average numbers in the corresponding weeks for the last ten years. The annual death-rate per 1,000 from all causes, which had been 16·0 and 16·2 in the two preceding weeks, declined last week to 15·8, a lower rate than has prevailed in any week since the 3rd of July last. During the 12 weeks ending on Saturday last the death-rate averaged 16·2 per 1,000, and was 3·6 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,298 deaths included 32 from measles, 20 from scarlet fever, 24 from diphtheria, 22 from whooping-cough, 11 from enteric fever, 78 from diarrhœa and dysentery, and 4 from cholera and choleraic diarrhœa. Thus 191 deaths were referred to these diseases, being 39 below the corrected average weekly number. No death from small-pox was registered, the corrected average being 5. In Greater London 3,247 births and 1,629 deaths were registered, corresponding to annual rates of 30·6 and 15·4 per 1,000 of the estimated population. In the Outer Ring 30 deaths from diarrhœa, 8 from diphtheria, and 7 from whooping-cough were registered. The deaths from diarrhœa included 4 in West Ham, 3 in Croydon, 3 in Brentford, and 3 in Walthamstow sub-districts. Of the 8 fatal cases of diphtheria 3 occurred in Edmonton and 2 in West Ham registration districts.

Effects of certain Gases and Vapours upon Health.—In a communication to the Bavarian Academy of Sciences Professor von Pettenkofer expounded the results of some recent investigations on this subject. It appears that the current views as to the quantity of certain gases and vapours which may be safely inhaled are very remote from the truth, and stand in need of rectification. (1) *Hydrochloric acid gas.*—Even 0·1 per thousand of this gas excites in rabbits, cats, etc., great restlessness and increased secretion of saliva, etc.; at 1·5 to 2 parts per thousand difficulty of breathing sets in, with conjunctivitis and opacity of the cornea, and catarrhal pneumonia, which is often fatal. Man is more sensitive to this gas than the lower animals. (2) *Ammonia.*—The action of this gas is similar to that of hydrochloric acid, but less intense. 0·3 per thousand is the point at which injurious action begins, and 0·5 per thousand is the utmost limit which men can bear after long practice. From 2·5 to 4 parts per thousand produce dangerous inflammation of the lungs on exposure for a few hours. (3) *Chlorine.*—Very small quantities (0·01 per thousand) produce irritation in the respiratory organs; 0·015 to 0·03 per thousand produce bronchitis and catarrhal pneumonia. Doses of 0·04 to 0·06 per thousand are dangerous, and 0 6 per thousand is rapidly fatal. (4) *Bromine* acts exactly like chlorine. The statements in books exaggerate the bearable quantities of ammonia, chlorine, and bromine at least one thousand-fold. (5) *Sulphuretted hydrogen.*—The poisonous nature of this gas is well known, but it is commonly supposed more dangerous than chlorine or bromine, which does not hold good. (6) *Sulphuret of carbon.*—Different qualities of this compound vary greatly in their poisonous action; some have very little action. (7) *Aniline* and *nitrobenzol.*—Aniline in the proportion of 0·1 per thousand is dangerous; cats and men are almost equally susceptible; rabbits and guinea-pigs are little affected. Nitrobenzol is not readily introduced into the system through the lungs. Pettenkofer is of opinion that the injurious influence of the above gases and vapours does not depend merely upon local changes in the blood, but upon morbific effects upon the nervous system, and especially the nerve centres. It seems also established that the higher the development of an organism the more susceptible it is to pernicious gases and vapours. Bacteria can tolerate poisonous gases in the air in proportions and for lengths of time which would be instantly fatal to men or to other warm-blooded animals. This is perhaps the reason why man requires in his dwellings a purer air than do the domestic animals.

The "Plastering" of Wines.—Mr. Griffin, United States Consul at Limoges, in a recent report states that since the great reduction in the amount of wines produced in the Bordeaux and Burgundy districts, the inferior wines of the central departments of France are being substituted for them, and chemistry is called in to increase their market value. "Plastering" consists in adding sulphate of lime after the first fermentation or while the wine is in the vat; it is also mixed with the grape-must. The general rule is to give 500 grammes of the "plaster" to the hectolitre of wine, but more usually it is thrown in without weighing. The advantages of the sulphate of lime are said to be increased fermentation and a brighter and more permanent colour in the wines, which will also keep much longer. The objections are that the chemical changes render the wine injurious to health, for it is said that the bi-tartrate of potash contained in wine in its normal state, when brought in contact with the "plaster," forms an acid sulphate of potash, and there is precipitated an insoluble bi-tartrate of lime, varying according to the degree of alcohol. The quantity of sulphate of potash in the wine is increased from five to ten fold by the action of the "plaster." Moreover, in wine treated in this way sulphuric acid is found in a free state, as well as sulphate of magnesia. The effects of the practice on the health of the consumers of the wine so treated were discussed in the Academy of Medicine, and one of the members, M. Marty, has made a report on the subject. As far back as 1857 the doctors in the department of Aveyron found that persons drinking "plastered" wines had an unquenchable thirst and an insupportable dryness of the throat; but different authorities gave different estimates of the effect on health of the consumption of these wines. Hygienic committees reported they were harmless; chemists said they were injurious to health; but M. Marty appears to settle the question from a hygienic point of view. It is an incontestable fact, he says, that "plastered" wines occasion functional troubles and organic injuries; they act as purgatives and caustics in certain cases; but it appears that moderate "plastering" is necessary to the utilisation, preservation, and transportation of certain of the poorer grades of wine, and in such cases it is recommended that the proportion of acid sulphate should not exceed two grammes per litre. As a general conclusion, the Academy is of the unanimous opinion that "plastering" wine is a custom detrimental to health, and advises that the laws against it be rigorously enforced.

SOME PHOTO-MICROGRAPHIC APPARATUS.

ONCE the initial difficulties are overcome, few occupations are more instructive or engrossing than photographing objects through the microscope. An impression exists among people who have not tried it, that photo-micrography is a very difficult branch of the photographic art. This is undoubtedly true when very high powers must be used, but it is not proposed to treat of such matters here, but only to describe a simple apparatus which can be acquired by most people, and which can be successfully used by any person possessing intelligence, a little manipulative skill, and patience.

The advantages of photo-micrography are that there is little or no trouble in getting ready the apparatus; that photographs can be taken either in the daytime or in the evening; that the illuminating power being, if artificial light be used, practically constant in intensity, the variation of the exposure is dependent only on the degree of magnification to be attained and the colour and nature of the object it is desired to photograph, thus eliminating the condition most difficult to determine in making a sunlight exposure, the ever-varying actinic power of daylight.

The absolute necessaries for taking a photograph are, a lamp, a microscope, and a camera with a dark-slide.

The lamp best suited to the purpose is the ordinary microscope lamp, sold by any optician. This lamp has a suitable screen or hood, with an aperture for the emission of the light, and facilities for turning either the flat or the edge of the flame towards the microscope. A vertical adjustment and a condensing lens are also desirable.

The microscope may be of the simplest form, provided a good coarse and fine adjustment be supplied, that it has suitable spring clips to the stage, and that it is so constructed as to allow of the body being brought into a horizontal position. A set of revolving diaphragms beneath the stage is also of great value.

A camera suitable for ordinary landscape photography will meet the requirements of a beginner, though the greater the extension of the camera the better. The only necessary points to observe are, that absolutely no light enters into the camera except that admitted through the objective of the microscope, and that the focussing screen and the dark-slide occupy, when in position, the same plane.

In arranging the apparatus it is advisable to procure a piece of dry, well-seasoned pine or mahogany, 3 ft. 6 in. by 10 in. by $1\frac{1}{4}$ in. thick, which will form a capital base-board.

Place the microscope on it, and bring the body of the microscope into a perfectly horizontal position; then with the greatest accuracy measure the distance from the board to the centre of the tube of the microscope. This will give the height of the optical axis above the base, and it is of great importance to maintain this line perfectly parallel to the base, from the lamp to the focussing screen of the camera. The centre line of the apparatus should also coincide in plan with the centre line of the base-board.

Having determined the position of the microscope, which should be about nine inches clear from the end of the base-board, mark the position of the claw foot of the microscope, and screw on small wood chocks or clamps to hold it in position; the microscope can then be moved from the board and replaced in position as desired. It is well also to fix a supporting block on the base-board, upon which the tube of the microscope should bed when horizontal, thus ensuring the microscope tube being readily brought to the required position.

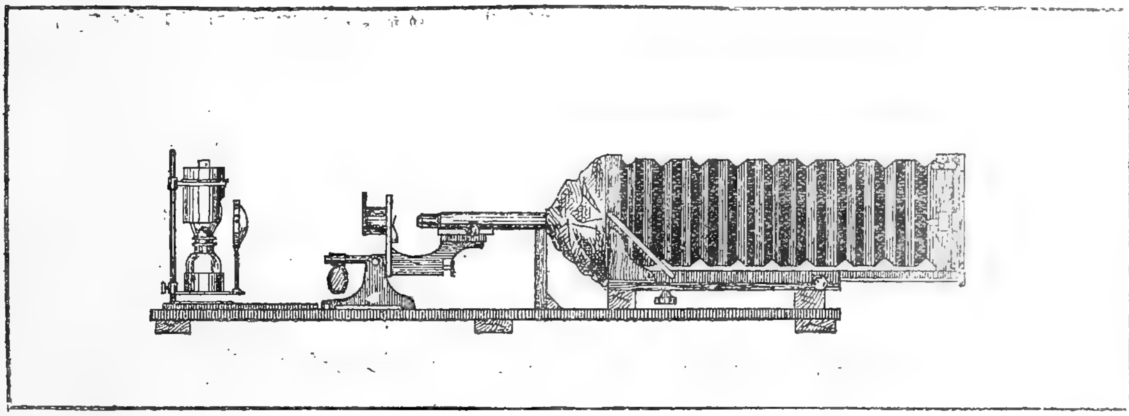

FIG. 1.—SIMPLE PHOTO-MICROGRAPHIC APPARATUS.

A suitable bed for the camera must next be prepared. It will probably be found that the height from the underside of the base of the camera to its axis will differ from that of the microscope, and that the camera will require to be packed up to the requisite height; this is best done in the method shown in fig. 1. A slot, 10 or 12 inches long should be cut in the centre of the supporting board of the camera, through which the tripod clamp screw, usually supplied with a camera will work. This arrangement will allow the camera to be moved up to or away from the eye-piece end of the microscope, and secured in any desired position.

The junction between the camera and microscope is best effected by means of a conical velvet funnel, secured to the body of the microscope by an elastic ring, the other end being passed all round the front of the camera. This allows the adjustment of the microscope to be readily effected, the eye-piece end of the tube working through the lens aperture in the front of the camera.

The lamp must then be centred, and should be secured to the base-board by means of two rebated fillets, between which it should work easily, thus enabling it to be moved towards or away from the microscope at will. The vertical adjustment is usually supplied with the lamps known as " Bocket lamps."

The writer, after many trials, has found that the most suitable illuminant is formed by adding to one pint of Defries' oil one ounce of camphor, and allowing it to dissolve. This gives a brilliant and powerful light, very rich in actinic rays, whilst little or no smell arises from it.

The wick should never be trimmed with scissors, but the charred portion should be rubbed off gently with the finger till it is level with the top of the burner, and all loose threads removed.

One of the most important details in the whole process of taking a photograph through a microscope must now be considered; and unless the points now to be mentioned are carefully kept in view, it is of little use to hope for a sharp negative.

The slightest error in registration between the focussing screen of the camera and the position occupied by the sensitive plate when in the dark-slide will produce lamentable results. This is the more likely to occur when an inner frame or carrier is used to hold the plate in the slide, and the writer, therefore, strongly advocates that the ordinary ground glass screen of the camera be discarded and that the focussing be done on a piece of ground glass fixed in the carrier in the dark-slide, and secured by means of spring clips, in the exact position which the sensitive plate will subsequently occupy. By this method the chances of faulty registration are reduced to a minimum, whilst by drawing out both the shutters of the dark-slide a capital focussing screen is formed.

Without dipping deeply into the somewhat complex optical question of objectives, it is perhaps well to mention here several matters which influence very essentially the focussing of an object for photographing, having regard to the correction of the ordinary microscope objective. In order that "chromatism" (that is, a coloured fringe round the object under examination) may be avoided, certain corrections are made in the objective supplied for ordinary microscopic research, and as a result the lenses composing it have two foci, known respectively as the chemical—*i.e.*, the point at which the blue rays are brought to a focus—and the visual focus, or the point at which the image of the object under examination appears sharpest, but at which very few of the actinic rays of the light are concentrated.

It therefore becomes necessary to determine the exact position of the chemical focus, since to the action of these rays is due the record we subsequently obtain on the sensitised plate. A ready method of roughly arriving at this was suggested to the writer. By placing the focussing screen at a skew of say $\frac{3}{32}$ inches on either side of the centre line of the camera, and focussing sharp for the middle of the screen, we shall have in the centre the true visual focus, and on either side an inclined plane, one in front of, and the other behind the visual focus. At some point within these planes the chemical focus of the objective will be found, some part of the plate being more sharply defined than the rest. The position of this zone from the centre should be noted, and the distance in advance of or behind the visual focus determined. Working, however, with such objectives is tedious and uncertain; and since at a small cost a correcting lens can be added to the objective, the writer strongly advocates this addition. Only the low powers. 3 in., 2 in., $1\frac{1}{2}$ in., and 1 in., require correction, and the additional lens does not impair the value of the objective when required for ordinary microscopic research. In the higher powers, $\frac{1}{2}$ in., $\frac{1}{4}$ in., $\frac{1}{8}$ in., etc., the visual and chemical foci are practically identical, and any actual difference is best disregarded, since the addition of a correcting lens would greatly reduce the amount of light admitted through the objective.

Suppose now the lamp to be ready, and that some object suitable for a trial is to be photographed.

Using the microscope in the ordinary position, the slip on which the object is mounted should be placed on the stage of the microscope and firmly secured by the clips, and an objective with, say, a 1 or 2 in. focal equivalent brought to bear upon it. The object should be brought exactly into the centre of the field, and should be well within its limits. Now place the microscope in its position on the base-board, and carefully bring it to the horizontal position, withdraw the eye-piece, and move the mirror reflector to one side, so that it does not interfere with the light from the lamp, and attach the velvet to the tube.

A very indistinct image of the object will now be seen upon the focussing screen of the camera, but before sharpening the image the illumination must be so adjusted that the whole of the field on the ground glass is evenly illuminated. This can, after a little practice, be readily accomplished by moving the lamp nearer to or farther away from the microscope; but it is well here to remark that uniform illumination can be more readily determined when a medium-sized stop is used in front of the stage than with a larger aperture. The field being satisfactorily illuminated, now sharpen the image on the screen by means of the coarse adjustment of the microscope. Should the image bear further amplification, and yet fall within the limits of the plate used, this should be effected by further extending the camera, though the writer strongly advises the use of $4\frac{1}{4} \times 3\frac{3}{4}$ plates only, and that the whole of the image falls within a circle $2\frac{3}{4}$ in. diameter, or a square $2\frac{3}{4}$ in. by $2\frac{3}{4}$ in., these being convenient sizes for subsequently printing off lantern transparencies from the negatives.

It is best to remove the eye-piece of the microscope, since it makes but a very unsatisfactory amplifier, and generally introduces distortion of the image, whilst it materially reduces the volume of light impinging on the screen.

Sufficient amplification can generally be obtained by extending the camera, but should the range be found insufficient, the distance between the micro-objective and the focussing screen can be readily increased by first removing the vertical sliding front, behind which in most cameras a sufficiently large aperture exists, and stretching out the velvet cone, or funnel, by which the junction between the microscope and camera is effected, as before described. The desired amplification being obtained, focus the image by means of the coarse and fine adjustments. When focussing for taking a photograph care must be taken that the frame in which the focussing screen is held lies in a plane at right angles in all directions to the optical axis.

(To be continued.)

Action of Ether upon Vegetable Life.—According to G. Bernstein, an atmosphere saturated with ether kills the sprouts of wheat and barley in about half-an-hour.

Natural History.

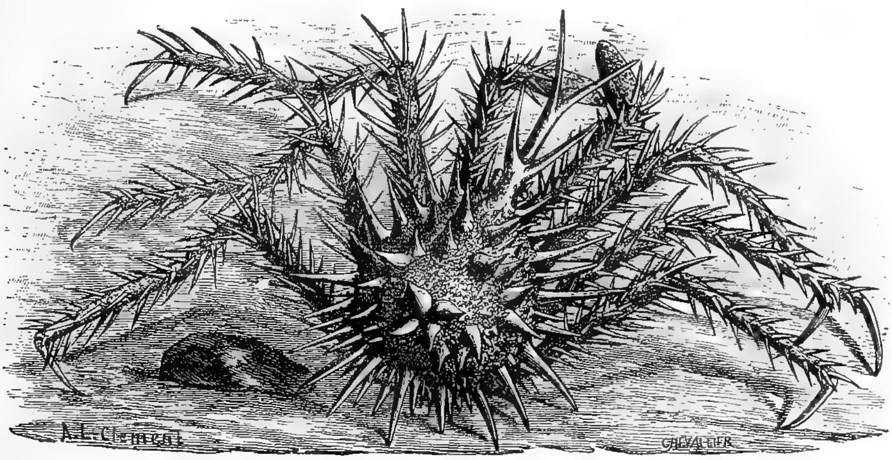
THE CRUSTACEA OF THE SEA-BOTTOM.

M. Fourques gives in *Cosmos* an account of a very strange crab dredged up during the expedition of the *Talisman*, from a depth exceeding 2,000 fathoms. The bottom of the sea was for a long time regarded as uninhabited. The operations required in the Mediterranean in 1881 for re-uniting a broken telegraph cable, immersed at the depth of 1,000 fathoms, revealed to the learned world, to its surprise, that at such depths there existed living beings, in a darkness incompatible with vegetable life, and at a pressure which seemed opposed to all the working of the processes of the animal world. Scientific expeditions were organised, and *savants* set out on vessels whose names have become historical. The *Challenger*, the *Talisman*, and the *Travailleur* carried out soundings at various depths, and a totally novel fauna was described and studied. Several remarkable fishes have been described which live at depths a thousand fathoms below the surface. These fishes do not differ in an essential manner from those of the pelagic fauna. The same species, or closely allied species, are met with at different depths. Their organs, however, present certain modifications imposed by the biological conditions of so peculiar a medium.

The light does not penetrate to such great depths, but nature, in compensation, endows many abysmal animals with luminous organs. Their tissues are, in certain cases and under certain conditions, phosphorescent, like certain *Medusæ* and various terrestrial animals. Our attention for the present must be turned to the *Crustacea*. These creatures—the crabs, lobsters, and their allies—are arthropods, breathing by gills. Devoid of an internal skeleton and of a cerebro-spinal system, they are in this twofold respect similar to insects. Filhol, speaking of marine crustacea—for there are also forms inhabiting fresh water—calls them the insects of the sea, an unfortunate term, since true insects are not entirely wanting in the sea. Their structure and their embryology have been latterly ascertained, and they have been found to undergo numerous and complex metamorphoses. The larval forms were long considered as forming not merely distinct genera but even families. Such are the Zoeæ, the larvæ of the crabs, and Phyllosoma, the larvæ of the shrimps.

These animals are encased in a thick calcareous shell, often armed with long, sharp spines. Their senses are highly developed. At the anterior part of the body they are provided with two pairs of antennæ, the organs of hearing and smelling.

In some species, however, the organs of hearing are lodged at the posterior extremity of the body, under the caudal plate. The organs of touch are very fine and numerous hairs are situated around the mouth. The eyes are sometimes fixed on stalks, and sometimes sessile. There are, indeed, few species subject to so many variations as the crustacea. No fewer than 5,500 living species are known, divided into ten orders, some of which live as parasites upon fishes and are deprived of eyes, and resemble worms in their appearance. Several inhabit the bottom of the sea. During the expedition of the *Talisman*, M. Filhol, one of the naturalists who took part in the expedition, captured a new species and gave it the name of *Lithodes ferox*. It is a very striking animal, of a light-red colour, bristling with spines. It looks like a chestnut which had fallen into the sea, become alive, and shot out arms and legs.



Lithodes Ferox: a Crustacean found at a Depth of 13,000 feet.

Its powerful and terrible armour has earned it the name of *ferox*, for it is impossible to seize it without being wounded, and it must be a very dangerous visitor to its neighbours, so much the more as the crustacea are very voracious and have the power of reproducing any limbs which have been cut or torn away.

Rymer Jones, as quoted by Filhol, gives a very curious anecdote. He had one day placed some crabs in an aquarium, when one of them seized one of its companions by the edge of the shell with one of its pincers, broke open the shell with the other pincer, and fell quietly to work to ransack the body, tearing out pieces of flesh and swallowing them! During this fratricidal feast another crab approached from behind, seized the devourer and holding him firmly, treated him in the same manner. Still he took no notice, but quietly continued his repast until his own death.

The habits of *Lithodes ferox* are little known, but, judging from its structure, it must be a dangerous animal.

A Gigantic Spider.—A correspondent writes to the *Calcutta Englishman*:—I have much pleasure in sending you a description of an enormous spider which was killed in a house here the day before yesterday, and I shall be glad if any reader will inform me whether the species be well known anywhere, or whether there be another Indian species at all corresponding with it in size. I take my description from the specimen in spirits, and can only indulge in regret that I did not see it alive. The creature was found clinging to a door-curtain, and when alarmed emitted a grating sound, but whether with its mandibles or with its feet could not be ascertained. It showed no disposition to run away or even to move from the spot where it was till it was thrown down, when it was killed with a blow of a stick. It is quite two inches in length and half an inch in breadth, and the two segments of the body are equal in size. It is distinctly short legged for a spider; but the eight legs are very strong and heavy. The body, too, is covered with fine short hair and is all of a dark-brown colour. The two fangs are like a sparrow's claws and exceedingly sharp, and if stretched out straight would, with the fleshy part, measure nearly half an inch each. I find it difficult to convey an adequate impression of the terrible and formidable appearance of the monster. The common large running spider, to be found in every house in Calcutta, unhesitatingly tackles and destroys the largest cockroach. Judged by that standard, this spider ought to make its prey of a small bird or a mouse, according to the tales that are told of the South American tarantula.

Sparrow Hawk and Water Hens.—In the *Newcastle Chronicle* a correspondent of Mr. Kerr describes a strange attack of a sparrow hawk on a brood of young water hens which he witnessed. He was trout fishing in the pool in question, a preserved piece of water, which is surrounded with trees, and well fringed with reeds amongst which nest several pairs of water hens and coots. The coots are most pugnacious and jealous birds, and they insist on maintaining possession of the upper part of the pool, driving the water hens to the lower end. As the weather was warm and the situation rathered sheltered, Mr. Kerr's friend got drowsy. At the time, several broods of water hens were sailing about on the pool. Suddenly he was aroused by a squatter and quacking, and on looking up he saw a sparrow hawk grappling with one of the young water hens, about the size of a dabchick. The hawk, when it dashed on its prey, had too much "way," and it nearly went overhead after his quarry. The old water hens at once came to the rescue of their chick, and the sparrow hawk went overhead several times. While the struggle was still doubtful, the hawk being heavily handicapped by having its plumage saturated, the coots sailed in, and made short work of the pirate, whom they pecked and forced under water till he gave up the ghost. The coots and water hens continued to peck the hawk and lash it with their wings long after it was drowned.

Walking Home.—A correspondent of the *Licensed Victuallers' Mirror* tells a marvellous story illustrative of the instinct of the Carrier pigeon, which he vouches for the truth of. A Birmingham man purchased from a well-known fancier in London a pair of carriers (Homers) of purest breed. He was warned that they would certainly fly back home if released. He kept them housed for ten days and gave them their liberty. They, of course, started for home at once. They were returned. The same treatment was repeated twice again with like results. Then he clipped the wings of those pigeons close. The next morning they were missing again. He advertised for them, but could get no clue to their whereabouts. Nearly a fortnight later he received a telegram from Coventry stating that two pigeons, both clipped, answering to the description given in the advertisement, had been captured a few miles from that town. When taken they were walking along the road to London.

Do Snakes Fascinate their Victims?—In a paper published in the last Journal of the Natural History of Trenton, New Jersey, Mr. F. Lucas discusses the alleged power of snakes to fascinate their victims and hold them spellbound by some natural inherent quality. He denies altogether the existence of this faculty, and attributes the general belief in it to the abhorrence, not of mankind only but of most of the lower animals, for snakes. The most absurd stories of this fascination are accepted and cherished as evidences of the potency of the snake's power over man and beast, but, when these are capable of examination and analysis, it usually turns out that, where they are not wholly imaginary, the victim was paralysed with fear rather than rendered powerless by mesmeric influence. It is to the intense nervous perturbation produced in strong men, as well as delicate, sensitive women, by contact with even the smallest of snakes, that Mr. Lucas looks for the secret of the prevalent error regarding the snake's influence. "Man and the lower creatures entertain such fear of the despised ophidian that when unexpectedly meeting one of these horrid animals they are in the proper condition to be peculiarly affected by the fascinating gracefulness and the general appearance of satanic cruelty so natural to the snake. The degree of stupefying influence thus exerted by the snake depends largely on the nervous sensitiveness or the natural timidity of the subject." There certainly are cases where animals have been so terror-stricken by snakes as to be helpless, and where even human beings have been so overcome as to require assistance, but in all such instances the explanation lies in the excessive fear or horror of the victim, and not in an inherent power of the snake to fascinate. Mr. Lucas concludes "that it must be accepted as a scientific verity that the power to fascinate so universally granted to the snake does not exist, but rather, in accordance with the Heaven-pronounced curse on the snake, animated nature in its highest and most sensitive form entertains such strong feelings of fear and repulsion towards this animal, as to suffer temporary paralysis when meeting it."

Animal Chlorophyll.—According to a contemporary, Mr. C. A. McMunn has detected chlorophyll in no fewer then ten species of British sponges, and other observers have detected the absorption-band of chlorophyll in the spectrum yielded by four other species.

The Return of the Sardines.—These little fishes, which had for some time forsaken the coasts of France, have returned in unprecedented numbers. The works of Audierne and its neighbourhood refuse to buy in further supplies at any price. To get rid of what they have already caught, the fishermen are obliged to sell them as manure at half-a-crown per cubic yard!

WATER EGGS OF INSECTS.

WE doubt if there be any equally common object so full of instruction to the young biologist as a string of the eggs of Chironomus. The flies which bear this name are often called midges. They might be summarily described as stingless gnats, which hover in clouds over water in still and warm weather. Their earlier stages are passed in water, but the fly breathes air.

At the time of egg-laying the female Chironomus approaches the water, and lays in it a chain of glutinous eggs. The viscid secretion immediately absorbs water, and swells to many times its original bulk. It then appears as a flexible, transparent cylinder, about three-quarters of an inch long, and perhaps one-tenth of an inch thick. Near the surface of the cylinder are embedded hundreds of yellow eggs, just visible to the eye as oval specks in a clear field. The cylinder ends in a sticky thread, by which the whole mass is moored to a stone or some similar object.

The naturalist who has a fountain in his garden may expect to find these chains of eggs almost constantly during the summer months. In brooks and ponds the eggs are no doubt equally common, but much harder to find.

For the study of the development of insects, no subject can be more advantageous. The eggs are almost perfectly transparent, and may be examined alive with the greatest ease, being afterwards returned to the water to continue their growth. A low power of the microscope, a live-box, and a little saucer of water are the only appliances requisite. The development occupies three days, and the eggs should be examined, whenever possible, at intervals of three hours. To study with profit, drawings to scale should be made with care and regularity.

In newly-laid eggs nearly the whole space is occupied by a granular yolk with many oil globules. At one end, afterwards the hinder end, the peculiar objects known as the polar cells may be seen. Early on the first day of hatching, a single layer of transparent cells is seen to invest the yolk, and within this a second layer rapidly forms. From the outer layer (epiblast) are developed the skin, nervous system, and sense-organs, while the inner layer (hypoblast) gives rise to the epithelium of the primitive alimentary canal.

Towards the end of the first day the yolk has altered its shape. A narrow extension runs out into the region of the future head. Another tongue-like process passes towards the transparent egg-shell, and opens upon the back of the insect, which is as yet in a most incomplete state. The top and side-views of the embryo are now for the first time materially different from each other. Two or three segments are indicated on the ventral surface. By the middle of the second day a considerable number of segments (body-rings) have formed. The dorsal wall is still incomplete. Paired appendages, the future antennæ, mandibles and maxillæ, are now to be made out in the region of the head. The polar cells, which have a singular history, have been taken into the body, but can still be made out. They ultimately undergo conversion into reproductive organs. By the morning of the third day all the segments are formed. The eye-spots are conspicuous. A folding-in of the skin from the head end has produced a long and narrow channel which leads nearly to the yolk. A similar folding-in at the opposite end of the body is in progress. The two new lengths of alimentary canal thus formed constitute the future œsophagus and intestine with their appendages. Uneasy movements are now to be seen, and a sort of peristaltic action of the intestine sets in during the early part of the third day. The body is by this time outwardly completed, and the organisation of the internal organs proceeds with great rapidity, every hour producing visible changes. At the end of about seventy-two hours the egg-shell contains a transparent little larva, which performs restless movements, and soon escapes from its prison. After a few days the larva acquires the red colour which has suggested the popular name of "blood-worm." Its subsequent history is deeply interesting, but we shall not pursue it at present.

Many other small flies lay eggs in water after the same fashion. The string of eggs of the caddis-fly is much larger than that of Chironomus, and the eggs are at first of a brilliant chlorophyll green colour. A curious analogy exists between the insect-eggs just described and the spawn of the frog or toad. In both of these very dissimilar groups of animals the some artifice is used. The oviduct secretes a gelatinous substance, which is poured out upon the eggs, binding them together into a sort of rope, which is small enough while still in the body of the parent, but swells greatly when passed into the water. The copious mass in which the eggs thus come to be imbedded serves more than one purpose. It is slippery, and cannot be seized by beak or claws—whether of bird or rapacious insect. Secondly, it is transparent, and thus serves to space the eggs widely, allowing light to pass freely to each. The influence of light upon the rate of development is very marked. Take any of the eggs named (Frog, Caddis, or Chironomus), divide into two parcels, place both in similar vessels, with the same supply of air and warmth, but keep one set in the dark and the other in the light. The eggs kept in the dark will be found to get on slowly, and a considerable proportion will not be hatched at all. Thus we see that the peculiar requirements of development under water have been independently met in precisely the same way by animals too remote zoologically to admit the supposition of a common tradition.

THE DISTRIBUTION OF COLOURS IN ANIMALS.

SIGNOR L. CAMERANO, after a prolonged study of this question, has laid before the Turin Academy of Sciences certain results which have scarcely received the amount of notice which they merit, and we accordingly submit them to our readers.

He arranges the colours of animals in the following order as regards frequency of occurrence:—1, brown; 2, black; 3, yellow, grey and white; 4, red; 5, green; 6, blue; and 7, violet.

These colours, however, are not uniformly distributed in the main groups of the animal world. Black, brown, and grey are relatively more abundant among vertebrate animals than among the arthropods. Red and yellow, on the contrary, are more frequent among the non-vertebrated animals. Green is common among the lower forms, with the exception of the molluscs, but it is also fairly abundant among the vertebrata, always excepting the mammalia. Violet and blue, the former especially, are the rarest colours. White is very irregularly distributed, but it is most common among dwellers in the waters.

The colours of animals are, on the whole, directly related to the medium which they inhabit. Parasitic animals have less decided and less manifold colours than those which lead an independent existence.

Aquatic animals have in general more uniform and less intense colours than terrestrial forms. Pelagic species have rare and strikingly deep colours—a fact perhaps connected with the frequent transparency of their bodies.

Sea-animals which live among algæ and generally in situations rich in marine vegetation, have a more varied and lively range of colouration than such as live among stones or on a sandy or muddy bottom.

The dull, sombre colour of fresh-water insects is too well known to need more than a passing notice. Some species, however, which pass their larval state in water, *e.g.*, dragon-flies, display a brilliant colouration when mature.

Land animals which live in the woods, beneath herbs, on bushes or on flowers, etc., have more varied and striking colours than the inmates of sandy or rocky localities. The "Desert colour" of the Arabian and Saharan fauna, the former more especially, has been particularly dwelt on by Canon Tristram.

Contrary to the somewhat premature assertion of Mr. Grant Allen, there is no universal and constant connection between the colouration of animals and the nature of their diet. Insectivorous, or rather zoophagous animals which live under leaves or among flowers, are often brilliant and varied in hue, whilst plant-eating species, if they do not regularly inhabit leaves and blossoms, are often dull and sombre in colour.

Still this generalisation is as far as that of Mr. Grant Allen from accounting for the gorgeous colouration of, *e.g.*, the genus *Phanæus*, devourers of carrion and excrement among which they make their abode.

The richer an animal group is in species the more varied, and in many cases the brighter is their colouring —a rule well exemplified in the humming-birds. But it fails us in not a few striking cases, among which we need merely mention the great group of the *Brachelytra* or rove-beetles, the *Harpalidæ*, and the genus *Aphodius*.

The development of colour bears no direct proportion to the quantity of light to which the animal is exposed. It is rather directly connected with the general development of the animal. Deficient nutrition and diseases impoverish the colours.

Large animals have, for the most part, a duller colour than smaller species. We need scarcely add that the views of Signor Camerano as regards the influence of light agree substantially with those of Mr. A. R. Wallace.

A very dry climate seems to darken colours, whilst a very moist one brightens or lightens them. The colours of animals are modified by the altitude of their station above the sea-level. The higher we rise, thinks Signor Camerano, the more intense are the colours which encounter our view.

With this proposition we cannot agree. A mountain fauna is generally more sombre than that of the adjacent plains—a remarkable contrast to the Alpine flora. This fact, indeed, has been cited as an argument against Mr. Grant Allen's theory of the colouration of animals.

Species confined to islands have often darker colours than those inhabiting continents. This conclusion holds strikingly good as regards many varieties inhabiting small islands.

It will be seen that the colouration of any given fauna is a result depending on a complex of factors, the respective influence of which it is hard to estimate.

The different zoo-geographical regions of the earth seem to have certain more or less predominating colours.

In the Palæarctic region, white, grey, black, and yellowish are frequent; in the Ethiopean, yellow and brown; in the Neotropical, green and red predominate (?); in the Indian the yellow tones occur very plentifully; whilst in the Australian dark colours, and especially black, take the lead.

In almost all groups of animals those parts which are less visible are often brightly coloured or spotted, whilst the other parts of the body are more frequently unicoloured, or dark. Here, however, we are reminded of the very numerous cases in insects where the brightest colours appear to be seated in projecting parts, such as the extremity of the abdomen, the tips of the elytra in *Coleoptera* and *Hemiptera*, the margins of the wings in butterflies, etc. So frequent is this phenomenon that some naturalists have regarded it as a protective arrangement—a bird, *e.g.*, being more likely to strike at these bright, outlying parts than at the more sombre vital regions.

In many cases the young of different species resemble each other closely in colouration, though the adults are quite distinct.

While thus giving an abstract of the very interesting results of Signor Lorenzo Camerano, we are fully aware that some of them require further consideration. It must have struck many of our readers that inquiries on the colouration of animals have, so far, left the physical side of the question scarcely touched. The production of the colouring-matters, their occurrence in one species and not in another, and the mechanism of their distribution have still to be dealt with. It strikes us that in the production of the design—in *e.g.*, the wings of a butterfly—the principles of capillary attraction and of diffusion must come into play. By mixing certain colours which have different rates of diffusion and placing a small drop of the mixture on white blotting-paper, designs may sometimes be obtained which roughly resemble those we meet with in the wings of Lepidoptera.

THE ELECTRICAL TRANSMISSION OF POWER.

A Lecture Delivered by Professor Ayrton, F.R.S., etc., before the British Association, on September 8th, and Re-delivered to the Working-Classes of Bath, on September 13th, 1888.

(*Continued from p. 321.*)

Let us study this electric transmission a little in detail. I pull this handle, and the bell at the other end of the room rings, but in this case there is no visible motion of anything between the handle and the bell. (Electric bell rung by an electric current produced by pulling the handle of a small magnetic-electric machine.) Whether I ring the bell by pulling a wire, or by sending an air puff, or by generating an electric current by the exertion of my hand, the work necessary for ringing the bell is done by my hand exactly as if I took up a hand bell and rang it. In each of the three cases I put in the power at one end of the arrangement, and it produces its effect at the other. In the electric transmission how does this power travel? Well, we do not know: it may go through the wires, or through the space outside them. But although we are really quite in the dark as to the mechanism by means of which the electric power is transmitted, one thing we do know from experience, and that is this—given any arrangement of familiar electrical combinations, then we can foretell the result.

Our knowledge of electrical action in this respect resembles our knowledge of gravitation action. The only thing quite certain about the reason why a body falls to the ground is that we do not know it; and yet astronomical phenomena can be predicted with marvellous accuracy. I mention the analogy since some people fancy because the answer to that oft-repeated question "What is electricity?" not only cannot be given exactly, but can only be guessed at in the haziest way, even by the most able that therefore all electric action is hap-hazard. As well might the determination of a ship's latitude at sea be regarded as a mere game of chance because we have not even a mental picture of the ropes that pull the earth and sun together.

This power of producing an action at a distance of many yards, or it may be many miles, by the aid of electricity without the visible motion of any substance in the intervening space is by no means new. It is the essence of the electric telegraph, and electric transmission of power was employed by Gauss and Weber when they sent the first electric message. I am transmitting power electrically whether I now work this small model needle telegraph instrument, or whether I turn this handle and set in motion that little electric fan.

But until about ten years ago the facility that electricity gave for producing signals almost instantaneously at a great distance was the main thing thought of. The electric power consumed for sending the telegraph messages was so small, the amount of power lost *en route* comparatively so valueless, that the telegraph engineer had no need to trouble himself with these considerations that govern us to-day, when we are transmitting power large enough to work a factory or an electric tramway. Although there are as many as 22,560 galvanic cells at the Central Telegraph Office, London, which costs some thousands annually to keep in order, what is that compared with the salaries of all the 3,089 superintendents, assistants, telegraph clerks, and the maintenance of 1,150 telegraph lines that start from the Central Office?

In all the last three systems on my list some form of power such as flowing water or the potential energy stored up in coal, wood, zinc, or other fuel, has initially to be utilised. This power is given to some form of air, water, or electric pump which transfers the power to the air, water, or electricity by which it is conveyed to the other end of the system. There it is re-converted into useful mechanical power by means of an air, water, or electric motor.

You will observe that I class together air, water, and electricity; by that I do not mean to imply that electricity is a fluid, although in many respects it acts like a fluid, like a fluid of very little mass, however, or, odd as it may seem, like a fluid moving extremely slowly, for electricity goes round sharp corners with perfect ease and without any of the phenomena of momentum possessed by rushing water. But what I particularly wish to impress on you by classing air, water, and electricity together is that electricity is not, as some people seem to think, a something that can be burnt, or in some way used up and so work got out of it. Electricity is no more a source of power than a bell wire is; electricity is a marvellously convenient agent for conveying a push or a pull to a great distance but is not by the using up of the electricity that electric lights burn or that electro motors revolve. It is by the electricity losing pressure, exactly as water loses head when turning the miller's wheel as it flows downhill, that work is done electrically.

This model shows in a rough symbolical way what takes place in the transmission of power, whether by air, water, or electricity. The working stuff, whichever of the three it may be, is first raised in pressure and endowed with energy, symbolised by this ball being raised up in the model; it then gradually loses pressure as it proceeds along the tube or wire which conveys it to the other end of the system, the loss of pressure being accompanied by its giving up power to the tube or wire and heating it. This is shown in the model by the ball gradually falling in its course. At the other end there is a great drop of pressure corresponding with a great transference of power from the working stuff to the motor, and finally it comes back along the return pipe or wire, losing, as it returns, all that remains of the pressure given to it initially by the pump. The ball has, in fact, come back to its original level.

The problem of economically transmitting power by air, water, or electricity is the problem of causing one or other of these working stuffs, air, water, or electricity, to economically perform the cycle I have described.

In each of the four stages of the process—

(1) Transference of power to the working substance at the pump,

(2) Conveyance of power to the distant place,

(3) Transference of power from the working substance to the motor at the distant place,

(4) Bringing back the working substance—

there is a loss of power, and the efficiency of the arrangement depends on the amount of these four losses. The losses may be shortly called—

(1) Loss at the pump,

(2 and 4) Loss on the road,

(3) Loss at the motor.

Until 1870 the pump most generally employed for pumping up electricity and giving it pressure, was the galvanic battery, scientifically an extremely efficient converter of the energy in fuel into electric energy, only unfortunately the only fuel a battery will burn is so expensive. A very perfect fireplace in which there was very complete combustion, and a very little loss of heat, but which had the misfortune that it would only burn the very best wax candles would be analogous with a battery. The impossibility of using zinc as fuel to commercially work electric motors has been known for the last half-century, and the matter was very clearly put in an extremely interesting paper "On Electric Magnetism as a Motive Power," read in 1857, by Mr. Hunt, before the Institution of Civil Engineers, a copy of which has been kindly lent me by Dr. Silvanus Thompson. Professor William Thompson, of Glasgow, I quote from the discussion on the paper, put the matter very pithily by showing that even if it were possible to construct a theoretically perfect electromotor, the best that could be hoped for if it worked with a Daniell's battery would be the production of a one-horse power by the combustion of 2 lbs. of zinc per hour, whereas with a good actual steam engine of even thirty years ago, one horse power could be produced by the combustion of exactly the same weight of the much cheaper fuel, coal. This argument against the commercial employment of zinc to produce electric currents is irresistible unless—and this is a very important consideration which is only beginning to receive the attention it deserves—unless, I say, the compound of zinc formed by the action of the battery can be reduced again to metallic zinc by a comparatively inexpensive process, and the zinc used over and over again in the battery. If the compound of zinc obtained from the battery be regarded as a waste product then it would be much too expensive to work even theoretically perfect electromotors if they were existent by consuming zinc. Suppose, however, a process be devised by means of which burnt zinc can be unburnt with an expenditure comparable with the burning of the same weight of coal, then it might be that although coal would still form the basis of our supply of energy the consumption of zinc in batteries might be an important intermediary in transforming the energy of coal economically into mechanical energy.

While then some experimenters are aiming at possibly increasing the working power of a ton of coal to eight times its present value by earnestly seeking for a method of converting the energy it contains directly into electric energy without the intervention of a wasteful heat engine, it should not be forgotten that in the cheap unburning of oxidised metal may lie another solution.

The solution of this latter problem is quite consistent with the principles of the conservation and dissipation of energy since the heat required to theoretically unburn 1 lb. of zinc is only one-seventh of that given out by the burning of 1 lb. of coal. Further, it involves no commercial absurdity like that found in the calculations given in the prospectuses of many primary battery companies which are based on zinc oxide, a material used in the manufacture of paint, maintaining its present price, even if thousands of tons were produced. Unless all those who use primary batteries on this expectation intend to have the painters doing up their houses all the year round, they will find themselves possessed of the stock-in-trade of an oil and colourman on a scale only justified by a roaring business in paint.

Now about waste No. 3—the waste of power at the motor. That also was gone into fully in the discussion in Mr. Hunt's paper, and Mr. Robert Stevenson concluded that discussion by remarking "That there could be no doubt from what had been said, that the application of voltaic electricity, in whatever shape it might be developed, was entirely out of the question, commercially speaking. . . . The power exhibited by electro-magnets extended through so small a space as to be practically useless. A powerful electro-magnet might be compared, for the sake of illustration, to a steam engine with an enormous piston but with an exceedingly short stroke. Such an arrangement was well known to be very undesirable."

And this objection made with perfect justice against the electro-motors of thirty years ago, might also have been made to all the machines then existing for the mechanical production of electric currents. I have two coils of wire at the two sides of the platform joined together with two wires. I move this magnet backwards and forwards in front of this coil, and you observe the magnet suspended near the coils begins to swing in time with my hand. Here you have, in its most rudimentary form, the conversion of mechanical power into electro power, and the re-conversion of electric power into mechanical power; but the apparatus at both ends has the defects pointed out by Mr. Hunt and all the speakers in the discussion on his paper—the effect diminishes very rapidly as the distance separating the coil from the moving magnet increases.

As long as electro-motors as well as the machines for the production of electric currents had this defect, the electric transmission of power was like carrying coals to Newcastle in a leaky wagon. You would pay at least sixteen shillings for your coals in Bath, lose most of them on the way, and sell any small portion that had not tumbled out of the wagon for say two shillings a ton at Newcastle—a commercial speculation not to be recommended.

A very great improvement in electro-motors was made by Pacinotti in 1860, but although his new form of electro-motor was described in 1864 it attracted but little attention, probably because any form of electro-motor, no matter how perfect, was commercially almost useless until some much more economical method of producing electric currents had been devised than the consumption of zinc and acids. Pacinotti's invention removed from motors that great defect that had been so fully emphasized by the various speakers at the reading of Mr. Hunt's paper in 1857. When describing his motor in the Nuovo Cimento in 1864 he pointed out that his principle was reversible, and that it might be used in a mechanical current generator. This idea was utilised by Gramme in 1870, who constructed the well-known Gramme dynamo for converting mechanical into electrical power, a machine far more efficient that even Pacinotti had contemplated, and gave the whole subject of electrical engineering a vigorous forward impulse. Every subsequent maker of direct-current dynamo, or motors, has followed Gramme's example in utilising the principle devised by Pacinotti, which was as follows :—In all the early forms of dynamos or motors there were a number of magnets and a number of coils of wire, the magnets moving relatively to the coils, or the coils relatively to the magnets, as you see in this rather old specimen of alternate current dynamo. To produce magnetism by a large number of little magnets is not economical, and Pacinotti's device consisted in arranging a number of coils round a ring in the way shown in the large wooden model, so that they could all be acted on by one large magnet. Instead of frittering away his magnetism, Pacinotti showed how it could be concentrated, and thus he led the way to dynamos and motors becoming commercial machines. Pacinotti's science engineered by Gramme not only made electric lighting commercially possible, but led to electricity being used as a valuable motive power. It was in their work that the electrical transmission of power in its modern sense sprang into existence.

Quite recently an improvement in the same direction has been introduced into alternate current dynamos by Mr. W. N. Mordey, for he has replaced the many magnets of the ordinary alternate current dynamos with one large magnet, and so with his alternator, weighing 41 cwt., which you see in this hall, he has succeeded in obtaining at a speed of 650 revolutions per minute an output of 53·6 horse-power with a high efficiency.

It may be convenient to mention at this stage the very valuable work done by the Doctors Hopkinson, Crompton, Kapp, and others in the improving dynamos and motors by applying scientific principles in the construction of these machines. Were I lecturing on dynamos and motors instead of on the electric transmission of power, I would explain to you how by putting more iron into the rotating armature, as it is called, and less wire on it, by shortening the stationary magnet, and generally by concentrating the magnetic action, these constructors have raised the commercial efficiency of these machines to actually as high as between 93 and 94 per cent.; further, how by recognising the force of the general principles laid down by Professor Perry and myself as to the difference that should exist in the contruction of a motor and a dynamo Messrs. Immisch have succeeded in constructing strong durable electro-motors weighing not more than 62 lbs. per effective horse-power developed.

The subject is so entrancing to me, the results commercially so important, that I am strongly tempted to branch off, but the inexorable clock warns me that I must concentrate my remarks as they have concentrated the magnetic action.

Of the power put into an Edison Hopkinson dynamo 87½ per cent. has actually been given out by the motor spindle, when 50-horse power was being transmitted. How does this compare with *combined* efficiencies of an air pump and an air motor, or of a water pump and a water motor? I understand that in either of these cases 60 per cent. is considered a very satisfactory result. As far, then, as the terminal losses are concerned, electric transmission of power is certainly superior to air or water transmission.

The next point to consider is the loss of power on the road between the dynamo at the one end and the motor at the other. This problem was perhaps seriously attacked for the first time in the discussion of a paper read by Messrs. Biggs and Brittle at the Institution of Civil Engineers in 1878, and that problem was considered in some detail, theoretically and experimentally, at the lecture I gave during the meeting of the British Association in Sheffield in the following year. It was then shown that, since the power developed by the generator and motor depended on the product of the current into the electric pressure, while the loss when power was transmitted through a given wire depended on the square of the current and was independent of the electric pressure, the economical transmission of power by electricity on a large scale depended on the use of a very large electric pressure and a small current, just as the economic transmission of much power by water depended on the use of a very large water pressure and a small flow of water. At that time it was not thought possible to construct a small dynamo to develop a very large electric pressure, or potential difference, as it is technically called, and therefore it was proposed to join up many dynamos in series at the one end, and many lamps or electric motors in series at the other, and to transmit the power by a very small current which passed through all the dynamos and all the lamps in succession one after the other.

You have an example to-night of the realisation of this principle in the fifteen arc lamps that are all in series outside this Drill Hall, and are worked with a small current of only 6·8 ampères, as indicated in the wall diagram; and a further example in the thirty arc lamps at the Bath Flower Show, which are also all worked in series with the same small current passing through them; but it is known now how to produce a large potential difference with a single dynamo, so that a single Thomson-Houston dynamo belonging to Messrs. Laing Wharton and Down supplies the current for each of the two circuits.

The electric pressure, or potential difference, between terminals of any arc lamp is not high, but it is between the main wires near the dynamo as well as between these wires and the ground. How far does this lead to the risk of sparks or unpleasant shocks. This is a point that can be looked at in a variety of ways. First there is the American view of the matter, which consists in pointing out to people exactly what the danger is, if there be any, and training them to look out for themselves; let ordinary railway trains, say the Americans, run through the streets, and let horses learn to respect the warning bell. Next there is the semi-paternal English system, which cripples all attempts at mechanical street locomotion, because we are Conservative in our use of horses, and horses are Conservative in their way of looking at horseless tramcars. Lastly, there is the foreign paternal system which, carried to its limit, would prohibit the eating of dinners because some people at some time choked themselves, and would render going to bed a penal offence because it is in bed that most people have died.

We laugh a good deal at the rough and ready manner adopted on the other side of the Atlantic. The Americans, no doubt, are very ignorant of the difficulties that properly-minded people would meet with, but it is a blissful ignorance where it is folly to be wise. Every English electrician who has travelled in America comes back fully impressed with their enterprise and their happy-go-lucky success. They have twenty-two electric tramways, carrying some 4,000,000 passengers annually, to our four electric tramways at Portrush, Blackpool, Brighton, and Bessbrook. Why, New York City alone, Mr. Reckenzann tells me, possesses 300 miles of ordinary tramway track, and Philadelphia city 430 miles, so that there is more tramway line in these two cities than in the whole of the United Kingdom put together. Now there would be no difficulty in proving to anyone unfamiliar with railway travelling that to go at fifty miles an hour round a curve, with only a bit of iron rail between him and eternity, would be far too risky to be even contemplated. And yet we do go in express trains, and even eighty miles an hour is beginning to be considered not to put too great a demand on the funds of life insurance companies. The American plan of basing a conclusion on experience rather than anticipations is not a bad one, and if we follow that plan, then taking into account that there are 75,000 arc lights alight every night on the Thomson-Houston high potential circuits throughout the world, and the comparatively small number of people that have suffered in consequence—not a single person, I am assured, outside the companies' staff, we are compelled to conclude that high potential now is what thirty miles an hour was half a century ago—uncanny rather than dangerous.

But it is possible to use a very large potential difference between the main wires, by means of which the electric power is economically conveyed a considerable distance, and transformed into a small potential difference in the houses where it is utilised. An electric transformer is equivalent to a lever, or wheel and axle, or any other of the so-called mechanical powers. You know that a large weight moving through a small distance can raise a small weight through a large distance; there is no gain in the amount of work, but only a transformation of the way in which the work is done. A large weight moving through a small distance is analogous with a high potential difference and a small current, while a small weight moving through a large distance is analogous with a small potential difference and a large current, and an electric transformer is for the purpose of effecting the transformation with as little loss of power as possible, so that what is lost in potential difference may be all gained in current.

Electrical transformation may be effected by

(1) Alternate current transformers,
(2) Motor-dynamos,
(3) Accumulators, or secondary batteries,
(4) Direct current transformers.

Of these apparatus the oldest by far is the alternate current transformer, as it is merely the development of the classical apparatus invented by Faraday in 1831, and familiar to many of you as the Ruhmkorff or induction coil. A combination of a motor and dynamo was suggested by Gramme in 1874. Accumulators are the outcome of Planté's work, while direct current transformers are quite modern and not yet out of the experimental stage.

After studying the literature on the subject, it appears, as far as I have been able to judge, that the first definite proposal to use a high potential difference in the street mains and transform down to a low potential difference in the houses, was made in the lecture given by me at the meeting of the British Association in Sheffield in 1879, on which occasion I explained and showed in action the motor-dynamo principle suggested by Professor Perry and myself. The apparatus on the platform is not unlike that shown on the former occasion; an Immisch motor working at 500 volts and with a current of 6·8 amperes is geared direct to a Victoria brush dynamo giving five times that current, and we will now use this larger current to produce an electric fire. Messrs. Paris and Scott have combined the motor and dynamo into one machine, which they have kindly lent me, and by means of which we are now transforming about 700 volts and 6·8 amperes into 100 volts and about 40 amperes used to light that group of incandescent lamps and work these motors.

Lastly, here is a working illustration of the double transformation proposed by M. Deprez and Carpentier in 1881, by means of which, while the potential difference between the mains may be two or ten thousand volts if you like, not merely is the potential difference in the house so low that you could hardly feel anything if you touched the wires, but in addition there is the same security against shocks in the dynamo-room. This alternate current machine is producing about 50 volts, which is transformed up to 2,000 volts by means of this transformer. At the other end of the platform, by means of a similar transformer, the 2,000 volts is transformed down again to 50 volts employed to light that cluster of low voltage incandescent lamps.

In this experiment there is, as a matter of fact, still more transformation than that I have yet mentioned, because, whereas in actual practice the alternate current-dynamo, as well as the small dynamo used to produce the current for magnetising the electro-magnets in the alternate current-dynamo, would be worked by a steam, gas, or water engine, I am working them both by electro-motors, since a steam engine or a water wheel would be an unsuitable occupant of the Drill Hall. Practically then, a steam-engine on the land belonging to the Midland Railway Company, on the other side of the lower Bristol road, is driving a Thomson-Houston dynamo; this is sending a small current working these high voltage, constant-current Immisch motors. The motors being geared with low voltage dynamos, the potential difference is transformed down, the first alternate current transformer transforms it up again, and the second alternate current transformer transforms it down, so that there are, in fact, three transformations taking place in this experiment on the platform before you.

(*To be continued.*)

Abstracts of Papers, Lectures, etc.

SOCIETY OF ENGINEERS.

On Tuesday, 25th September, this Society visited the London and South-Western Railway Locomotive Carriage and Waggon Works at Nine Elms.

These famous works, which were originally designed by the late Mr. Joseph Beattie, and at that time considered very complete, have been, owing to the increase of traffic and stock, considerably altered and enlarged by Mr. William Adams, the present superintendent.

The works, which cover 45 acres of ground, are situated at Nine Elms, which is on the south-east side of the main line after leaving Vauxhall station; and between 2,000 and 2,500 men are employed.

The locomotive department consists of machine, erecting, wheel, smiths', fitters, cylinder, brass, coppersmiths, boiler, tender-fitters', mounting and pattern shops, grindery, iron and brass foundries, and running sheds. The "short" machine shop is a large brick building, well lighted, and is 164 ft. long by 57 ft. wide. It is well fitted with the most modern classes of machine tools, milling machines being conspicuous by their large numbers, notably an horizontal milling machine by Messrs. Muir, of Manchester. These machines leave the work in such a state of perfection, that further attempt at finishing with a file would only spoil it. On leaving the "short" machine shop the cylinder shop is entered, which is provided with a very useful overhead travelling crane, made at Nine Elms. Here there are two very fine vertical milling and drilling machines, which are used for machining the valve faces of cylinders. This shop is 57 ft. long by 29 ft. wide. In the fitting shop, which is 118 ft. long by 58 ft. wide are several "vortex blast pipes," the invention of Mr. W. Adams. There is no doubt that when this pipe is designed on thoroughly scientific principles that a great saving of fuel is effected, and this has been proved by the gradual decrease of coal consumption during the last three years on the South Western Railway. We may here mention that the average consumption of fuel in 1885 was 30 lbs. per engine mile, which has now been reduced to 26½ lbs. per mile. This has effected a total saving, since June, 1885, of nearly £34,000. In the brass shop is made the white metal piston and valve rod packing, which is a standard now with all new engines of the South Western Railway, and is giving the greatest satisfaction. The millwrights' shop is 85 ft. long by 58 ft. wide, and is fitted with very modern machinery. The "long" machine shop is 300 ft. long by 57 ft. wide—the standard width of the shops at Nine Elms. A piston-rod grinding machine is here in use. The rods are first roughed down in the lathe and finished off here.

The erecting shops consist of two bays, each 500 ft. long by 57 ft. wide, and which have accommodation for seventy engines. There are three roads in each bay.

Each erecting shop is provided with two 25 tons overhead travelling cranes, which are capable of lifting an engine bodily from one road to another, and each is capable of lifting and travelling transversely and longitudinally at one time, all of which operations are controlled by one man. Hydraulic piping, supplied with water at a pressure of 1,500 lbs. per square inch, is laid throughout the entire length of these two shops, so that small hydraulic tools can be worked from this source of power. The boiler shop, which is 178 ft. long by 116 ft. wide, is divided into two bays, the first of which contains the machine tools. There is also a plate-grinding machine which has been recently made at Nine Elms, and is found to be thoroughly efficient. A very large number of boilers are in progress of manufacture. Steel, with the exception of the firebox and tubes, is wholly used in their manufacture; manganese steel stays are now replacing copper for the firebox. In the adjoining bay is fixed one of Tweddell's stationary hydraulic rivetters, having 11 ft. 6 in. gap. In connection with this is a 7 tons hydraulic crane. In the hydraulic engine house are fixed two pairs of engines by the Hydraulic Engineering Company of Chester, which supply water at a pressure of 1,500 lbs. per square inch to an adjoining accumulator, from which all the hydraulic tools in these shops, including three turntables, are worked. The smiths' shop is 194 ft. long by 57 ft. wide, and contains twenty-six forges, inclusive of bolt makers' fires. The forge and spring makers' shop is a large brick building 176 ft. long by 51 ft. wide. The iron foundry is served by two 5 tons steam cranes by Appleby Bros. Adjoining this is the brass foundry, which is fitted with Fletcher's furnaces and the usual appliances. The carriage building shop is a well-lighted building 194 ft. long by 60 ft. wide, in which the bodies and under-frames of coaches are built. This shop is heated by exhaust steam. In the saw mill all the saw-dust, etc., is automatically conveyed by a fan to a collecting tower, from whence it is utilised to raise steam in one of the stationary boilers. The whole of the shafting for driving the various machines is fixed below the floor, which arrangement keeps all the driving bands out of the way, and does not necessitate the use of counter-shafts.

In the carriage machine shop, which is 194 ft. long and 57 ft. wide, are numerous drilling, nut tapping, shaping, and slotting machines. There is also a brick factory, in which the fire bricks for the brick arches of locomotives and furnaces at Nine Elms are made. The running shed is 235 ft. wide by 180 ft. long, and is capable of holding 60 engines. At the east end of the works, *i.e.*, towards Vauxhall Station, is situated a large shop 225 ft. long by 170 ft. wide, in which are made the road vans and outstation furniture, and attached is a small saw mill and smithy, with the necessary tools for quickly despatching this class of work. Four of the arches under the main line are fitted up as dining halls for the workmen; the remainder being used as shops and stores. The South Western Railway has now in operation about 850 miles of line, which is served by 550 locomotives, 3,000 carriages, and 8,000 waggons.

This completed a very interesting tour of the London and South Western Railway shops; but, perhaps, the chief characteristic that pervades the works is the evidence of vitality and vigour of the Management, which is sufficient to account for the rapid progress made by this establishment under the superintendence of Mr. William Adams during the last few years.

MANCHESTER MICROSCOPICAL SOCIETY.

At the meeting held on September 13th, Mr. James Hart, F.C.S., read a communication on "Insect Powder." After referring to powders previously used as insecticides, he described the insect powder in most common use to-day, which is prepared from the flowers of *Pyrethrum roseum*, or *P. cinerariefolium*, the former known as Persian, and the latter as Dalmatian insect powder. The powder from Dalmatian flowers is acknowledged to be the best and strongest, owing, perhaps, to the fact that fewer double flowers are found in it than the Persian. More than twenty years ago a German traveller described this powder as a sure protection against all kinds of insects, and by making a tincture of the flowers, diluting it with water, and sponging his body he was enabled to sleep without even the protection of the mosquito net. An American naturalist describes the action of the powder on different insects. The smell does not affect them, but, when carried to the maxillæ or mandibles, complete paralysis of the motor nerves takes place, the legs being paralysed in regular order, beginning at the first pair. Different classes of insects are susceptible in varying degrees to its influence, all insects having open mouthparts being peculiarly liable to its influence, whilst others, such as the Hemiptera, owing to their peculiarly-shaped mouths, are able to vigorously resist it. The plant itself is quite inactive and utterly valueless as an insecticide. The best powder is prepared from half-open or closed flowers, that prepared from open flowers being much weaker. After describing the structure of the flowers by means of drawings, Mr. Hart drew the attention of the meeting to an adulterated powder which is being sold in large quantities at a price fifty per cent. below that at which the genuine can be procured. This powder is made by grinding up the entire plant, which, as before stated, is innocuous. It also contains at least twenty-five per cent. of wheat starch and twelve per cent. of yellow ochre, so that the insects who come across this so-called insecticide must have had quite a joyful time of it, for twenty-five per cent. of it they can devour with impunity, and the rest will not have the slightest effect upon them.

An interesting discussion followed the reading of the paper, more especially as to the use of the microscope in detecting adulterations. The general impression seemed to be that for mineral adulterants it was not of much use, chemical analysis in these cases being requisite, but that in the detection of organic adulterants it was a most valuable instrument to the analyst, as is shown by the numerous illustrations of the microscopic appearance of various food-stuffs which are given in the standard works on the subject of analysis of food and drugs. As to the percentage of adulteration which it is possible to detect by a microscopical examination, considerable difference of opinion seemed to prevail. In the case of an adulteration by means of starch it was held by some that five per cent. of the adulterant would escape, whilst others thought that so low a percentage as one per cent ought to be detected by anyone acquainted with the microscopic appearance of the commercial starches. It was agreed by all that if the adulterant were rice starch one per cent. ought to be detected, owing to the peculiar character of the grains of rice starch.

Mr. Edward Ward, F.R.M.S., described some microscopical objects met with in an afternoon's ramble, and showed under the microscope slides prepared from them. He mentioned an instance of what he considered communication on the part of the ants. Wishing to obtain some he found that they climbed a certain plant, from which he could brush them into his collecting bottle, but after a time very few ants came upon the leaves, and those that did so turned back, his impression being that they had been warned by others of the danger attending such a course. He gathered a number of flowers of the mallow (*Althœa officinalis*), the anthers and pollen grains of which make beautiful microscopic objects. He had found that in preparing it from the fully-opened flower, most of the pollen grains fell off, whereas, by gathering the unopened buds, stripping off the leaves, and drying the anthers out of reach of dust, much better results were obtained. He had also noticed that wheat was largely infested by a fungus (*Ustilago segetum*) commonly known as the corn smut. This fungus, however, does not damage the flour, as the fungus reaches maturity, dries, and is scattered by the wind before the corn is ripe. The other fungus which affects wheat, the wheat bunt (*Tilletia caries*) is not so common, but is much more destructive, and is a more insidious foe to the farmer. In the case of this fungus the ears of wheat remain green and externally there is no appearance, except to the practised eye, that anything is wrong. There is no black impalpable dust about the ears as in the "smut," but stealthily and secretly the work is accomplished, and until the bunted grains make their appearance in the sample the disease may, perchance, be unchallenged. When the grain is broken, the farinaceous interior will be found replaced by a minute black dust of a very fetid, unpleasant odour and greasy to the touch. Flour which contains a large proportion of bunt is injurious in proportion to its extent. The prevalence of these fungi on wheat is due to the wet summer we have had, as it is well known that many fungi flourish in proportion to the wetness of the season.

Mr. Parkes read a paper on the nest of a trap-door spider found at Ajaccio in Corsica, and exhibited four nests.

Malton Naturalists' Society.—At the meeting held on September 24th, Mr. Matthew B. Slater, the curator, reported a most interesting discovery during the recent excursion of the union to Houghton Woods, Market Weighton. In a fir forest there a Mr. Marshall had found eight specimens of *Goodyera repens*, which Mr. Slater states has never previously been found in Yorkshire, and only once before in England. The "find," he added, was an interesting one, geologically as well, as the *Goodyera* is an old Arctic plant, found chiefly in the North of Europe, and flourishes in the fir forests of North Britain.

Leicester Working Men's Club and Institute.—Mr. A. Berry delivered the first lecture of the season on September 25th, taking "The Moon" as his subject.

Liverpool Science Club.—On September 22nd a large number of the members of this club met in the Museum, William Brown-street, to hear a lecture by the Rev. F. F. Grensted, M.A., on "Egyptian and Babylonian Antiquities." Beginning with a clean-cut Egyptian tombstone, carved some 3,500 years before the Christian era, the lecturer showed the peculiar religious belief of the Nile dwellers of that age. The growth of language was also pointed out, and the strange developments of totemism as shown by the mummy cats and other strange animal forms preserved in the museum. The pictures of the last judgment, as taken from the book of the dead and figured on one of the mummy cases, attracted much attention, as showing the peculiar notions of the Egyptians with regard to a future state. The tools of the ancient races were compared with the tools of the modern mechanic, and it was shown how nearly allied we are in many respects to the long perished races, and comparisons were made on points of labour, language, literature, and religion.

Sydney Natural History Association.—The fifth excursion of members of the association took place on Saturday, June 30th, the locality selected being on the western slope of Bellevue Hill, and in the adjacent gully. The following plants were found and examined: *Persoonia tenuifolia*, *P. lucida*, *Hakea rostrata*, *H. acicularis*, *H. bifurcata*, and *H. flexilis*, *Banksia serrata*, *B. marginata*, and *B. integrifolia*, *Lambertia formosa*, *Grevillea sericea*, and *Xylomelum pyriforme*, the "wooden pear" of the settlers. Among leguminous plants collected and examined were *Bossiœa ensifolia* and *B. scolopendria*, *Hardenbergia monophylla*, *Hovea linearis*, and four or five species of acacia. It was rather early in the season for the majority of flowering plants; but some of the genera Rutacæ were just commencing to unfold their charms, the species collected being *Correa speciosa* (known to bush children as the native fuchsia), *Crowea saligna*, *Boronia ledifolia*, *B. floribunda*, and *B. parviflora*. The epacrids were also beginning to display their beauty, being represented by the handsome though cosmopolitan *Epacris longiflora*, *E. microphylla*, and *E. pulchella; Styphelia tubiflora*, *S. viridis* (much sought after in the summer season for its fruits, known as five-corners), and *Astroloma hemifusa*. Among ferns collected in the gully were *Todea barbara*, *Davallia dubia*, *Lomaria discolor*, *Gleichenia circinnata*, and *G. rupestris*, *Schizara dichotoma*, and *S. rupestris*. Here also was found, growing in the spongy soil, saturated with the drip of water from the rocks above, that curious plant, *Drosera binata*, one of Darwin's carnivorous plants, with broad, deeply-cleft leaves, the lamina presenting the figure of a V; while the petioles are several inches in length.

Agri-Horticultural Society of Burma.—From the proceedings of the meeting held on August 11th, we learn that during June and July special attention had been paid to moth collecting, as Colonel Swinhoe, who is naming them for the Museum, intended leaving India for Europe at the end of this year. Good specimens of a large number of species had been obtained, of which over one hundred were new to the collection. Two or three of each variety had been sent to Col. Swinhoe for identification, and very many were most likely new to science. In such cases he would take them to Europe with him, and describe them there, and then return the specimens. He has several specimens now with him which he considers new, but for want of sufficient books of reference has not described. He has as yet only returned a small number of those sent to him in the beginning of June. The Rev. Latham Browne has again sent over an hundred moths collected at Thayetmyo by him, many of these are new to the collection Major Bingham has presented the museum with five rare moths and three butterflies, besides a collection of beetles lately collected in Maulmain.

RECENT INVENTIONS.

The following list has been compiled especially for the SCIENTIFIC NEWS *by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents, of 323, High Holborn, London, W.C.; Newcastle Chambers, Angel Row Nottingham; Ducie Buildings, Bank Street, Manchester; and 6, Lord Street, Liverpool.*

HORSE SHOE.—A horse shoe has been patented by Messrs. R. Lamb and J. Surthenbank. It is formed of metal, and is fastened to the hoof and to the shoe already upon it by means of suitable devices. This second shoe has in it spikes or projections which prevent the horse from slipping, and may easily be placed upon or taken off when desired without disturbing the ordinary shoe.

TEA.—A method of preparing tea has been patented by Mr. H. Jackson. By the use of this invention the astringent quality known as "tannin" is neutralised or destroyed. It is carried out by spraying over the tea a solution consisting of water and a suitable proportion of carbonate, and then drying it so as to evaporate the water, leaving the alkali on the tea. This has the desired effect.

BOATS.—A collapsible boat has been patented by Mr. C. Henderson. The object is to construct boats so that they may be stowed over each other in great quantities under the present launching appliances on the decks of vessels and without taking up more room than hitherto required. The frames of the boat are jointed to their gunwales and to fore and aft sides at the keel. These longitudinal moving sides allow the frames to slide in a fore and aft direction, and the gunwales to fall in a perpendicular manner; the boat thus collapses, and may be folded down to a horizontal position.

FUEL.—An artificial fuel has been patented by Mr. W. H. Nevill. This invention utilises the inferior sorts of fuel such as breeze, small anthracite, and other inferior fuel or hydrocarbons. To any of these substances is added pitch prepared by adding to it in a boiling state ordinary silicate of soda, after which it is allowed to set and then crushed for mixing with the above substances. This mixture is heated to produce an intimate admixture. While so heated common coal tar in a boiling state is added. The entire compound is then well mixed, then placed in moulds and subjected to pressure, after which it is ready for use.

ELECTRIC CIRCUITS.—An apparatus for detecting and localising faults in alternate current electric circuits has been patented by Mr. W. P. Thompson, on behalf of Mr. G. Westinghouse. The invention consists in placing two electric converters in circuits which may be completed from the respective poles of a generator with the earth, and in applying to each an indicating device, such as an incandescent electric lamp, included in their respective secondary circuits. In case there is a ground connection with one of the lines, the converter connected with the corresponding line will be short-circuited, and the consequent variation in the light will indicate that such false connection is made.

SODA.—An improved manufacture of soda has been patented by Mr. J. B. Thompson. The invention consists in reducing the whole of the sulphide solution to neutral carbonate by heating the solution as soon as bicarbonate has been deposited, which decomposes the bicarbonate into neutral carbonate and carbonic acid, and this acid reacts upon the residual sulphide, producing neutral carbonate and hydrogen sulphide, which passes off and leaves in solution neutral carbonate only. The form of carbonator consists essentially of a series of discs mounted on a spindle, the discs having been cut down and twisted into the whorls of a continuous screw, and has an arrangement of pipes and cocks for the gas and solution.

SECRET WRITING.—A method of secret writing has been patented by Mr. M. A. Weir. The method can be applied to any type-writing machine, and may be carried out as follows:—The machines are in duplicate, so that the two index scales correspond in the arrangement with each other, but differ in the arrangement of the characters from any other pairs of machines. Each machine is capable of writing in cipher. The index scale pointer and type are made moveable, so that they may be shifted out of their correct position, thus when writing with the machine the characters which the operators appear to be writing are really different. In deciphering it is only necessary to shift the movable parts in the opposite direction, and then, by printing the characters of the secret communication, the correct one will be printed.

ELECTRIC BELL INDICATOR.—An indicator for electric bells has been patented by Messrs. A. Morley and H. W. Wilson. The core for the electro-magnet is made of malleable cast-iron in one casting, with an angle bracket for fixing it in place, and with a taper flange at each end of core; it has also a flange for affixing a spring which carries the armature. This casting is japanned, which serves for insulation. The core is wound with silk-covered wire. An indicator is combined with the armature, and is of the usual disc form, and at one end of a double-armed lever where it has a notch that catches over a peg on the armature, the fulcrum screw for the lever being at the end of the casting, and the other arm of lever having an eye with a half-twist. This eye connects it to a re-setting bar. As the keeper is attracted the disc is released from the peg and falls down until stopped by a stop thereon coming in contact with a part of the casting.

ELECTRIC CIRCUITS.—An apparatus for making and breaking electrical circuits in connection with alarm boxes has been patented by Mr. F. T. Schmidt. The periphery of the wheel secured on the "click wheel shaft" of the call box is divided into separate parts, each part having projecting pins corresponding to the number of the box, and an arm extending from the shaft. At the central station is fixed a similar apparatus, but having the distance from the periphery of each part to the centre varying, by which means the electric current is diverted from one local magnet to another. When a signal is sent from an alarm box, the electric current sets in motion the apparatus at the central station, connected to two local magnets which operate dial pointers for actuating a needle, by which a revolving disc controlled by a clock is pierced in a manner so that the time and number of district from whence the signal was sent is indicated thereon in addition to the number being given by the pointers.

A SAFE INSECTICIDE.

Referring to the notice in your columns of to-day of the application of sulphate of copper as an insecticide, it is stated in the first Annual Report on the injurious and other insects of the State of New York, by J. A. Lintner, the State entomologist, that "Sprinkling with a weak solution of blue vitriol, one ounce to a pail of water, kills many kinds of larvæ." In the exhaustive account which is given in this volume of the remedies for insect depredations known in the United States, the safety of the application is regarded; and virulent poisons, such as blue vitriol, require extreme caution in their manipulation.

The sulphate of iron, which is probably the most fatal of any chemical to the smaller forms of insects, is so harmless to human life that five grains are given as a dose, and minnows are unaffected by a solution of eight grains of this sulphate in a gallon of water. Vol. xiii. of the Professional Papers of the Corps of Royal Engineers, contains an account of the destruction of aphides, micro-organisms, and those more recently discovered forms of life to which the phenomena of putrefaction are now attributed, by a very weak solution of iron; and where the destructive enemies of plant life are too large to be thus rapidly destroyed, the solution still acts as an andidote to their attacks, as few, if any, insects will approach a vegetable that has been watered with a solution of iron.

The simplest mode of obtaining a stable solution of iron for the use of the garden or greenhouse is to draw it off from the cup of the ferrometer. This is an instrument for household purification, which is described in the professional paper cited. It is manufactured by Messrs. Filmer and Mason, of Guildford; is now in use at Windsor Castle, Buckingham Palace, Hatfield House, Albury Park, and a number of other places. The perfect sweetness of the dwelling-house is the main result of the use of the instrument; but the subsidiary value for the garden and greenhouse is not to be despised. FRANCIS R. CONDER, M. Inst. C.E.

Guildford, Sept. 22nd, 1888.

STRANGE ACTION OF A BEETLE.

I was amused at reading of the beetle's strange conduct, for I happened to be acquainted with a man of science who acts exactly in the same way. He goes round and round so many times a certain piece of ground to take a constitutional, and when he has accomplished a certain number of rounds he knows that he has walked a certain number of miles. The *one eye idea* (see SCIENTIFIC NEWS Sept. 7th) I should hardly think sufficient to account for it, but in *Nature* I remember reading some account of an American experiment in walking blindfold. Often people have one leg a little shorter than the other, and in this case the tendency is to walk when blindfolded, in the direction of the shorter leg.

The beetle's strange conduct *might* have something to do with this, but I do not think so. It is probable that insects are much more intelligent than we generally suppose them to be. A READER.

THE SATELLITES OF MARS.

There is a paragraph in your journal for September 14th, page 279, in which the theory of M. Dubois is mentioned, but I think there are very few astronomers who will give it their adhesion. The satellites of Mars, instead of being captured planetoids, very probably date their origin from a period coeval with their primary. This conclusion is upheld by the analogies of the solar system. Bode's law of planetary distances is, we know, exemplified in a remarkable manner, and there also appears a definite law in regard to the number of satellites. They increase, in duple proportion, according to their distance from the sun thus:

Earth.	Mars.	Jupiter.	Saturn.
1	2	4	8

Uranus and Neptune would probably further bear out this law, could we view them with greatly increased telescopic power, for the known satellites of these remote members of our system form but a small proportion of the whole number of satellites which belong to them. It is probable that Uranus has 16 and Neptune 32 satellites. We are justified in this assumption by the regular increase in the number of moons attending Mars, Jupiter, and Saturn, which is very likely to be extended to the two outer planets of the system. We are probably cognisant of all the satellites revolving round the earth, Mars, Jupiter, and Saturn, but the immense distances of Uranus and Neptune preclude us from discovering any but the most brilliant of *their* satellites. These bodies were evolved or formed as the result of a comprehensive and harmonious scheme, and we are not driven to such an erratic inference that the moons of any of the major planets are due to the capture of planetoids.

A MEMBER OF THE LIVERPOOL ASTRONOMICAL SOCIETY.

FOOD OF THE LEECH.

Can any of your readers inform me of the general food of the common leech? In the ponds which it inhabits it seldom has the opportunity of feasting on blood, and it does not readily attach itself to the skin even when laid on the hand.

Perhaps leeches feed on aquatic plants, as they are often to be found adhering to the stalks of weeds, such as *Alnacharis alsinastrum.* I do not think they ever attach themselves to fishes, as I have sometimes placed sticklebacks in with them without their attempting to fasten. I have never noticed any allusion to their food (when living in ponds) in any book, and should be pleased to know the real facts of the case.

F. P. P.

THE SPARROW *(Passer domesticus).*

In my notes made in 1886 I stated that the large quantity of fine dust found in the nest of the sparrow was not accidental, but placed there intentionally; this appears to be the fact, for I have seen the sparrow collecting the fine dust from the road on pieces of material for building.

By way of leading up to what I am going to say, I may again state that in 1886 I found from 20 to 25 per cent. of infertile eggs, and in 1887 about 30 per cent.; but in the season of 1888 just passed I found the percentage of infertile eggs considerably reduced, and also a very considerable reduction in the number laid, the average clutch being four eggs, whereas in 1887 it was four and a half eggs. I stated in my paper last year that the eggs laid in 1887 were not so highly coloured as those of the previous year, and the infertility greater; but when I made this statement I little thought that colour and fertility were intimately connected; nevertheless it appears to be the case, for the eggs of the season just past, of which I have ninety perfect clutches before me, are most certainly of a darker colour than those of the previous year. I may here state that the odd egg in the clutches just referred to is not so pronounced as it is in the clutches of the two previous years, and its infertility was not greater than any of the eggs of the ordinary type. This accounts for the fact that, as a rule, the more pronounced the odd egg the greater its infertility, and that in the two previous years the clutches bring one half egg larger and of a lighter colour, and with a more conspicuous odd egg, proves that what I said as to the high percentage of infertility in the odd egg about correct.

The discrepancy between eggs and brood of the season just passed appears to have been about 16½ per cent., the average clutch being four eggs, and the average brood three and one-third young birds, against three and one-eighth last year. The general discrepancy is not altogether brought about by the actual sterility of the eggs, but by many of them producing only a weak young bird, which either died in the nest or was turned out to die. This is a fact about which there can be no doubt. Another circumstance which appears usually to assist the general discrepancy between eggs and brood is the delicate texture of the shell of the odd egg, which often gets broken in the nest. I found that by taking two eggs of equal weight from the same clutch, *i.e.*, the odd egg and one other, that the shell of the odd egg was considerably the lighter; again, in a set of four, with a most conspicuous odd egg, which was the largest of the set, the shells when carefully blown were all of equal weight—namely, four grains each. The following gives the size and weight of each egg: ·90 × ·70, weight 60 grains; ·86 × ·66, 54 grains; ·85 × ·65, 51 grains; ·81 × ·61, 45 grains. These figures show how much more delicate the shell of the odd egg is; moreover, when drilling the holes for blowing I found the shell of the odd egg to cut so much more easily. I am informed by those who are well up in rearing poultry that the eggs of the turkey, which are sometimes laid with the colouring matter collected into hard excrescences, making the shell quite rough, are of no use for incubation, as they always get broken before the time for hatching arrives. Some turkeys' eggs I have now before me show the peculiarity referred to, but in a greater degree than in the odd egg of the sparrow.

Having for the past three years paid considerable attention to the habits of the sparrow, I yet fail to understand why it should vary the number of its eggs to produce about the same number of young birds, and why the eggs when more fertile should be more highly coloured is to me an enigma. I occasionally heard of broods of five young birds, all strong and healthy, being found, and one brood of six was reported, although I must say that personally I have not seen more than four good flyers from one nest, but I have seen several nests in which the brood was represented by one, and sometimes two young birds only.

Want of careful observation of the habits of this bird is, I have no doubt, the reason of its receiving so much persecution. There can be no doubt that it does some harm, but I have every reason to believe that it does some good which more than counterbalances. So far as my personal observation goes, it is the best fly-catcher and caterpillar-eater we have, as it stops with us all the year, other fly-catchers paying us a visit only for the pick of our entomological production.

I cannot close these notes on the sparrow without giving an instance of their slow productiveness. A pair of sparrows built their nest in a hole in a tree about ten feet from the ground; three eggs were laid, and two young birds hatched; shortly after these had flown they repaired the nest and again laid three eggs, but this time only one young bird was reared. They again laid three more eggs, and no August 4th there were two more young birds ready to fly. Five young birds for three broods are most certainly not many, and I believe that this is not at all an uncommon occurrence. The foregoing came under my personal observation, so I can vouch for its accuracy.

The average weight of fresh-laid eggs is 46 grs., but I find those taken on rich clay soil, where there is plenty of water, to give a better average than those taken on poor, dry chalk soil; this, I presume, is owing to the birds getting a better supply of insects at the period of nidification.

Royston, 1888. JOSEPH P. NUNN.

ANSWERS TO CORRESPONDENTS.

J. T. GAINE.—We have heard of a similar occurrence before. Probably, although you thought you had made everything secure, you left a portion of the paper without any weight upon it, and the newt was able to push it up and escape.

TECHNICAL EDUCATION NOTES.

UNIVERSITY EXTENSION IN LONDON.—We understand that the Society for the Promotion of University Teaching in London have made arrangements for seventeen lecturers to deliver twenty-nine different courses, many of which are repeated at more than one centre during the coming season. Eight are devoted to Literature, five to History, two to Social Science, two to Art, and twelve to Natural Science, all of them being full courses of ten or twelve lectures, with the single exception of one on Spectrum Analysis, which is to be given at Dulwich. Mr. Churton Collins supplies five of the literary courses, others being given by Mr. J. A. Hobson, Mr. E. J. Macmullan, and Mr. P. H. Wicksteed. Historical subjects are discussed by Mr. T. H. Attwater, Mr. S. R. Gardiner, and Mr. E. L. S. Horsburgh. Mr. Ernest Radford lectures on Art and on Architecture, Mr. G. Armitage Smith on Political Economy, and Mr. P. H. Wicksteed on Sociology. Of the scientific courses, Chemistry is taken by Professor V. B. Lewes, Astronomy by Mr. J. D. McClure and Mr. E. J. C. Morton, Physiology by Mr. Walter Pye and Mr. D. W. Samways, Electricity by Mr. W. Lant Carpenter, Physical Geography by Mr. A. W. Clayden, and Geology by Professor H. G. Seeley.

THE GRESHAM LECTURES.—The lectures founded by Sir Thomas Gresham will be read to the public on the following days in English, at 6 o'clock each evening, in the theatre of Gresham College, Basinghall Street, in the following order:—Physic (Dr. E. Symes Thompson), October 2, 3, 4, and 5; Rhetoric (Mr. J. E. Nixon), October 9, 10, 11, and 12; Astronomy (Rev. E. Ledger), October 16, 17, 18, and 19; Law (Dr. J. T. Abdy), October 30 and 31, and November 1 and 2; Geometry (the Dean of Exeter), November 5, 6, 7, and 8; and Music (Dr. Henry Wylde), November 13, 14, 15, and 16. In consequence of the death of Dr. Burgon, the Dean of Chichester, no lectures on Divinity will be delivered this term.

THE FORESTS OF EUROPE.—The French Ministry of Agriculture has recently issued some interesting statistics respecting the distribution of forest in Europe. The total area of Europe laid out in forest—exclusive of Turkey, Bulgaria, Bosnia, and Herzegovina, omitted in the official statement—is set down at 286,989 million hectares, or about 708,862 million acres; that is, about 18·7 per cent. of the total area of Europe is forest land. In proportion to its total area Great Britain and Ireland has of all countries in Europe the least extent of forest, amounting to only 4 per cent. of its surface, and, in proportion to the number of its inhabitants, enjoys by far the least allotment of forest, amounting to only 0·036 hectare, or 0·089 acres—*i.e.*, considerably less than the tenth of an acre to each inhabitant. The country in Europe next lowest in the forest scale is Denmark, with 4·8 per cent. of forest land, or 0·09 hectare to each inhabitant. That is to say, in Denmark there is an average of between two or three times the extent of forest land to each inhabitant that there is in Great Britain and Ireland. The third of the countries of Europe in the ascending forest scale is Portugal, with 5 per cent. of forest land and 0·11 hectare to each inhabitant—*i.e.*, an average of three times the amount of forest land to each inhabitant of Portugal that is allowed to each inhabitant of the United Kingdom. Holland has 7 per cent. of forest land and 0·05 hectare to each inhabitant, or about one and a-half times as much as to each inhabitant of the United Kingdom. The country in Europe possessing most forest is Russia in Europe, with 200,000 million hectares—*i.e.*, 37 per cent of its whole area and 3·37 hectares to each inhabitant—that is, each inhabitant of Russia in Europe has an average of nearly 94 times the extent of forest land allotted to each inhabitant of the United Kingdom. In its percentage of forest land and the amount of forest to each inhabitant, Sweden, however stands still higher. With 17,569 million hectares of forest Sweden has 39 per cent. of its land in forest, and so 3·84 hectares of forest to each of its inhabitants. Norway, with 24 per cent of its area in forest, allows each of its inhabitants an average of 4·32 hectares forest, or 120 times as much as is allowed to each inhabitant of the United Kingdom. Hungary has 29 per cent. of its area in forest, or 0·58 hectares of forest to each inhabitant. France possesses 9,888 million hectares of forest, or 17·7 per cent. of its total area, and so allowing 0·25 hectares of forest to each of its inhabitants—nearly seven times as much as is allotted to each inhabitant of the United Kingdom.

The Charge for Advertisements in this Column is Sixpence for the first sixteen words, and Sixpence for every succeeding eight words. Advertisements for this Column should be received by first post on Tuesday to insure insertion in the following number.

Astronomical Telescope, 9 in. object glass and 4 powers, late the property of a gentleman (deceased).—Apply, JAS. BARNES, Brunswick New Road, Norwich.

To Microscopists.—First-class unmounted objects, Rock and coral sections, 3s. 3d., series of six varieties; 9 doubly stained botanical sections, 18 miscellaneous, 1s. 1d. each series. Full instructions. All mounting requisites. Quality guaranteed. List, stamp.—MASON, 24, Park Road, Clapham, S.W.

8 in. Achromatic Astronomical Telescope, from the observatory of the late John Watson, Esq., F.R.A.S., for sale, a bargain, comprising 8 in. object glass by Wray (cost £140), six eye-pieces and spectroscope by Browning, metal stand, and driving clock, and all fittings, cost about £700, price £150.—H. L. FOX, 121, Bishopsgate Street Within, London.

The Rev. T. W. Webb's 9⅓ in. silvered glass Reflector.—For sale, the reflector with which he made the observations referred to in his book "Celestial Objects for Common Telescopes." The mounting is a Berthon equatorial.—Full particulars on application to W. J. L., 1, Wellington Crescent, Ramsgate.

Amateur Mechanics supplied with Lathes, Drilling, Planing Machines, Castings, etc. Cash, or easy payments.—Britannia Company, 100, Houndsditch, London.

Britannia Co. *Bona-fide* makers of 300 varieties of lathes, and other engineers' tools. Prize medals. Makers to the British Government.

Practical Hints on Electro-Plating, etc. One stamp.—Address HENRIC, 234, Great Colmore Street, Birmingham.

Amalgamating Brushes, Scratch-brushes, Polishing Sand, Calico Mops, Rouge and Crocus Compositions, Nickel Salts and Anodes.—HENRIC, 234, Great Colmore Street, Birmingham.

Do your own Electro Plating and Gilding. System inexpensive. Particulars one stamp.—PERKS, 47, Alexandra Road, Richmond, Surrey.

Watts' Gas Engines, all sizes, from 1½ bore, slide explodes charge, simple. Lists, 3 stamps.—Below.

Watts' Gas Engines, work without noise, are easily made up. Castings supplied. List, 3 stamps.—Below.

Dynamos for plating and lighting, experimental dynamos, electro motors, separate parts, wire, punchings, etc.—Below.

Dynamos, highest efficiency, castings or finished. List, 2 stamps. —WILLIAMS, WATT, AND CO., Belshaw Street, Homerton, E.

Mica or Talc cut for all purposes. Mica chimneys, Mica covers, etc.—C. JOHNSON, 87, New Oxford Street, W.C.

EXCHANGES.

Exchange Notices will be inserted in this Column at the rate of Sixpence for the first twenty-four words, and Threepence for every succeeding eight words. Advertisements for this Column should be received by first post on Tuesday to insure insertion in the following number.

Powerful Electro-Motor, Grigson's pattern, on polished mahogany stand. Exchange for lantern slides, chromatropes, etc., to value 30s.—G. HARRIS, 17, York Street, Nottingham.

Student's Microscope, 2 achromatic powers, in mahogany cabinet, with 2 dozen best mounted slides. Exchange lantern slides to value £2.—G. HARRIS, as above.

SELECTED BOOKS.

A Text-Book on Steam and Steam Engines. For the Use of Students Preparing for Competitive Examinations. By A. Jamieson, C.E., F.R.S.E., Prof. of Engineering, Glasgow Technical College. With 200 illustrations and four folding plates. Third Edition. London: Charles Griffin and Co. Price 7s. 6d.

Kirke's Handbook of Physiology. Twelfth edition. Thoroughly revised and edited by W. Morrant Baker, F.R.C.S., and Vincent Dormer Harris, M.D. London: J. Murray. Price 14s.

The Industrial Self-Instructor in the leading branches of Technical Science and Industrial Arts and Processes. With practical, useful, and technical notes, facts and figures for ready reference. Profusely illustrated by working drawings, designs, and diagrams. In five volumes. Price 7s. 6d. each. London: Ward, Lock and Co.

A Dictionary of Technical and Trade Terms of Architectural Design and Building Construction. Being practical descriptions, with technical details of the different departments connected with the various subjects: with derivations of, and French and German equivalents. Price 5s. London: Ward, Lock and Co.

A Text-Book of Physiology. By Michael Foster, M.A., M.D., LL.D., F.R.S., Professor of Physiology in the University of Cambridge, etc. With illustrations. Fifth and thoroughly revised edition. In three parts. Part I. comprising Book I., Blood—The Tissues of Movement—The Vascular Mechanism. Price 10s. 6d. London: Macmillan and Co.

NOTICES.

The Title Page and Index to Vol. I., now ready, price 3d.

Binding Cases for Vol. I., price 2s. each.

Cases and Binding, Vol. I., including Title Page and Index, price 3s.

Vol. I., bound in cloth, with Title Page and Index, 9s. 6d. —by post 10s.

The Back Numbers of SCIENTIFIC NEWS can be obtained from all Booksellers and Newsagents, or direct from the Publisher, 138, Fleet-street, London, E.C. Price 3d. each, or by post 3½d.

CONTENTS.

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

All who have reflected on the subject must have been glad to learn that the subject of gas fuel has again been discussed at the British Association. My detestation of English coal fires and their dirty surroundings has been frequently expressed. These heresies have been described as "crotchets," a very honourable epithet, seeing that the wise men of all ages have been called heretics or crocheteers by the—*i.e.*, the others.

Considerable progress has been made in gas heating since the subject was first brought before the Association in 1881, but much more is demanded.

Mr. Dowson has practically proved that fuel gas may be made at very small cost in a small apparatus, and that such gas does admirable work in driving gas engines, and in various factory applications—so far so good, and very good, but this is merely a preliminary step. The great desideratum is a supply of cheap fuel gas that we may use for warming our houses and cooking our food, so that all the dirtiness of coal heavers, coal cellars, coal scuttles, fenders and fire-irons, of smoky chimneys, and soot and dust and chimney sweepers, may be utterly and for ever abolished.

When this is done—as it must and shall be done—London will become a beautiful city, a city in which an artistic architect may follow his vocation. At present it is the metropolis of grimy abominations, dirty-faced streets, dirty public and private buildings, many of them beautiful *underneath*, but all stuccoed with soot, besmeared with black streaks and blotches that conceal and deface the original design.

There is a great deal of very fine relievo work on many buildings, both in the City and West-end—work, which if visible, would vie with the best to be found in Italian or any other Continental cities. Some time ago I suggested to an enthusiastic amateur-photographer that instead of travelling abroad for subjects, he should rise early on summer mornings and take pictures of such works—naming samples. He approved of the suggestion, but on examining the samples perceived at once that the light and shade, upon which such pictures must depend, was all obliterated by soot smears; the stone cherubs are dirtier than the street arabs in the mud below, and the allegorical females would come out in the picture with black eyes suggestive of Tom Cribb and Ben Caunt, rather than goddesses of peace and plenty.

We have not only dirty streets, dirty homes, dirty faces and dirty hands, but the very air we breathe is abominably dirty.

Frankland has shown that the distinctive character of the "London particular," the choking brown fog (which, by the way, is not the exclusive property of London, but is shared by all our large towns), is due to the coating of watery particles with a film of tarry filth produced by the condensation of the hydro-carbon vapours that are poured into the air by the imperfect combustion of bituminous coal. Such products of that barbaric device, that devoutly worshipped national fetish, "The Englishman's fireside," not only renders artistic refinement impossible, but irritates the lungs, and by familiarity with grime, reacts upon the worshippers, and induces no small amount of moral degradation. This is demonstrated by the toleration the dirt receives.

Fletcher, of Warrington, and other manufacturers, offer us gas stoves of admirable construction for both cooking and warming purposes; all that we now want is the gas at such a price as to compete with the cost of coal, in which cost we must include that of dragging coal about the house, of cleaning, chimney-sweeping, and the wear and tear it involves. At present prices of ordinary gas, the cost of a gas fire in an ordinary sitting-room is, hour for hour, between two and three times that of an ordinary open coal fire. In cases where the fire is only occasionally used, it may be cheaper than the coal fire in spite of this difference. It is needless to discuss the prime cost of gas so long as, in London, its supply to a given district is a monopoly.

That picture of the Dowson gas apparatus in the Scientific News of September 21st, inspires hope, as it shows that heating gas may be made on a moderate scale in the back-yard of an ordinary London house, and therefore, that the inhabitants of any given street, or square, or two or three streets combined, may form a small syndicate, make their own gas close to their own back doors, and supply themselves, at cost price, by purely domestic arrangements of main pipe and branches. To cover uncertainties, the charge per 1,000 cubic feet should be a little above cost, and the surplus divided, *pro rata* of consumption, in the form of bonus, as is done by the Northern Co-operative Societies.

There now exists in London some very convenient nuclei for initiating this reform. I refer to the blocks of tall houses that are divided into flats, such as those near to the Palace of Westminster, on the site of old Oxford Market, in the Marylebone Road, and other places. They are compact, and usually under single proprietorship. Surely the enterprising proprietors of some of these blocks might be persuaded to pioneer that most desirable innovation. The fact that the tenants are emancipated from the vulgar cockney prejudice against flats proves that there are reasoning beings that are not afraid of domestic innovations.

The five years' work at the Gloucester Asylum, decribed in Mr. Dowson's paper, is a step in the direction of domestic gas heating. The cost of 8d. for an equivalent of 1,000 feet of ordinary gas settles the economic question, for if we could be supplied at one shilling, nothing but dogged stupidity could prevent the general domestic use of gaseous fuel.

In reference to this subject it is desirable to brush aside the old water-gas fallacy, which still lingers in the mind of some. Water being composed of hydrogen and oxygen, which may be dissociated by heat, and these gases when separated being addicted to such energetic combustion on re-uniting, it has been supposed that we can create abundant calorific energy by the simple dissociation of water, and re-uniting its elements. If such were the case as supposed, the doctrine of the conservation of energy would be a great mistake. But the fact is, that the work of dissociating water by heat demands precisely the same amount of heat as is given out by the reunion of its elements. The case is strictly analogous to the evaporation of water, and the recondensation of the steam. Neither must it be supposed that in passing steam over heated coke or anthracite, and thus obtaining a mixture of carbonic oxide and hydrogen, or in passing air over the same, and thereby obtaining a mixture of combustible carbonic oxide and nitrogen, we create any heat beyond that which is due to the combustion of the fuel that is used for the production of the gas. We actually obtain less by the final combustion of the gas, because some is inevitably lost by radiation and convection in the gas-making apparatus. The advantage consists in the exchange of gaseous for solid fuel, in obtaining our fuel in a form that is so much more manageable, that can be utilised exactly when and where it is wanted in quantities admitting of practically exact regulation, and with little or no labour, and no dirt.

In an ordinary open coal fire, from eight to nine tenths of the heat goes up the chimney to warm the clouds. With a gas fire the proportions are reversed, eight to nine tenths are used effectively as required, and only one or two tenths are lost.

PHOTOGRAPHING A RAINBOW.—Professor H. Kayser, of Hanover (*Naturwissenschaftliche Wochenschrift*), has succeeded in photographing a rainbow from the Rigi-Kulm. He took special precautions, and used dry plate coloured with azaline.

SOME PHOTO-MICROGRAPHIC APPARATUS.

(*Continued from p. 362.*)

IN cases where an uncorrected objective is used, after obtaining the sharpest possible visual focus, the back of the camera must be racked into the position at which it has been determined the actinic focus lies.

When very great accuracy of focus is required, it is best to use, as a focussing screen, a piece of plain glass slightly greased by rubbing it upon the hand, and an adjustable focussing glass, set to focus the ground or greased surface of the screen. Through this the grease globules will be readily seen, together with the image of the object falling on the surface of the glass; and as both lie on the same plane, accuracy and sharpness may be relied upon.

It now remains to substitute the sensitised plate for the focussing screen, and to expose it.

The exposure must of necessity be long, varying according to the colour of the object, the amplification, the volume of light passing through the objective, and the class of plate used. A long exposure is desirable, and with this view, use a medium stop in front of the objective.

The actual exposure is most readily made by drawing out the shutter of the dark-slide, and when it is judged to be sufficient closing it in again. Some people effect the exposure by placing a small cap over the objective, others by placing a piece of card in front of it, and removing and replacing this for the exposure; but in the writer's experience the gradual drawing out of the shutter of the slide does not cause any disadvantage, whilst it is certainly the handiest and safest method. The removal of the cap or card always leaves a chance of interfering with the object on the stage of the microscope. Any light other than that given by the lamp should be prevented from entering the objective. A piece of velvet carefully placed over the stage and tube of the microscope will prevent this.

Such is the apparatus which can be most readily prepared, and the necessaries for which are to be found in most households nowadays.

Specially designed apparatus for the purposes of photomicrography are to be bought, and it may be useful to examine their structure.

In fig. 2 is shown a simple form of photo-micrographic camera designed by Messrs. Watson and Sons, of High Holborn, which can be used with any microscope, all that is necessary in this case being some packing beneath the frame on which the camera slides, in order that the axis of the camera and the optical axis of the microscope when in a horizontal position may coincide.

A base-board, which is detachable, extends to a sufficient distance in front of the camera to admit of a large microscope and lamp, with ample range for the adjustment of the illumination. The microscope and lamp are fitted on to a board which rotates on the top of the base-board on suitable metal centres, thus enabling the operator to turn the microscope and illuminating apparatus free from the camera, and into such a position as he may find best suits his convenience for examining and centering the object, with the assistance of an ordinary eye-piece. The rotating table is fitted with a lock which comes into action when the microscope is moved back into its central position, this ensuring accuracy of position on its return.

The front of the camera is made to slide back from the microscope to facilitate this latter function.

The camera itself has a range of 30 in., and the amplification is obtained by sliding back the focussing screen frame of the camera, which has guides, working in grooves in the framed base, with clamp screws to fix it in any desired position.

A graduated scale is let into the base of the camera whereby the distance between the lens and the focussing screen can be accurately known, and the desired amplification readily calculated.

By means of a rod running along the side of the camera the fine adjustment of the microscope can be actuated from the back of the camera.

Altogether it is a very simple, efficient, and well thought out instrument.

Messrs. J. Swift and Son, the well-known opticians of Tottenham Court Road, are the manufacturers of several very beautiful forms of photographic apparatus. Their latest, which is represented in fig. 3, is novel in several respects.

In this instrument a specially constructed microscope is used. The tube of the microscope being immovable, the stage and sub-stage traverse a strong horizontal bar, by means of rack and pinion motion, by moving which the coarse adjustment is effected.

The bar carrying the stage is fixed to a stout brass plate into which also the short body-tube is fitted, the whole being secured to the vertical front standard of the camera. The fine adjustment is accomplished by means of a milled head which acts on the stage.

The camera is compound, and consists of a conical leather bellows attached behind to a rectangular mahogany o x, and in front to the strong vertical standard before-mentioned, to which the special microscope is also secured. In this apparatus the front end of the camera is absolutely immovable. The back portion of the camera traverses a suitable raised platform or support, to which it can be clamped in any required position.

To centre the illumination and the object on the stage, the camera is closed up to the microscope as far as it will go, and a board, into which is centered a brass fitting to take a microscopic eye-piece, is fitted into the grooves, which receives the dark-slide. The camera is thus made to form the body-tube of the microscope, and on inserting an eye-piece the object on the stage can be examined with comfort; everything being satisfactorily arranged there, the camera is extended, and the focussing done as usual.

The whole apparatus is mounted on a mahogany base, and is very light and portable.

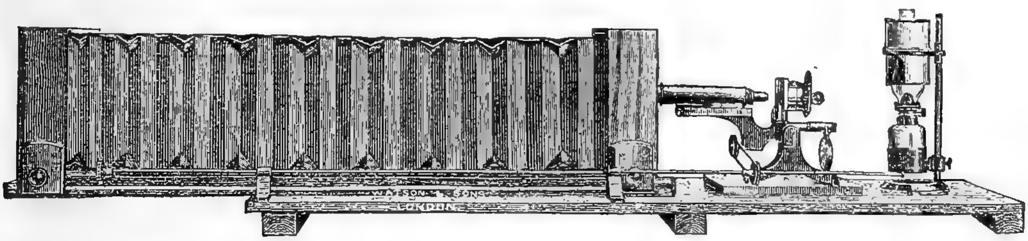

FIG. 2.

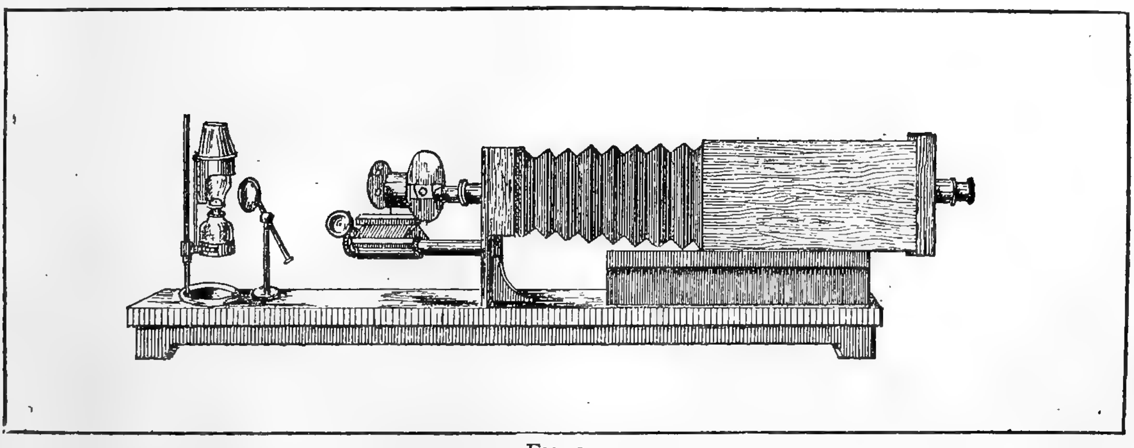

FIG. 3.

THE ANCIENT INHABITANTS OF THE CANARY ISLANDS.

A PAPER READ BY MR. J. HARRIS STONE, M.A., BEFORE THE ANTHROPOLOGICAL SECTION OF THE BRITISH ASSOCIATION.

(Continued from page 359.)

THE narrative of the conquest by Jean Bethencourt, a Norman nobleman, is written by Brother Pierre Bontier and Messire Jean le Verrier, priest, "both learned clerks," to give their own estimation of themselves in their own language.

An admirable translation is given by R. H. Major, in one of the volumes of the Hakluyt Society.

In this narrative there is little direct information respecting the ancient Canarians. The priestly narrators devote great space, as was the custom of the time, to religious details and glorifications, and the sad story of the conquest of Peru and Mexico is foreshadowed. Yet withal that Bethencourt himself managed to endear himself to the natives. He personally seems to have been a judicious and capable man. The natives were a loving, as well as a long-suffering and simple-minded race. Once, when Bethencourt returned to Lanzarote, after a visit to Normandy, the natives cried out:—"Here is our king coming," and so great was their joy, "that they leaped and danced and kissed each other." The same happened at Fuerteventura. "It is impossible," say the learned clerks, "to describe the joy which they testified, after their fashion; they seemed to fly for joy." And again, when Bethencourt left the islands, never to return, "all the inhabitants were to be seen weeping and lamenting, the Canarians more bitterly than the Normans."

Physically the ancient inhabitants were a fine race of people. This is stated over and over again by the conquerors and other travellers, and, coming from Normans, the statement may be taken at its full value.

Morally, it may be said, they were surprisingly high up in the scale we are accustomed to guage by in these days. In many respects they were the superiors in culture and manners of their conquerors. Their character has been thus succinctly and truthfully summed up by Viana:—"They were virtuous, honest, and brave, and the finest qualities of humanity were found united in them; to wit, magnanimity, skill, courage, athletic powers, strength of soul and body, pride of character, nobleness of demeanour, a smiling physiognomy, an intelligent mind, and patriotic devotedness," and, I would add, great gentleness.

From the skulls which I have examined in collections, and have myself found in their cemeteries, the people apparently possessed good brain-power. From an examination of many hundreds of skulls in the islands, I was struck by the fact that a great many possessed an indentation—about the size of the tip of the little finger—on the frontal bone, generally the left. I saw such indented skulls in Palma, Canaria, and Tenerife, and recently, on examining the collection at the Royal College of Surgeons of England, to my surprise I noticed that, out of the twenty-six skulls there labelled "Guanche," no less than fifteen had this indentation, and no less than ten on the left frontal bone. These indentations were evidently made during life, and after the infliction of the injury the subject appears to have lived in some instances for many years. At present no explanation can be given for the frequency of the occurrence of this indentation. To imagine that these skulls are all of people damaged in battle is to suppose a constant concurrence of circumstances which is well nigh impossible. It would necessitate that the blow was always given by the same weapon, on the same place, and with about the same force, and that, too, not a fatal force. The curiously frequent occurrence of these indentations is not mentioned in the catalogue of the museum, but a few remarks made in the catalogue of the Barnard Davis Collection are worth quoting: "No. 505 is very European in its look, with a narrow face and long aquiline nose." "No. 506 is a small ovoid skull of beautiful proportions, with a fine aquiline nose." The teeth of all these skulls are sound, not decayed, but very much worn, as we might expect from the "gofio" food. In the general remarks in this same catalogue occur the following significant words concerning the skulls: "All agree in being small. They belong to the ovoid division of skulls, that which is the common form among Europeans. The whole series is non-African, and would be classified in Blumenbach's Caucasian division, notwithstanding the Guanche cranium has a certain typical physiognomy which distinguishes it from all others." There was a Guanche mummy once at the museum, but it was divested of its flesh for the purpose of obtaining the skeleton, which is there now, disarticulated, in a drawer. A photograph was taken of it before it was subjected to the boning process, but this could not be traced. The museum also possesses, hid away in the recesses of a

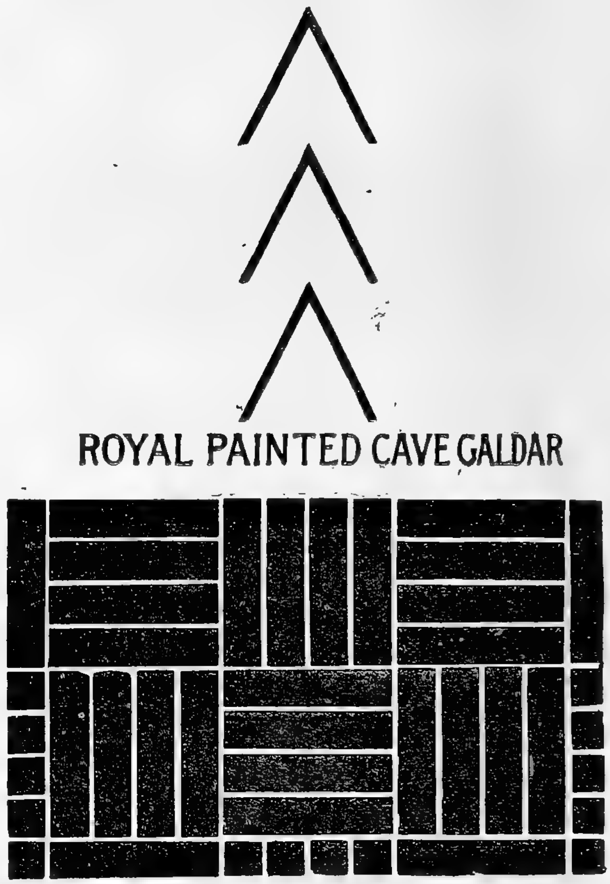

FIG. 2.—ONE-TENTH ACTUAL SIZE.

distant room, at the bottom of a box, specimens of brown, straight hair from a Guanche mummy, found in a cave at Tacoronte, and sent by Don Sebastian Casilda, the founder of the Tacoronte Museum.* The paper containing it is dated 10th March, 1854, and is distinctly greasy—an interesting point, for the Guanches used grease in heir process of embalming. I have seen no black hair belonging to this ancient people. It is always red, reddish-brown, or dark brown. One of the oldest accounts of the people say: "Their long, light hair veiled their bodies down to the waist." The famous, beautiful, and courageous Princess Dacil is distinctly stated to have had fair hair.

* This Museum is, I hear, now for sale. The British Museum should not lose the exceptional opportunity of acquiring the Guanche remains which are there.

The Guanches were good builders of structures made of stones without the aid of mortar. They built a stone wall right across the island of Fuerteventura, separating the two ancient kingdoms of that island. Though much given to living in caves, they also dwelt in stone and wood houses. These were neat and regular in appearance. The roof was composed of rough beams placed close to one another and covered with branches of trees and earth. I saw, and photographed, a good specimen in Gran Canaria from which fig. 1 (page 357) is drawn, and I also measured the interior. The entrance is set back a little, a seat being on either side. The house is rudely circular. It is fifteen and a half feet from the door to the opposite wall. The wall on the left is three feet thick at the bottom, and seven and a half feet high to the beams.

Some of the caves in which the nobles of the people dwelt were elaborately decorated. That of the beautiful Andamana at Galdar, in Gran Canaria, is one of these. When we were there we had this cave partially cleared out of the rubbish which filled it. The entrance way is four feet six inches wide by three feet high The principal cave is nearly circular, and where it could be measured was eighteen feet in diameter. It is possible that the walls sloped upwards, and that at the bottom, if it had been clear of rubbish, it would have been larger. Another cave to the right of this is also painted.

The painting is done in sections, generally running round the cave in widths of ten inches. The designs upon the walls and ceiling, of which figs. 2 and 3 are reduced copies, are in squares like a chess board, white lines being drawn across the squares; then come red circles of two rings, the outer being ten inches in diameter; next are triangles, that fit into each other, the base of one being inside the apex of the other; these are painted alternately black and red. The row beneath is a double-lined zigzag, the points or elbows being at top and bottom. Between the lines, the cave is painted red, but the spaces at the bottom are white Below these are plain squares divided by white lines; the squares are alternately red and black. Two more designs we noticed, one in squares bisected at the angles, the upper half being black and the lower red; and on a stone we saw red lines like inverted V's, one above the other. There are, no doubt, other designs down to the floor, but owing to the rubbish, we could not ascertain the fact. I am glad to say that, in response to vigorous expostulations, this cave has been purchased by the authorities of Galdar, cleared and enclosed, so that future visitors will not experience any difficulty in seeing it.

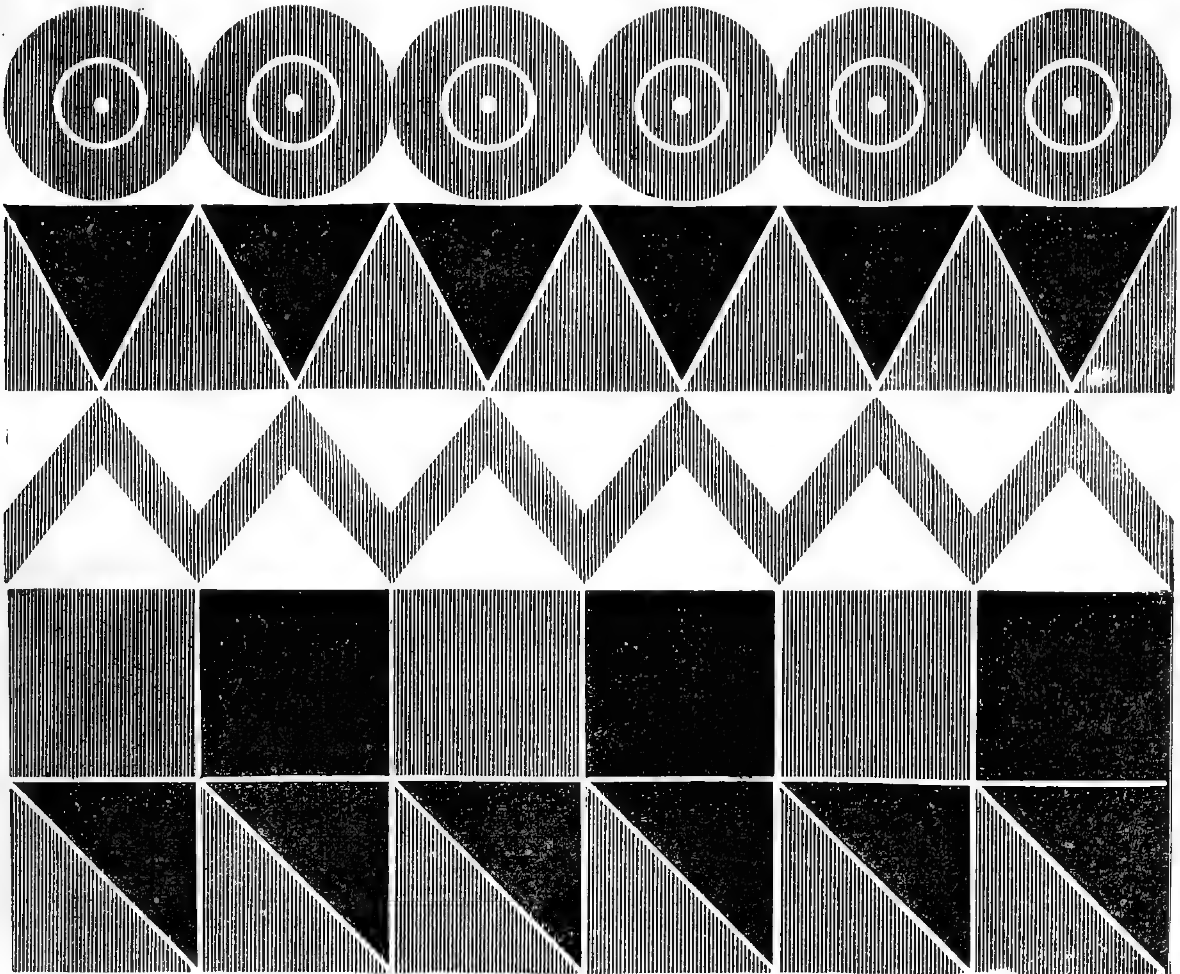

Fig. 3.—ROYAL PAINTED CAVE GALDAR (One-Tenth Actual Size).

(To be continued.)

ON THE STABILITY OF THE FAUNA OF ANY COUNTRY.

(*Continued from p.* 78.)

WHAT circumstances render it possible for a food-species to become very numerous? Above all, as it has been already intimated, great protection. It seems paradoxical to say that the more voracious the devourers—*i.e.*, the larger the minimum quantity upon which they can prolong life, the more numerous becomes the devoured species. A greedy devourer can exist only where great masses of nutriment are available. He begins to die out as soon as the food-species declines in number, and thus the increase of the latter is again rendered practicable. It would be worst for the mice if shrews could increase everywhere freely, and on the the other hand the mice would fare best, and would multiply most rapidly if the lion had to support himself upon mice. Great fecundity affords to a food-species no advantage, their numbers being determined only by the dexterity of the devourer, and the minimum ration upon which he can subsist.

What circumstances allow the devourer to become most numerous? The first condition, as we have already seen, is that he must find hunting as difficult as possible, as he otherwise would reduce too greatly the numbers of the animal upon which he preys; the second condition is high fecundity of such species, so that, if we may use the expression, the capital of food-animals may bring in a high interest. The fecundity of the victim, therefore is an advantage not to him, but to the devourer.

Circumstances take a different aspect when we have to consider not two, but several animals.

Such beasts of prey as feed upon the same species may be called competing devourers, which unite their powers to root out the victims. Those devourers which hold out longest, *i.e.*, which by reason of their skill in the chase, and their power of enduring hunger can still maintain themselves on a very scanty supply of victims will come off victorious. The less skilful and more greedy species perish of want. Whilst, therefore, a beast of prey existing without rivals, finds its advantage in small skill and great need of food; this advantage, in case of competition becomes a grave disadvantage. Nature encounters here a dilemma which she solves very ably. She is continually creating new devourers and equipping them with greater skill in pursuit, so that they may find it possible to rout their old competitors. But now, lest the world should become constantly poorer in individuals, she creates at the same time victims which are more and more skilful in concealment, whereby the success of all devourers is equalized, and that of the new beasts of prey is of course depressed, and the number of individuals is increased. We have thus a race among the devourers which is never ended because the goal, the victim, escapes just as rapidly.

Those food-animals which are decimated by the same enemies may be called fellow-victims. Those which are hardest to catch will multiply most rapidly, and by their great fecundity will support such an army of devourers that all their slower and less fruitful fellow-victims will be rooted out, unless secured by especially favourable circumstances.

The most fruitful and the best concealed species thus eliminate their fellow-victims by the instrumentality of beasts of prey. As fellow-victims are for the most part at the same time competitors (*i.e.*, as the quail and the partridge, both victims of the fox, are competitors on the corn-field) fecundity and concealment benefit a victim in as far as they hinge on the suppression of competitors by rearing a great army of devourers.

What circumstances determine the number of a species? Such number is stable when mortality and fecundity balance each other. Fecundity is heightened by abundant normal food and general comfort, and decreased by every kind of privation. But what determines mortality? The existence of every animal species depends on a number of conditions (temperature, food-plants, dryness, nesting-places, etc.), and where any one of these conditions is in default the species cannot exist. If, *e.g.*, we were to draw up a map of Europe for the capercailzie (*Tetrao urogallus*), marking the places of suitable temperature; on a second map the spots supplying suitable food; on a third, a third condition. We should then find that all the marked places would coincide only at a few spots. For the *urogallus*, Europe is not a continent, but a group of some large islands. For the viper, Europe might thus be called an archipelago of very small islands. Probably many an animal which we regard as rare has reached *in its world* the highest possible number, but this world, in which alone it is able to live, is only a small isolated part of a continent or a sea. From such centres, the species range on all sides as visitors, but without any one forming a permanent settlement.

Within the habitable districts, the existence and the plenty of a species depends especially on its relation to other species, the question being whether the local conditions expose the animal to its enemies, or afford it the opportunity of concealment. We have seen that the greatest abundance of animals will occur where their pursuit is the most difficult. Hence we can understand that certain animals, not dangerous to each other, and dependent on the same conditions, do not co-exist in the same regions or countries, but seem to avoid each other. If two victims have the same enemies, but in district A, Nature favours the concealment of one, but in B, that of another, then in each district the more protected animal will indirectly extirpate the less protected, by increasing rapidly, and thus enabling the devourers to multiply to such an extent that they destroy the other victim. If, conversely, of two devourers which depend on the same diet, here the one and there the other is favoured in the chase by the nature of the ground, then in each case the stock of food animals is depressed to such an extent that the competitor is starved out.

A beast of prey is formidably armed if he can feed upon more species than his rivals. Suppose the devourer, A, lives exclusively upon mice, and requires a stock of 1,000 per square mile, whilst the devourer, B, lives exclusively upon small birds, and likewise requires 1,000 per square mile. If now a fresh devourer, C, makes his appearance in the district, able to live both on mice and on birds, and needing only 1,000 food-animals per square mile, he then reduces the total stock of both mice and birds to 1,000, and thus starves out A and B.

The worst inmates of a district are a beast of prey which devours very many species, and a food-animal which is very fruitful and conceals itself well. As an instance of the latter kind we may take the mouse, but for which we should have a greater variety of small animals. The fauna of any district is the richer the more specialised is the nutriment of the beasts of prey.

General Notes.

Sedimentary Lands and Coal.—According to *Cosmos*, the theory of Fayol that coal-beds are deposits formed by streams at their entry into lakes or into the sea is gaining ground daily.

A Belgian Superstition.—Among the Walloons a meteoric stone is held to be the surest method of discovering a thief. It must be ground to powder, mixed with flour and made into bread, which no thief will be able to swallow.

The Part Claimed by France in the Development of Science.—*La Liberte*, in enlarging on the death of Professor Debray, asks what the Germans and the English would have made of science had it not been for French Rationalism.

The Godwin-Austen Peak.—This mountain, 28,250 feet above the sea-level, and at present reputed the second highest summit of the world, has only just received a name in honour of its discoverer, the first explorer of the Mustakh ranges.

A New Use of Artesian Wells.—In two instances at least, one in San Augustine, in Florida, and the other at Yankton, the ascending column of water from Artesian wells serves to drive various machines, and especially to work dynamos for an electric light installation.

Manchester Scientific Students' Association.—On September 22nd this Association made an excursion to Hayfield, under the leadership of Mr. John S. Pollitt, it being the last excursion of the season. In the course of the walk a number of autumn flowers were gathered.

The Hong Kong Colonial Surgeon on Opium Smoking.—The surgeon, after careful examination, concludes that opium smoking is not to be compared in its evil effects with the European vice of spirit-drinking, a habit to which the Chinese, as a nation, are not given.

A Colossal Raft on the Rhine.—According to *Cosmos*, an immense raft has lately set out from Mainz, on its way to Breeswyk, near Utrecht. It was 220 yards in length, 51 in width, and consisted of 4,000 logs of timber of the value of 500,000 francs. It carried a small village of a dozen huts, destined to accommodate the crew of 120 men.

The Principles contained in Cod-liver Oil.—According to MM. Gautier and Mourgues, cod-liver oil contains six alkaloids, not all of which are salutary. One of them, butylamine, provokes fatigue, stupor, and vomiting. Another, amylamine, is a violent and active poison. Hexylamine is less poisonous, and dihydrolutidine is injurious, occasioning paralysis!

Compressibility of Oxygen, Hydrogen, Nitrogen, and Air.—M. Amagat, in a communication to the Paris Academy of Sciences, shows that under very strong pressures oxygen, nitrogen, and air have almost the same compressibility. At 3,000 atmospheres it is approximately equal to that of alcohol under the normal pressure. The compressibility of hydrogen is almost double.

A Sweeping Sanitary Measure.—The town of Plant-city having been entirely forsaken by its inhabitants on account of the epidemic of yellow fever which had been raging in its neighbourhood, the Hygienic Council of Southern Florida has given orders to burn the city and all its contents. This heroic remedy will, we fear, be of little use unless the mosquitoes could be burnt also.

Hyacinths in the 18th Century.—According to *Le Jardin*, in the last century hyacinths commanded prices similar to those now paid for orchids. A bulb of the variety *Regina vera*, was worth 300 francs. There were four varities which sold at 200 francs each, It must also be remembered in judging of these prices that the value of money was then about four times what it is at the present day.

The Reform of the Calendar.—M. G. Armelin, writing in *Ciel et Terre*, points out not a few irregularities in the established Gregorian calendar. He proposes that the quarters of the year should always begin on the same day, and that in each quarter we should always have a month of thirty-one days, followed by two of thirty, whilst the week should fit in exact with the quarter and with the year.

The New Definition of Steel.—Compounds are now known perfectly free from carbon, but possessing all the mechanical properties of steel. Hence the *Revue Universelle des Mines* proposes to define steel, not as a carbide of iron, but as "a peculiar condition of iron, produced by the union of this metal with bodies the nature of which may vary," and among which rank carbon, manganese, chromium, silicon, and tungsten.

Action of Water upon Pipes of Galvanised Iron.—Messrs. W. R. Nichols and J. K. Russell, of Boston, have undertaken experiments on this question. Zinc was found both in suspension and solution, if the water was allowed to remain in the pipe from 7 to 70 hours. The portion in solution does not increase proportionately to the time, like that in suspension. The layer of zinc deposited on the sides of pipes and cisterns dissolves slowly but continuously.

The South London Entomological Natural History Society.—At the meeting of this Society on September 27th, mention was made of the unusual abundance of the rare and beautiful hawk-moth (*Deilephila galii*) in Britain. Specimens have been taken not merely on the South coast but inland, as well as in Ireland and Scotland. A gentleman present had obtained near Deal 196 of the larvæ. They were feeding chiefly on *Galium verum* (the yellow flowering species). The larvæ varied considerably; some of them, in place of their normal brown or black hue, being of an ochrey colour, or what artists call brown pink. The yellow side-spots were sometimes white and sometimes altogether wanting.

The Sanitary Institute.—The first meeting of the Council of this Society, which has recently been incorporated, was held at the Parkes Museum on Friday last. Sir Douglas Galton, K.C.B., F.R.S., was unanimously appointed Chairman of the Council, and Mr. G. J. Symons, F.R.S., the Registrar. The Institute is founded to carry on the objects of the Amalgamated Sanitary Institute of Great Britain and the Parkes Museum, and it was decided to hold the Institute's first examination for local Surveyors and Inspectors of Nuisances on November 8th and 9th. A programme of lectures for the winter session is in course of preparation. A letter was read from the Charity Commissioners saying that they considered that the new Institute was likely to prove a powerful means for the diffusion of sanitary knowledge, and promising to grant facilities to the Institute to deliver lectures in the various buildings which the Commissioners proposed to establish in different parts of London.

Mexican Agriculture.—In a recent report on the agriculture of the Mexican State of Vera Cruz, the British Consul describes the primitive manner in which maize is cultivated in the Minatitlan district, where three crops are raised annually, but never on the same land. No ploughing is done; one man makes with a pointed stick a series of lines of holes about two feet apart; another man follows, dropping two or three grains into each hole, and the rain is left to fill the holes in. The harvest is calculated at a hundred times the weight of the seed, and is gathered in 16 weeks after the planting. No manuring is done, except when the land is first cleared, and then the ashes of the burnt underwood, rank grass, and stumps are used as fertilisers. This method of cultivation prevails in remote and low-lying districts; on the higher levels maize is cultivated on ploughed lands, and farming there is becoming more and more systematic and on many haciendas scientific. Lack of capital is the cause of the exceedingly rude cultivation of cotton, maize, and other products in Mexico. Even in the case of tobacco many planters never plough or manure, and never plant the same land twice, yet the reputation of Mexican tobacco is rapidly increasing, and the manufacturers of Vera Cruz are increasing the size of their factories and the number of their operatives. The present annual production is almost 6,000,000 lb., produced at an average cost of 5½ per lb. Twenty-three per cent. of the whole is exported, about half of which is manufactured and goes chiefly to England.

Old Roman Plank-Roads.—The Prussian Minister of Education, Von Gossler, having learnt that Professor F. Knoke had lately found traces of old Roman plank-roads on the moor between Mehrholz and Brägel, not far from Diepholz, in Lower Hanover, invited that gentleman to fully investigate the matter. He has just completed the task. He was able to trace the lines of two parallel plank-roads right across the moor, presenting all those distinctive features which are found in Roman works of this kind. One of them shows evident signs of having been demolished by force, the boards, which were originally fastened with pegs to the bearers, having been violently torn away and buried in the bog to the right and left of the track. The other road seems to have fallen into decay, but their are signs of repairs executed even during the Roman period. For in places boards have been found fastened over the original planks, the fashion of both being the same. Those repairs seem to have been carried out hastily, for in one place a mallet, employed probably to drive home the pegs, was found on the track, forgotten, no doubt, by the workmen. The local archæologists feel assured that they have here the *pontes longi* which were used A.D. 15 by the Roman commander, A. Cæcina, in his retreat from Germany to the Ems.

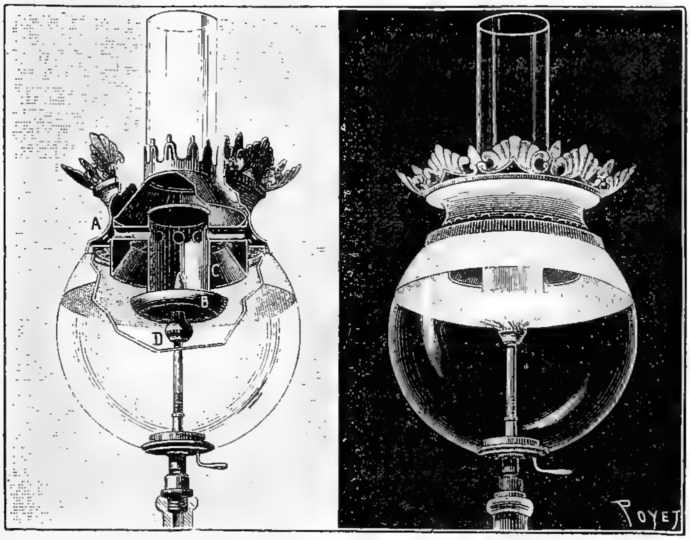
The Atmospheres of the Stars.—Mr. Orray T. Sherman (*Popular Science Monthly*), whilst studying the star-spectra, comprising bright lines, finds that whilst the bright line does not vary in place it may vary in intensity. This peculiarity affords a distinction between bright-line light, bright-background space, and any incidental disturbance the spectrum-light may suffer. Collating his own observations, especially of β Lyræ, with Lockyer's results on the solar atmosphere, he concludes that we may represent to ourselves the condition of the stellar atmosphere and the action therein somewhat as follows:—An outer layer of hydrogen positively electrified, an inner layer of oxygen negatively electrified, and between them a layer of carbon mingling on its edge with hydrogen. The electric spark passing through the mixture forms the hydro-carbon compound, whose molecular weight carries it into the oxygen region, when combustion ensues with the formation of carbonic acid and watery vapour, both of which, descending under the influence of their molecular weight, are again dissociated by heat, and return to their original positions. Under the insight which this result gives, we have found the spectra of the nebulæ referable to low excitation hydrogen, the spectra of the bright-line stars referable to high excitation oxygen and hydrogen, or hydrogen of lower excitation according as the central star is of high or low magnitude. There is also reason for thinking that a similar atmosphere in similar physical conditions lies between us and the sun, and it seems as if we might consider that from the faintest nebula to the most highly-finished star we have but progressive stages of the phenomenon here presented.

The Public Health.—The Registrar-General's return for the week ending September 29th shows that the deaths registered during that period in 28 great towns of England and Wales corresponded to an annual rate of 18·3 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The six healthiest places were Huddersfield, Halifax, Birmingham, Bristol, Nottingham, and Oldham. In London 2,395 births and 1,314 deaths were registered. Allowance made for increase of population, the births were 325 and the deaths 94 below the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had been 16·2 and 15·8 in the two preceding weeks, rose again last week to 16·0. During the 13 weeks ending on Saturday last the death-rate averaged 16·2 per 1,000, and was 3·4 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,314 deaths included 30 from measles, 22 from scarlet fever, 27 from diphtheria, 13 from whooping-cough, 13 from enteric fever, 77 from diarrhœa and dysentry, and not one from small-pox, typhus, ill-defined forms of continued fever, or cholera; thus 182 deaths were referred to these diseases, being 34 below the corrected average weekly number. In Greater London 3,158 births and 1,634 deaths were registered, corresponding to annual rates of 29·8 and 15·4 per 1,000 of the estimated population. In the Outer Ring 14 deaths from diarrhœa, seven from diphtheria, and six from scarlet fever were registered. The deaths from diarrhœa included three in West Ham, three in Croydon, and two in Tottenham sub-districts. Three fatal cases of scarlet fever occurred in West Ham, and three of diphtheria in Walthamstow sub-districts.

GAS-BURNER ON THE LEBRUN SYSTEM.

THE apparatus which we (*La Nature*) are about to figure and describe is based on the same principles as the Siemens burner, the Wenham lamp, etc., though its mode of construction is different. Our figure shows the external aspect of the lamp and the principal internal arrangements. It consists of a glass globe, at the lower part of which enters the copper tube (D) conveying the gas. Above this burner is placed a cylindrical cover (C), closed on all sides, but having its lower part (B) pierced with a multitude of small holes, whilst the upper part communicates with the external air by the pipes (A).

The upper part of the globe is closed by a metallic crown; a disc of asbestos interposed between this crown and the globe forms an air-tight joint, so that there is no communication with the external atmosphere except by a glass chimney traversing the crown.



GAS BURNER ON THE LEBRUN SYSTEM.

The lower part of the globe is formed by a trap, which is opened only at the moment of lighting the gas.

The working of the system is easily understood. When the gas is lighted at D and the trap closed the air in the globe is heated and escapes by the chimney. There is thus produced a draught, which forces the external air to arrive by the pipes (A) into the cylindrical cover (C), and to escape by the small holes made in B. Hence it is intimately mixed with the crown of flame of the burner (D), and the combustion is as complete as possible.

The light is very white and very steady, the gas is almost entirely utilised, and for an equal illumination there is a decided economy in the consumption. This burner is constructed of three different sizes, having an illuminating power of 4, 9, and 16 carcels respectively. The apparatus has a screw thread, so that it may be placed in gaseliers, candelabra, etc., instead of the old burners.

It is recommended, *e.g.*, for use in provincial theatres where the expense of an electric light installation is out of the question. Of course the three great objections against gas—the heat, the danger of fire, and the production of sulphurous acid—remain as in the case of ordinary gas-burners.

ON THE PART PLAYED BY SYMBIOSIS IN CERTAIN LUMINOUS MARINE ANIMALS.

THE following communication has been made to the Academy of Sciences of Paris by M. Raphael Dubois:—"In former communications I have been led to admit that the fundamental reaction necessary for the production of light in animals belonged to the class which take place under the action of ferments. In the session of May 12th of the present year, I made known to the Society of Biology the existence, in a normal state, in the walls of the syphon of *Pholas dactylus* of micro-organisms (*Bacillus pholas*), which give a fine light when cultivated in a decoction prepared with the phosphorescent tissues of the living animal. These tissues contain the substance which I have provisionally named *luciferine*, upon which the ferment acts. The reaction requires for the production of light a suitable medium; it must be rendered saline and alkaline in certain fixed proportions. During life the liquid is furnished by the animal, which modifies it as the case requires. It is not the same in the mollusc at rest, which does not shine, as in one which is excited and emits an abundant quantity of the phosphorescent liquid.

We have, therefore, in *Pholas dactylus* a new case of symbiosis, most interesting from several points of view.

I found, in June last, in the mucus secreted by the mantle of *Pelagia noctiluca*, a micro-organism which may be extinguished or rekindled at will by varying the conditions of the medium.

During its changes of physiological activity the *Bacillus pholas* possesses a great morphological fixity. It is not the same with the new organism of the pelagia (*Bacterium pelagia*). If cultivated in gelatine it rapidly excavates funnels filled with a liquefied substance, in which are found abundance of longer or shorter filaments filled with very small spores, perfectly rounded and regularly distributed. They are stained only by Erlich's reagent, and that after some hours. Along with these filaments are found free spores and some movable rods, which become spore-bearing filaments. In pure gelatine these filaments are not luminous, but if they are transferred into liquids of an alkaline reaction, suitably salted and containing phosphorised nitrogenous matter (nucleines, lecithines, etc), they emit a fine blueish phosphorescence in the parts exposed to the air. We find, then, scarcely any filaments with spores or movable rods, but almost exclusively spores.

These luminous liquids obey the same influences as the luminous tissues of phosphorescent animals.

Further, we see in the culture-liquids an accumulation of that characteristic birefrangent substance which forms the chalky layers of the Pyrophori, the Lampyridæ, the Podurae, and which is found in the tissue of the syphon of the pholas, in the epithelium of the digestive tube of phosphorescent myriapods, etc., and the existence of which we have recognised even in the phosphorescent sea-water of the port of Mentone.

This substance, which resembles leucine in certain respects, presents in culture-solutions all the forms which we have met with in the animals studied : fine rounded birefrangent granulations, either homogeneous, or having at their centre a brilliant part representing a vacuole (*Vacuolides*); rounded corpuscules, scintillating in polarised light (sphero-crystals); or small radiating or isolated prismatic needles. We may easily follow all these transformations of one and the same substance, which we have considered as forming one of the elements of the photogenic reaction, when it now seems, according to our most recent researches, to be merely the result.

Along with this product which is deposited in the phosphorescent solutions, as in the organs of luminous animals, we find a considerable quantity of crystals of the double phosphate of ammonium and magnesium, and of carbonate of lime, and in the liquor alkaline phosphates in solution. These phosphates are almost entirely formed by the oxidation of the phosphoric nitrogenous matter contained in the solution. We must admit that these phosphoric nitrogenous matters, though not directly oxidizable in the air, yield, under the influence of the ferment, a substance which possesses this property.

The researches enable us to reconcile the theory of a photogenic fermentation with the hypothesis of the oxidation of a phosphoric matter.

It explains the rôle of the alkaline and saline blood in the acid photogenic tissues of the Elateridae and Lampyridæ, which we have observed without being able to explain. Lastly, we conceive how the phosphorescence of the sea may be produced by the disagregation of marine animals.

NOTES FOR YOUNG COLLECTORS.

(*Continued from p.* 178.)

In our last notes, whilst speaking of rivers in flood as often yielding a harvest for the entomologist, we omitted to call attention to the rubbish which streams deposit along their banks above the ordinary high-water mark after heavy rains. This rubbish consists of grass, straw, twigs, reeds, etc., and often conceals numbers of insects, especially beetles and land and fresh-water shells which have been swept away from the banks, the bushes, and the adjoining fields. The search should not be long delayed, or the insects will have had opportunity to make their escape.

There are various baits, artificial or provided by nature, to which insects resort very eagerly. Among such may be mentioned holes bored into a tree with a large gimlet, so as to set the sap flowing. This is especially attractive in spring and the early part of summer. Excrements of various animals and dung-heaps are often visited not merely by two-winged flies and the so-called dung-beetles of which the species are multitudinous, but by the most beautiful butterflies. A dead rat, mole, or weasel nailed to the stem of a tree at a convenient height is an excellent bait for the "purple emperor" (*Apatura iris*). The gorgeous papilios and ornithopteras of hot climates will come down from the tree-tops to recent human excrement and to over-ripe fruits. Perhaps a half-rotten banana is their favourite lure.

Another trap for a great variety of insects seems quite unnatural, and is yet very successful. It is simply a white cloth spread out on the ground and examined from time to time on both sides, both by day and by night, of course in the latter case by the aid of a lamp. This method of trapping is practicable only either in very unfrequented places or in private enclosures. Elsewhere the cloth will often be found to disappear altogether.

In warm climates it is very necessary to kill all insectivorous creatures which may visit the cloth, such as scorpions, centipedes, tarantulas, galeodes, etc., or they will take the first choice among the specimens.

In waste grounds, especially if sandy, gravelly, or chalky, and covered only with a scanty vegetation, good work may be done by digging holes with a garden trowel, making the sides steep. Insects which do not fly when taking their excursions by day or night get in, and cannot get out again. Such holes should be visited early in the morning.

Many night-flying species, both moths and beetles, can be captured by the aid of lights properly fixed. An electric light, or in its default a powerful paraffine lamp, with a good reflector, is fixed either within a room with open windows or in a verandah. The best situation is an eminence overlooking woods, gardens, or fields, and the best time is the absence of moonlight. The collector waits at hand with his net, and captures the insects as they rush to the light. There are also lamp-traps, which dispense with the net, though not with the attendance of the collector, as if not promptly captured the specimens will damage themselves with fluttering.

A very common method of catching moths, especially of the *Noctua* group, is "sugaring." A part of a tree-trunk, at a convenient height, is painted over with a composition, of which coarse sugar is the principal ingredient. Rum or stale beer is added, to bring the whole to the consistence of a thin paste. On calm, dark nights the collector goes round with a lamp, examines the sugared trees, and dextrously encloses the moths in pill-boxes, transferring them then to the "killing-glass," where they inhale the vapour of cyanide of potassium. Various beetles, even some of carnivorous habits, will also come to sugar. The beetles, if desirable, can, of course, be captured. Spiders occasionally appear, and earwigs in great numbers. They are, of course, treated as poachers, since they frighten away the moths.

In all these various methods of collecting, take care, as far as possible, that you are not watched, especially by boys.

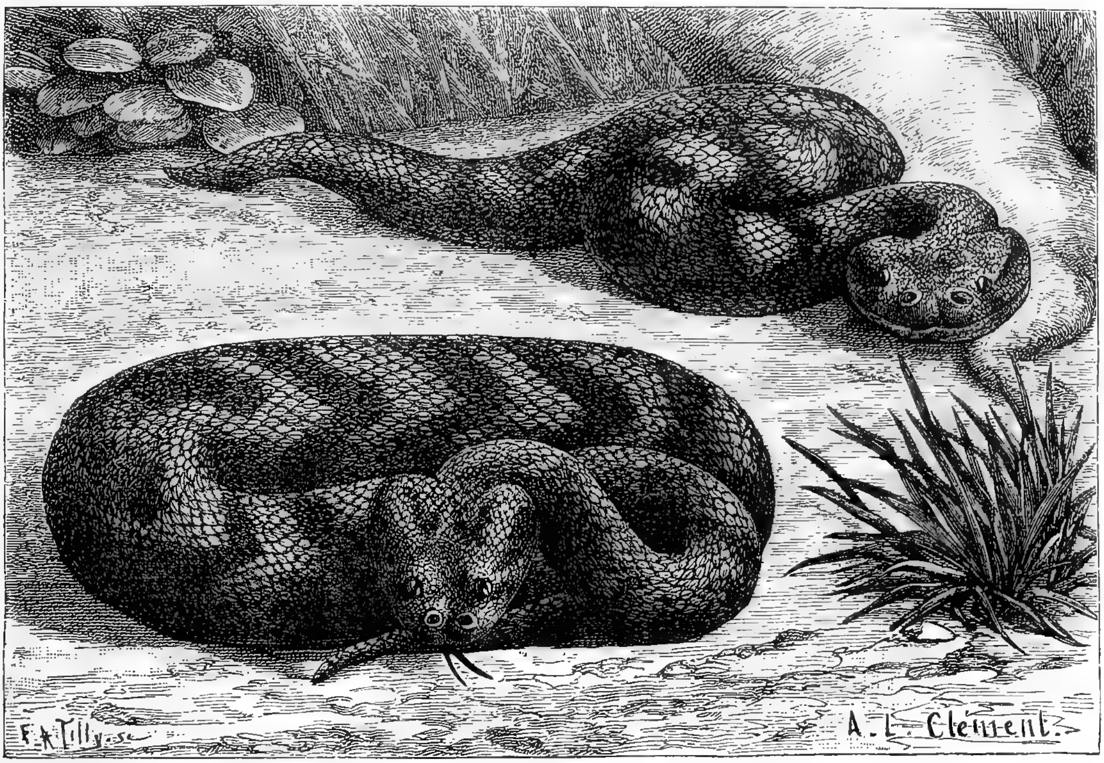
Natural History.

THE PUFF-ADDER.

AFRICA certainly produces neither rattle-snakes, nor bothrops, nor lance-heads (*Trigonocephalus*). But she is by no means deficient in venomous serpents. Not to speak of at least one member of the royal house of the death-snakes, *Naja haje*, she abounds in vipers. The puff-adder (*Clotho arietans*), a figure of which we borrow from our contemporary *La Nature*, and which we are about to describe, inhabits all Africa except the portion to the north of the Great Desert, and is especially abundant along the south-western coasts as far as the Cape. Two fine specimens of this species have been recently brought from Senegambia, and are living in the reptile-house of the museum at Paris. The body of this serpent is short, thick, and squat, and rarely exceeds four feet in total length. It becomes thinner in the region of the neck, and ends in a triangular head with rounded angles, rather heart-shaped, much broader than the neck, and very flat. The tail is conical and short. Its massive and apparently disproportionate form gives it a hideous aspect. The nostrils, which are wide and have a margin devoid of scales, are very near to each other, and are situated exactly above the muzzle, and not at the sides as in several kindred species of the true vipers. Behind and lying outside the nostrils are the eyes, which are at no great distance, on account of the shortness of the muzzle.

As in all vipers, the upper jaw is armed on each side and in front with a set of three to five grooved poison-fangs, highly developed, but unequal. They are moveable, conical, curved backwards, but become erect when the serpent opens its mouth. The channel which traverses them gives passage to the venom, and opens at their anterior edge, near the point, by a long slit. These fangs are extremely sharp, and their conical form enables them to penetrate into the tissues without tearing them. As soon as they are withdrawn from the wound, which is a mere prick, the skin, by its elasticity, returns to its place and imprisons the poison which has been injected, and which is almost instantly carried by the circulation into all parts of the organism. The upper part of the body, including the head, is clad with carinated scales, arranged with much regularity.

The colour of the puff-adder is very variable. In the specimens now in the museum the prevailing colour is a light-brown, verging upon fawn colour. It is relieved on the back by a series of V-shaped marks of a darker colour, opening forwards and generally edged with yellow behind. At the lower part of the sides there is a longitudinal range of dark spots, and the top of the head is crossed at the level of the eyes by a brown band, which descends on each side to the margin of the upper lip.



THE PUFF-ADDER (*Clotho Arietans*).

The puff-adder is excessively slothful, and remains, in general, completely motionless, coiled upon itself, the head resting upon one of its folds. The lower figure in our illustration represents it in this state of repose. Its repugnance to motion is such that it may be almost touched without disturbing itself. It moves only when seeking its food, when attacking or taking to flight, but it then executes rapid movements which contrast with its ordinary sluggishness. If molested, it places itself on guard by withdrawing its head and bending its neck into the form of an S, ready to be shot out like a spring in the act of biting. At the same time the body is alternately swelled out and contracted, and it utters a loud and prolonged hiss. It has the singular habit—whence its specific name—of preluding an attack by striking with its head like a ram.

In a state of liberty this snake preys on rats, mice, and squirrels. In captivity it is fed on rats and on young rabbits. The interval between its meals is on the average twenty-five days.

Making allowance for its slowness in deciding upon an attack, it proceeds much in the same manner as the other vipers. If it finds an animal suitable to become its prey it folds its neck in the manner just described, its breathing becomes more quick and more profound, and it darts out its forked tongue. At last it projects itself, open-mouthed and with the speed of an arrow, against its prey, which it pierces with its long, poisonous fangs. The snake then retreats with the same suddenness, and waits until the venom has accomplished its work. The victim, which seems at first struck with astonishment, quickly falls upon one side as if paralysed, and in the space of a couple of minutes it dies after a few convulsive movements. The serpent then slowly returns, passes its muzzle over the body, which it lastly seizes by the head and swallows.

The venom of the puff-adder yields in nothing to that of the rattle-snake, or rather, we should say, it is the more powerful. Large dogs quickly succumb after having been bitten, and even man cannot always resist its action. It said that the Hottentots use the venom of the puff-adder for poisoning their arrows.

This reptile bears captivity well if kept sufficiently warm; it takes its food regularly, and may be kept alive for years.

Granular Ophthalmia and Flies.—The part played by flies in the transfer of the microbia of tuberculosis has recently, according to the *Revue Scientifique*, been proved in our midst by direct experiment. M. Howe, in a communication to the Congress of Heidelberg shows the *role* of these insects in the propagation of ophthalmia. On visiting Egypt, and remarking the innumerable quantity of flies which settle on the eyes of the natives, led by their indolent nature and by the necessities of mendicity to a complete immobility, we understand how these insects become the real and very frequent cause of the propagation of ophthalmia. M. Howe has likewise verified this fact experimentally by placing flies upon plates of nutrient gelatine, and finding that wherever their feet have touched there are formed colonies of the microbia regarded as the specific germs of ophthalmia. These facts have to be connected with the propagation of the germs of yellow fever by mosquitoes. Further information on the two-winged flies as the colporteurs of zymotic disease will be found in Slater's "Sewage Treatment and Utilisation" (p. 60).

Use of the Antlers of Deer.—At a recent meeting of the Wellington Philosophical Society, Mr. J. W. Fortescue spoke of the rapid increase of deer that have been acclimated in the New Zealand mountains. Having had special facilities for observing these creatures, he proceeded to state some interesting facts as to their habits. At the close of his address Sir James Hector asked Mr. Fortescue, as an expert on the subject, whether the chief use of the antlers was not so much for fighting as for facilitating the progress of the stag through dense woods. He had considerable experience with the wapiti, in North America, and found that by throwing up the head, thereby placing the horns along the back, the animals were enabled to go forward with great rapidity and follow the hinds. He asked this, as it had been stated at a previous meeting of the Society that the antlers tended to entangle the deer. Mr. Fortescue said that Sir James Hector was quite correct in stating that the antlers assisted the stags in penetrating dense forests. Mr. Higginson also bore out this statement from his experience in India.

A Migration of Spiders.—According to *Cosmos* the inhabitants of Abilene (Texas) were surprised to see passing over their heads several balloons, following each other at short intervals. These balloons, when attentively examined, proved to be great cobwebs from which hung down long streamers filled with spiders. Numerous insects, whose organisation seems to render them stationary, are provided with means of transport which explain their sudden appearance at points remote from their place of origin. Birds are thus often the unconscious messengers which convey seeds and small living animals attached to their feathers. Another instance is that of Acari which cling to the body of flies, and are thus conveyed to regions which to them are inaccessible.

A Colony of Beavers on the Elbe.—According to No. 30 of the *Weidmann* for the current year (quoted in the *Naturwissenschaftliche Wochenschrift*), a colony of about thirty beavers have established themselves since the middle of March, above Kanies, near Schœnebeck, on the Elbe, in the province of Saxony, and have sought shelter in the bushes which cover the Elbe embankment. Latterly they have begun to undermine the embankment. Hence it is doubtful if these visitors will meet with permanent toleration. They have been probably driven by floods from their former habitation.

A Parasite of the Cockchafer.—M. Rolland Banès (*La Nature*) has discovered a fungus belonging to the genus *Isaria (Isaria farinosa)*, which takes root upon the living cockchafer and occasions its death. If this fungus can be multiplied, perhaps the number of these destructive insects may be reduced. M. Rolland is of opinion that another parasite (*Cordyceps entomorrhiza*) is developed upon the larva of the cockchafer.

Migration of Wood-Lice.—*Cosmos* records an immense migration of a species of wood-louse not accurately determined, which is said to be now taking place in Pennsylvania. These animals are moving eastwards in millions, travelling by night and in the cool of the morning and evening, and resting by day under stones or in heaps piled upon each other. They do not seem to commit any depredations on their way, and they are not attacked by poultry or by small birds.

Poison of Spiders.—According to the researches of Brieger (*Humboldt*), two spiders regarded in Russia as poisonous, a *Phalangium* and a *Trochosa*, are harmless. A third species known by the Russians as Cara Curt is most intensely poisonous. It occasions damages among cattle which must be estimated by millions. Sheep, oxen, horses, etc., when grazing are bitten in the tongue or the mouth and quickly die. The poison is found in all parts of the spider, even in the eggs. Chemically speaking, this poison, which makes up one-fourth of the weight of the spider ranks among the "enzymes," peculiar, albumenoid bodies which are readily decomposed. If heated to 140 degs. F., or mixed with alcohol, it is rendered harmless. If introduced into the stomach it takes no effect, but if admitted into the circulation that $\frac{1}{10000}$-part of the weight of the body proves fatal to a man or any other warm-blooded animal. It appears to surpass in virulence all poisons except that of serpents. Among the spiders of Germany Brieger finds such a poison present only in *Epeira diadema*, and that only when young.

DEATH FROM THE STING OF AN INSECT.—At Carlisle a man has recently died from a sting in the hand. It is not known whether the offending insect was a wasp or a bee. We evidently do not yet know under what circumstances such stings may have serious effects.

SPECIES OF EMPUSA.—The fungoid genus *Empusa*, and the two small kindred genera *Massopora* and *Basidiobolus* include, in the United States alone, twenty-eight species. As most of them attack and destroy flies, gnats, mosquitoes, etc., they must rank as highly useful. The common *Empusa muscæ* is unusually abundant this season in England, and accordingly dead flies are found attached to the window-panes and surrounded by a halo of the fungus.

BEES AS WEATHER PROPHETS.—Professor Emmerig regards bees as the most trustworthy indicators of weather for the day. If a storm is impending they become restless and irritable, and are even dangerous to approach. When the bees and the weather glasses differ, the insects will be found to be in the right.

THE PRODUCTION OF SILK IN THE WORLD.—The total yield of silk in the world has increased from 9,926 lbs. in 1884, to 11,740 lbs. in 1887. Of this total 4,550 lbs. were last year produced in Europe and 6,430 lbs. in Asia. The production of India was merely the most unsatisfactory quantity of 800 lbs., and Australia, with its great natural facilities for this industry, does not figure in the list at all.

INTRODUCTION OF LOBSTERS INTO THE PACIFIC.—After two unsuccessful attempts to transport living lobsters from the Atlantic to the Pacific a third trial has proved successful. The animals were packed in special cases between layers of sea-weed, and were daily sprinkled with sea-water. Each case contained six specimens. The cases were placed in larger boxes, and the intermediate spaces were filled with broken ice. A special drainage prevented the fresh water from the melting ice from penetrating to the lobsters. On reaching San Francisco 350 were still alive and were at once placed in the sea, half of them to the north and half to the south of the city.

THE SENSES OF BEES.—We have had occasion to mention that bees clearly distinguish beet sugar from cane sugar, rejecting the former. It now appears that not only they but ants and even flies utterly ignore "saccharine," which some human beings think identical in taste to sugar.

CATERPILLARS ON FRUIT TREES.

THE following valuable paper has been issued by the Agricultural Department:—In many of the principal fruit-producing districts caterpillars have lately caused most serious injury to apple, pear, plum, damson, filbert, and other fruit trees, so that in some cases the whole crop has been lost; and it is feared that the fruit-bearing powers of a number of trees have been affected as regards the next season.

As methods of prevention should be adopted during this autumn, and before the winter, with respect to the most destructive species of these insects, it is most important that fruit growers should be informed concerning these at once, and before the appearance of the annual report of the agricultural adviser, to be published in January, which will give full details of the mischief caused by caterpillars, as well as of the history and habits of the numerous species noticed on fruit trees this season, together with remedies against them.

When the blossom buds and leaf buds of fruit trees in many places began to unfold, it was seen that they were attacked by legions of caterpillars. Soon the blossoms and leaves were entirely devoured, or so much injured as to be useless. The fruit plantations in parts of Kent, Hereford, Worcester, and some other counties where fruit is extensively grown, looked as if a hot wind had passed over them.

The caterpillars of various small moths were the authors of this serious mischief. Among these the chief offender was that of the Winter moth, *Cheimatobia brumata*.

Other species did considerable harm, whose life history is much the same as that of the Winter moth, as, for instance, among others, the pale brindled beauty, *Phigalia pilosaria;* the mottled Umber, *Hybernia defoliaria*, and *Hybernia aurantiaria*. These may be placed in one group with regard to the methods of prevention to be adopted against them.

In another group are included the Lackey moth, *Clisiocampa neustria;* the Ermine moth, *Hyponomeuta padella;* and the figure of 8 moth, *Diloba cæruleocephala*, whose caterpillars were more or less destructive this year.

THE FIRST GROUP OF MOTHS DESTRUCTIVE TO FRUIT CROPS.—Methods of prevention are comparatively simple in the case of the first group, because of the peculiarities of the female moths, which are practically wingless, and must, therefore, remain not far from the spots where they have passed their chrysalis stage, and hard by the trees upon which they lived during their caterpillar existence.

They may, therefore, first be destroyed while in the chrysalis condition, which terminates towards the end of October, in the ground around the fruit trees, by digging, hoeing, and the application of caustic substances.

Second, the female moths may be prevented from ascending the trees for the purpose of egg laying by means of bands of cloth or hay, and other obstacles put round the stems.

The Winter moth is taken as the type of the first group, and its life history is briefly described.

The male moth varies in colour from ashy grey to light brown, with dark streaks upon the wings, whose expanse is about an inch. It is about half an inch long. It flies at twilight. Swarms of these insects were noticed last November hovering under fruit trees and quickset hedges, in the foggy evenings, in search of the females.

The female is not quite so long as the male, of the same colour, without wings, having an inelegant, distended body, and might be mistaken for a large spider in the dusk when it comes out and crawls up palings, posts, and the stems of trees. Each female lays from 150 to 200 very small cylindrical eggs, greenish at first, but reddish later on, which she fastens to the buds, or to the twigs and spurs, with a sticky substance.

In the first warm days of spring caterpillars are hatched from the eggs, grey and thread-like in their early life, becoming green with slightly brown heads, and rather yellowish as they approach the pupal period. When full grown they are half an inch long. Having no ventral feet they move like other "loopers," making a loop with their bodies. They glue the petals of the blossoms and the leaves together to form a shelter, and clear off all vegetation within reach, if the conditions are favourable. When they attain the allotted term of caterpillar life, or food fails, or becomes unsuitable, they let themselves down to the ground with silken cords and bury themselves from two to three inches beneath the surface, making cocoons of particles of earth bound together with silk. This takes place usually in the first or second week in June. Towards the end of October the moths begin to appear, and may be seen throughout November and even through December, if the weather is mild.

Methods of Prevention in Orchards.—In orchards, that is, where fruit trees are planted upon grass land, after an attack of caterpillars the grass should be fed off close, or brushed off close. Strong liquid manure may be applied advantageously, or water having paraffin oil in it, towards the latter part of October. Dressings of lime, gas lime, or soot might be put on thickly some distance round the trees.

Lime, or gas lime, or soot, or other pungent materials put on thickly close round each tree, so as not to injure it, would for a time hinder the moths from getting to the trees. It must be borne in mind that the possible area occupied by the chrysalids is some distance beyond the boughs of the trees, so that in old orchards where the trees are very large, putting lime or other substances in lumps close round the trees is the more feasible plan.

After an attack like that of the last spring it is most advisable to take active measures of this kind. Knowing where the authors of the mischief are concealed, fruit growers should take steps to make their summer lodgings as unwholesome as possible. It should be remembered that grass land around fruit trees, being undisturbed, affords shelter also to other insects injurious to fruit crops.

As plants naturally grow towards the light, so the female moths instinctively go up the stems of fruit trees nearest to them as soon as they are transformed. They cannot fly; they must, therefore, crawl up. If they are unscathed by pungent applications, or succeed in getting over circles of hot lime or ammoniacal soot, their progress must be arrested by means of obstacles placed round the trees.

That which is put round trees for this purpose must be fastened very tightly and closely to their stems, so that the moths cannot get under it.

Hay bands dipped in tar, or smeared with tar and cart grease, or with Davidson's composition,* may be used for this. Oilcake bags or manure bags are better, dipped in a mixture of soft soap, without water added, or paraffin oil, or carbolic acid. Calvert's carbolic soft soap would be also applicable for this.

American fruit growers, whose orchards are infested with insects of similar habits, put guards of different constructions round the stems of the trees.

This guard consists of a girdle of tin and stout linen fixed low down round the tree. The linen is sewn to a cord which is firmly and closely fastened round the stem. To the lower edge of the linen a circle of tin is tacked, three or four inches wide, and of sufficient diameter to stand three or four inches from the stem. The inside of the tin is smeared with tar and cart grease, soft soap and paraffin, or carbolic soft soap, or some other offensive, sticky composition, to keep the moths from going beyond the guard. Occasional examinations must be made, and the composition renewed, if necessary, from time to time.

Before the spring comes the bark of the stem below the guard should be well scraped, and soft soap and paraffin, or carbolic soft soap, worked well in with a stiff brush, to remove any eggs which may have been deposited there by moths in despair of finding their accustomed places.

It should be said that these guards ought to be put in working order in August, in order to keep back the caterpillars of the Codlin moth, *Carpocapsa pomonella*, which go up the stems of apple and pear trees, after they have come from the apples which they have spoiled. This caterpillar wriggles up the stem and changes to a chrysalis under the bark. It has done enormous injury this year in most orchards.

* "Davidson's composition" may be obtained of Messrs. Dickson, Newton Nurseries, Chester.

Methods of Prevention on Cultivated Fruit Land (Fruit Plantations).—In addition to the guards and obstacles prescribed for trees upon grass land, it is possible to get at the chrysalids in fruit plantations by thoroughly digging and working the ground all round the fruit trees with spuds and prong hoes in October, as well as by digging in lime, soot, and other caustic substances. After the ground has been dug it should be knocked to pieces by means of prong hoes.

This is especially necessary in the case of filbert and cob-nut trees, as it would not be practicable to put guards round these.

When filbert trees and cob-nut trees have been badly attacked by the winter moth and its allies, they should not be pruned until January, after the eggs may have been deposited. The larger part of these will then be cut away with the wood that is pruned off, which should be removed and burnt.

The bark of apple trees should be to some extent removed from the stems and large lower limbs beyond the fork, and these should be well brushed over with soft soap and paraffin, or carbolic soft soap. Pear, plum, and damson trees should also have their stems brushed with offensive compounds.

The Second Group of Moths Injurious to Fruit Trees.—With regard to the second group of moths injurious to fruit trees, it may be said generally that it is important that the stems and large lower limbs should be denuded of their rougher bark, and rubbed over with soapy or oily compositions, mixed with paraffin or carbolic acid.

In the case of the Lackey moth, its caterpillars change to chrysalids under rubbish, grass, and clods near to the fruit trees they have injured. As they do not go deeply into the ground it is advisable to brush off grass and weeds round the trees, and to rake up and burn all rubbish, also to apply lime and other caustic materials. Digging and hoeing are likely to be very efficacious upon cultivated land.

The female moths of this group can fly, and some of them place their eggs upon twigs and spurs of fruit trees in the summer, where they remain until the spring. It would be advantageous to throw finely powdered quicklime over and up into the trees during the winter after an attack. This should be done in a damp fog, not when there is a drip from the trees, but with merely sufficient moisture to hold the lime upon every part of the twigs and spurs.

For mossy apple trees this treatment is admirable, as it destroys mosses and lichenous growths, which harbour all kinds of insects.

It is obviously more difficult to use means of prevention against the moths of the second group than those whose females are wingless. Fruit growers must depend somewhat more upon remedial measures in their case, and the experiences of the last season have indicated several remedies which proved more or less satisfactory, and will be described later on in detail.

Japanese Copper Mines.—The copper mines of Ashiwo are situate in the mountains, about 30 leagues to the north of Tokio, whence they are easily accessible by railway. They employ no fewer than 4,600 workmen, including those engaged in felling timber as fuel. Coal can only be brought at a prohibitive price, and there is reason to fear that the adjoining forests will soon be exhausted, as they are cut down without system and without replanting. The mines have been worked since the beginning of the 18th century, and until lately have belonged to the Crown, but have lately become the property of an individual capitalist who owns several other mines. In 1886 they produced 4,150 tons of metallic copper, being a yield of about 4 per cent. on the ore. The crude metal is conveyed to Tokio, where it is refined. The ore is slightly argentiferous, yielding from 500 to 1,250 grammes of silver per ton of copper.

Reviews.

Reports of the Scientific Results of the Exploring Voyage of H.M.S. "Challenger." Prepared under the direction of the late Sir Wyville Thomson, F.R.S., and now of Mr. Jno. Murray. Vol. xxiii. : Zoology. I. and II. : Reports on Pteropoda (part ii., Thecosomata; and part iii., Anatomy), by Paul Pelseneer, D.Sc. III. : Report on Hydroida, by Prof. G. J. Allman, M.D., LL.D., F.R.S.S. L. and E., etc.

The above reports on the curious minute molluscs, scientifically known as Pteropoda, but from their shape and movements more popularly termed "winged snails" and "sea butterflies," form the second and third memoirs which Dr. Pelseneer has contributed on this subject to the *Challenger* series, he having dealt with the Gymnosomata, *i.e.*, those Pteropoda which in the adult state have neither a shell nor mantle skirt, in a previous volume ("Zool. Chall. Exped.," part lviii.). In the first report in the present volume the author gives a full systematic description of the other great division of the Pteropoda—the Thecosomata—which in the adult condition possess both shell and mantle. This memoir and the following one are based on a very extensive set of specimens, including, besides the *Challenger's* spoil, those collected by the *Triton*, by Mr. Rattray in the *Buccaneer*, and by the Italian *Vettor Pisani* in its three years' scientific cruise, as well as collections made at Malta by Surgeon D. Bruce, M.B., and by Dr. Pelseneer himself at Naples, a wealth of material rarely available, and of which the writer has rendered ample account. It seems at first sight rather curious to learn that although the *Challenger* specimens were taken from seventy different stations in all parts of the world, and included shells dredged from the deposits of "Pteropod ooze," only one form worthy of a new name was discovered. This ceases, however, to be very remarkable when we find that only forty-two species of Thecosomata exist; indeed, the really striking thing is this small number of species, for the Pteropoda not only occur in all the great seas from Arctic to Antarctic regions, but they swarm to such a prodigious degree that, though of very minute size, they often actually colour the surface of the water for several square miles in the Arctic seas, where they are said to form an important part of the food supply of the Greenland whale.

The Thecosomata, as looked at from the general student's point of view, have left Dr. Pelseneer's hands in a greatly simplified condition—out of a previously possible thirty-four genera he has abolished all but eight, while among the species the slaughter of names has of course been proportionately heavy. Thus the fourteen species of Clio recognised by Dr. Pelseneer, have hitherto rejoiced in six generic and fifty-seven specific designations, and his genus Cavolinia of eight species represents four genera and fifty-four species under old systems of classification. This is indeed something to be thankful for.

The second report (part iii.), which deals with the structure and classification of the Pteropoda, will be of much wider interest than the two previous memoirs. In it the author discusses the comparative anatomy of each genus of both the great Pteropod divisions in as far as the main organs have in his opinion either been hitherto imperfectly understood, or are calculated to throw light on the affinities and systematic position of the group. This part of the work seems to have been carried out with great thoroughness, and, as might be expected, involves many differences of opinion and corrections, as well as confirmations of the work of his predecessors, Souleyet, Van Beneden, Huxley, Fol, Gegenbaur, and others. What may be called the battle of the ganglia is fought at great length, and the partial twisting of the body, on which the proof of affinity to other groups of Mollusca so much depends, receives its share of attention. Perhaps, however, the reasoning in these two questions would have been more readily followed if one or two additional illustrative diagrams or drawings had been introduced. The conclusions of Dr. Pelseneer from these studies are that the Pteropoda are not a branch of the cuttlefish group or Cephalopoda, nor are they a class (of equal value with the latter) of the Mollusca, both of which views have prevailed and still prevail among zoologists, but that they are a subordinate branch of the Gastropoda or snail-like Molluscs. This itself is enough to cause a mild surprise, but we are positively startled to learn that the two divisions of Pteropoda themselves are not at all related to one another as Pteropoda, but that although both are derived from Tectibranchiate Gastropoda, the Thecosomata spring from a family of which Bulla may be taken as the type, while the Gymnosomata originate from a not very distant family represented by Aplysia, the "sea-hare," the modifications in their form arising from the adoption of a life on the high seas remote from land and the consequent necessity of habits of continual swimming.

The Pteropods are thus not a primitive group which has existed without much change from remote periods, but a recent and terminal one. They certainly possess the following characteristics of terminal groups quoted from Prof. Giard. (1) They are profoundly modified in adaptation to a special mode of existence. (2) They exhibit very slight variability. (3) They include a very small number of species. If, however, the Pteropoda are a recently developed group, it may be asked what becomes of Theca, Conularia, Cleodora, Tentaculites, and other Palæozoic and secondary fossils hitherto classed as Pteropods. The answer is short. Dr. Pelseneer ejects them all from the group without hesitation, and recognises no fossil Pteropoda below the Tertiary. In this he is probably right, and on the conchologist and palæontologist, who appear equally to lack his esteem, will devolve the task of finding a new home for the outcasts. It should be mentioned that, as Dr. Pelseneer points out, De Blainville was the first to show the near relationship of the Pteropoda to the Gastropoda, and that his views have been since supported by Souleyet, Spengel, Grobben, and Boas. As no classification can now be accepted which lacks the aid of embryology, it is to be hoped that this test will shortly be applied to the views so ably expounded by Dr. Pelseneer. It is, perhaps, worth pointing out that on page 88, fourteenth line from the top, the perplexing word "Aplysoidea" is evidently a misprint for "Thecosomata."

III. The Report of Prof. Allman on the Hydroida deals with the Tubularinæ, Corymorphinæ, Campanular næ, Sertularinæ, and Thalamophora; the Plumularinæ and Hydrocorallinæ having been already described, the former by Prof. Allman and the latter by Prof. Moseley ("Zool. Chall. Exp.," part vii.). It is divided into two parts, the first being a complete "Exposition of Hydroid Morphology from the standpoint of our present knowledge," and the second a description of the various genera and species collected in the expedition. Thirty-nine splendid plates drawn by the author and Miss M. M'Daniel, a map giving the track of the *Challenger*, and tables of the geographical and bathymetrical distribution of the specimens taken on the voyage, add greatly to the beauty and usefulness of the volume. The wide geographical distribution of some genera, such as Sertularia, which is found in nearly all parts of the globe, from Britain to Cape Horn, and the varying depth at which others are dredged, as Cryptolaria from near the surface and a tropical temperature in Mid-Pacific down to depths of over three miles at 34°, prove how these apparently delicate organisms can adapt themselves to extreme conditions of temperature. One giant of seven feet in length, Monocaulus by name, the most remarkable Hydroid obtained in the cruise, was brought up from a depth of 2,900 fathoms, or nearly four miles.

What Dr. Allman modestly styles a "Sketch of Hydroid Morphology" is a remarkably clear and simple, and at the same time, as might be expected from one who is *facile princeps* in this department, able and complete exposition of the structure and development of the group as at present known. Lack of space prevents us from referring at further length to this interesting division of Prof. Allman's work, but we may add that a description of the curious genus Myriohela, and of its aberrant embryonic changes, forms an important section of this part of the memoir, which is worthily ended by a clear tabular classification of the chief Hydroid groups.

TOTEM CLANS AND STAR WORSHIP.

A Paper Read by Mr. George St. Clair, F.G.S., before the Anthropological Section of the British Association.

A TOTEM may be described as the badge or crest of a clan or gens, owned and used by all the members of the clan, and serving to distinguish them from members of other clans in the same tribe or in other tribes. It is commonly of an animal form, such as a bear, wolf, turtle, etc., and may be tatooed on the body or inscribed on the shield, or put forward in other suitable ways. Those who use such a crest—as bear or wolf—call themselves bears or wolves, or sons of the animal. They regard the animal as their ancestor, sometimes as their creator and god, and often show some religious reverence for it. They shrink from killing and eating the animal after which they are named, while they have no objection to killing the sacred animal of their neighbours. They credit stories of men having been changed into animals, and in some instances they look forward to a similar transformation for themselves after death. Totemism is thus seen to be connected with the doctrine of the transmigration of souls. It is also connected with the practice of exogamy, or marriage out of the clan; for it is a general rule among barbarians that no man is to marry a woman of the same totem-crest or clan-name with himself. The existence of totemism is almost universal among the natives of Australia, among the Red men of America, and is widely prevalent in Asia and Africa; while its former existence among the early Arabs, and the ancient Greeks and Egyptians can be shown.

These are the principal facts, and as some of them have no appearance of necessary connection, the meaning of them has proved difficult to fathom.

I have been led to connect the clan divisions with divisions of the year and periodical duties; and, through the seasons and months, with the constellations of the months, and the animal forms of the constellations.

Beginning with a small community, which has its camp to guard, and perhaps its religious tabernacle, let us suppose that the eldest son of every mother is liable to military service. As the guard need not be too numerous, the camp is divided into four quarters, and the young men serve in turn for a fourth part of the year. In larger tribes the division may be into twelve, a number suggested by the fact that the year is already divided into months. The religion of the tribe is astral, like that of the ancient Chaldeans, and the watchers know what constellations are uppermost in the various months. If the first band finds the bull constellation in high heaven in the dead of night during its month, it will reverence the bull; the young men will return to their tents at the month's end and speak of the bull; they will remember that when the bull is next in the ascendant they will have to do duty again; and will come to be known as the bulls. For the like reason others become goats and scorpions, or kangaroos and blacksnakes, according to the names of the star-groups with different peoples. The bulls tattoo themselves with the bull crest, and carry it as a military ensign. The members of the bull clan become known as the bulls, or are designated by the equivalent expression, "sons of the bull," the bull is said to be their father, the father of the clan, their great ancestor, and is not to be used as food. But no sooner is the original tribe thus divided into twelve clans, than a great danger threatens its existence, and the integrity of its worship. In the first instance, the whole tribe reverenced all the host of heaven, and was interested in the rise of each zodiacal constellation in turn; but now they are becoming separately enamoured of special gods. The good object of the division into clans was to divide labour and to protect the whole community from outsiders; but the result threatens to be to convert the tribe into so many antagonistic clans. For the division into twelve, or into four, was local and territorial, and the clans thus formed and kept apart are now coming to have separate interests. It is therefore mutually consented, that no man shall take a wife from his own clan, though he may go to either of the other three or eleven. It is already the custom of society that children are reckoned to their mother's kin; and so this new rule of exogamy ensures that no son shall ever be of the same clan as his father, while every clan must see its daughters dispersed among every other throughout the tribe. Thus, notwithstanding the twelve clan divisions and the twelve special gods, provision is made for preserving the integrity of the original tribe, as far as barbarian statesmanship can do it. This is a brief synthetical statement of the system, as I regard it, and of the logical connection between the several features of totemism.

Against this view there is the preliminary objection that barbarians would not be advanced enough to frame a religious and social system upon an astronomical basis. Frazer says it is remarkable how small a part is played in totemism by the heavenly bodies. . . . . A star or constellation appears only twice (pp. 25, 26). But in the same connection he allows that the sun occurs as a totem in Australia, Africa, and America, and on another page (30) he quotes Indians who painted the moon as well as the sun, and divers birds and beasts as totems upon their shields.

Mr. Dawson, a writer who is credited with understanding the Australian aborigines, assures us* that "their knowledge of the heavenly bodies greatly exceeds that of most white people, and is taught by men selected for their intelligence and information." But are barbarous tribes influenced by sentiments of religion and worship? They are, for Mr. Morgan, in his profound work on "Ancient Society," tells us that "after the fashion of barbarians the American Indians were a religious people. The tribes generally held religious festivals at particular seasons of the year, which were observed with forms of worship, dances, and games."† The preliminary objection, therefore, founded on the supposed ignorance and irreverence of early men, is met and removed.

The *Journal of the Anthropological Institute* for August, 1888, containing further important notes on the Australian Class Systems, by Mr. Howitt, only reached me after the present paper was finished and sent in. Mr. Howitt, like all other writers, confesses that "to explain the rise of totemism is as yet one of the unperformed tasks of anthropology." He is apparently as far as possible from imagining an astronomical origin. Yet he supplies facts which lend the strongest

* See A. Lang, "Custom and Myth," p. 126.

† "An cient Society." By Lewis H. Morgan, LL.D.

confirmation to my views, only the facts are scattered, and require to be rightly allocated.

To begin with his conclusions: "The class systems of Australia have been developed from the original division of a community into two exogamous groups." Over very extensive districts "the meaning of the two primary class names is almost everywhere Eagle-hawk and Crow." Native names for Eagle-hawk and Crow are *Bunjil* and *Waa*. "Bunjil is one of the fixed stars, probably Fomalhaut." "A native legend recounts how Bunjil left the earth with his sons and ascended to the sky in a whirlwind. Woiworung astronomy points out where they now are. Bunjil is Fomalhaut, and as my informant said, 'He is looking at what men are doing.' The 'sons' of Bunjil are all stars of the southern hemisphere, and all come into one quarter of the circle, with Fomalhaut—the brightest star in *Piscis Australis*—at one extreme. I should have expected them to extend over half a circle, with Fomalhaut midway; and when I observe that the native informant gave only six stars as sons of Bunjil or Fomalhaut, and placed five of them by the fingers of his left hand, saying that this was usual with his tribe, I suspect that some stars of the other quarter circle are counted as sons of Bunjil*; and that the lost clan stars of Waa occupied the remaining semi-circle (with the star Alphard, *cor Hydræ*, as the parent, equivalent to Waa).

Further confirmation of the astronomical origin is afforded by the diagram, which Mr. Howitt's native informant made by arranging sticks upon the ground. There were thirteen sticks, all radiating from a centre, their directions determined by the sun, and number one placed in a direction due east. The unequal angles of the others can be best understood by supposing that they indicate the meridians of stars. "The direction in which the sticks pointed indicated how the individual was to be laid in his grave." Nine of the sticks represented the principal totems of Krokitch, which was only one of the primary classes out of two; but in the diagram the entire nine occupied scarcely more than half a circle.

Next "we find among the Iroquois six annual religious festivals, which were common to all the gentes united in a tribe, and which were observed at stated seasons of the year. Each gens furnished a number of 'Keepers of the Faith,' both male and female, who together were charged with the celebration of these festivals."† Here at least we have among barbarians public duties, probably of a combined military and religious character, and a conscription of persons to perform them. This reminds us of the Hebrew arrangement, in which the Levites performed duties partly military and partly religious in connection with the tabernacle.‡ Before these duties were devolved upon the tribe of Levi alone, they were performed by contingents from all the twelve tribes,§ and when the change was made, the rebellion of Korah, Dathan, and Abiram showed that much dissatisfaction was felt at the apparent usurpation. Henceforth the tribe of Levi served as substitutes for the eldest sons of all the tribes,|| for each of whom they received a redemption price of five shekels. The High Priest stood as the representative of all the twelve tribes; he wore their names upon his shoulders,¶ and upon his breast the twelve precious stones which were representative of the twelve months of the year and the zodiacal signs.** At a later period, when the work of the Levites had become more specialised as religious work, a national militia was organised by David, in twelve regiments, one from each tribe, to serve monthly.†† The description of the Israelitish camp in the wilderness shows us the twelve tribes in four groups—north, south, east, and west of the tabernacle. In marching, the groups are headed severally by the tribes of Reuben, Judah, Dan, and Ephraim, each carrying a standard. What these ensigns were we are informed by Aben Ezra, and in the Targuin of Jonathan Ben Uzziel, Reuben carried a bull, Judah a lion, Dan an eagle or a basilisk, and Ephraim a man. Taking the basilisk as equivalent to a scorpion, these four signs also head the four quarters of the zodiac; and it is worthy of note that while the bull is the first of the zodiacal signs in the ancient writers, and the lion is always fourth from the bull, Reuben was the first-born son of Jacob, aud Judah his fourth son.

Frazer tells us (p. 81) that when a North American tribe is on the march, the members of each totem clan camp together, and the clans are arranged in a fixed order in camp, the whole tribe being arranged in a great circle, or in several concentric circles. When the tribe lives in settled villages or towns, each clan has its separate ward. In Mexico there were four divisions of the army, which were drawn from the four phratries of the people;* and Morgan tells us that Herrera, after mentioning a chapel of lime and stone for the idol, says that the idol gave orders for the division into four wards, leaving itself in the middle.

If we regard the division into four as being based on the seasons of the year and the quarters of the heavens, we see how very natural it is, and how likely to have been suggested independently to the men of different continents. Nearly all the towns or tribes of the Aztecs were divided into four clans, or quarters, whose chiefs constituted the great council. They were of separate lineage, and had distinguishing standards and costumes, and went out to war as separate divisions. The Munniepores, and the following tribes inhabiting the hills round Munniepore—the Koupouees, the Mous, the Murams, and the Murring—are each and all divided into four familes, which may not intermarry with those of their own name.

If the division into four is based on the four quarters of the year, and of the heavens, there is one arrangement which is simpler still, and that is a division into two, representing summer and winter, or light and darkness, the upper and the under sky. Plutarch tells us that the Persian twelve were classed as six of the Light and six of the Darkness. The Australians have a grand classification of all things in nature into two phratries. The eagle and crow in their myths were continually at war, like the Persian Ormuzd and Ahriman. The same eagle and crow are constellations, and at the same time progenitors of the human race, and as creators they divided the Murray Blacks into two classes.† Again, with the Australians, the sun, the summer, the wind, and the kangaroo, etc., belong to one grand division; the moon, the winter, the rain, the alligator, etc., belong to the other. But a time came when the two great phratries had to be subdivided, and now nearly all the tribes consist of four classes—for instance, Ippai, Kubbi, Murri, and Kumbo—two in each phratry, and each marrying into the opposite phratry. The Seneca-Iroquois are divided into two phratries of four gentes each. They recognise a Great Spirit and an Evil Spirit, besides a multitude of inferior spiritual beings. Both in America and Australia we may notice that when the divisions are more than four, they are apt to be eight or twelve or sixteen, which are multiples of four. Among the Altarians in Siberia we find twenty-four sections, each having its own patron divinity and religious ceremonies. In most instances these larger numbers may have been arrived at by subdivision of the clans; but in the case of the number twelve, the division of the year into months would lend its aid as a determining cause.

Abstracts of Papers, Lectures, etc.

SOCIETY OF ENGINEERS.

At a meeting held on October 1st, Mr. A. T. Walmisley, president, in the chair, a paper was read on "Light Railways," by Mr. William Lawford, M. Inst. C.E.

The paper first drew attention to the fact that the subject was not a new one, having been brought before other scientific bodies about twenty years ago, and also that since that period very little appeared to have been done with Light Railways, in this country at least, and that amongst those that had been constructed, few, if any, had proved commercially successful. The author endeavoured to show the reasons for this, and contended that up to the present time they had scarcely had fair play shown them, and that greater facilities for construction should be granted by Act of Parliament. He then showed that, comparatively speaking, the so-called "Railways Construction Facilities Act" was not made much use of; the ordinary Act of Parliament, notwithstanding its additional cost, being evidently preferred.

The development of steam tramways and road railways was then brought forward, and the term "Light Railways" properly defined, and the latter was exemplified by a description of the Wotton Tramway constructed for the Duke of Buckingham and opened for traffic in 1871.

The author next introduced the subject of break of gauge, as many light railways have been made on a less than the normal gauge of this country, which necessarily involved a break of gauge; this was exemplified in the case of the Festiniog Railway, which has a two feet gauge; and the opinions of some engineers of eminence were given on the gauge question.

The suggestions of the Report of the Commission on the Depression of Trade was shown to have some bearing on this question, from the fact that Light Railways or steam tramways would be the means of greatly assisting the transport of agricultural produce generally, so as to bring it rapidly and cheaply to market, the assumption being that such districts as those alluded to might bear the expense of making and working a Light Railway, whilst the population was too sparse and too widely scattered to support a railway of heavy or ordinary construction.

Certain light railways in Russia, known as the "Maltzeff" railways, were alluded to, but all that is known of them is that their cost is barely one-fifth per mile of the ordinary heavy lines in that country, and that they pay an annual surplus profit of $3\frac{1}{4}$ per cent. on the cost of construction.

The conclusions arrived at were that if light railways can be made to pay their promoters in other countries, why should they not do so in this? And the author gave it as his decided opinion they had not yet had fair play accorded to them.

ENTOMOLOGICAL SOCIETY.

At the meeting held October 3rd, Mr. Poulton exhibited a larva of *Smerinthus ocelatus* feeding on nut-leaves. He finds that if the larva of this species has lived for some time upon willow leaves it will starve rather than eat nut leaves. But if it finds itself upon nut leaves, on emerging from the egg it accepts the strange food. Mr. Poulton showed the importance of this principle in accounting for the spread of moths and butterflies in new countries.

Major Elwes exhibited an interesting collection of butterflies captured this summer on a journey from Mexico to California. Many of the specimens were rare, and some probably new to science. He discussed the phenomena of seasonal and climatic di- or polymorphism. In the very difficult genus *Colias* ("clouded yellows") he gave an instance of two apparently distinct forms obtained from the same brood of eggs, both being *unlike* the parents. The speaker recommended the eastern side of the Rocky Mountains up as far as the 60th parallel of latitude as a happy hunting ground for entomologists, which is by no means thoroughly explored.

Among the exhibits were a damaged specimen of *Daphnis nerii* (the oleander hawk-moth) found in a street of Burton-on-Trent, a collection of Longicornes from New Guinea, and a huge moth sent by Mr. Oliffe, of the Sydney Museum. This species has the fore-wings resembling those of a *Saturnia*, whilst the hind wings approach those of *Hepiolus*. The female of the species measures 10 in. across the wings.

Mr. Poulton read a very suggestive page on the ontogeny of the larvæ of *Sphinx convolvuli* and *Aglia tau*, which have never before been closely examined in their earlier stages. The most important point established was that *Aglia tau* has very remarkable affinities with the *Sphingidœ*, and connects the latter family through the *Saturnia* group to the *Bombyces*.

Falmouth Naturalist Society.—The annual meeting of this Society was held on Tuesday, 2nd Oct., the president, Mr. Howard Fox, occupied the chair. The hon. secretary, in the annual report, said that there was much cause for gratification, on the completion of this the first year of the society's existence, although little practical work had been done, yet there was every reason to believe that what had been done would prove of value and be productive of good results. During the session ten papers had been read before the society, including "Some Notes on British Plants," by Rev. A. R. Eagar, B.D.; "Cragside, Northumberland," by Mr. Howard Fox, F.G.; "Conchology," by Rev. C. Crawshaw; "Sun Spots," by Rev. Wm. Rogers, M.A.; "Seven Days in the Bermudas," by Mr. F. J. Stephens; "Persecuted Birds.—I. The Owl," by Mr. H. C. Oakshott; "Bees, and Bee Keeping," by Mr. John Gedge, jun.; "Dragon Fies," by Mr. W. H. Bath, of Birmingham. During the session twelve ordinary and six field meetings had been held, all of which had proved very successful, and were well attended. The financial state of the Society was very satisfactory, a balance of several pounds being in hand. The Rev. A. R. Eagar, B.D., was elected President for the next session; Messrs. A. Pendarves Vivian, F.G.S., W. L. Fox, F.R. Met. Soc., and Howard Fox, F.G.S., were elected vice-presidents. A long discussion followed as to the best means of increasing the usefulness of the society, and many valuable suggestions were made. It was resolved that a conversazione should be held in the Town Hall on Tuesday 23rd inst. A large number of microscopes, collections of specimens, curiosities, etc., had been lent, and the meeting hoped that it would prove successful. The first ordinary meeting for the session will be held on Monday 15th inst., when the Rev. A. R. Eagar will read an opening address.

THE ELECTRICAL TRANSMISSION OF POWER.

A Lecture Delivered by Professor Ayrton, F.R.S., etc., before the British Association, on September 8th, and Re-Delivered to the Working-Classes of Bath, on September 13th, 1888.

(Continued from p. 370.)

A VAST district in London, extending from Regent's Park on the north to the Thames on the south, from the Law Courts on the east to Hyde Park on the west, has over 20,000 incandescent lamps scattered over it, all worked from the Grosvenor Gallery in Bond Street by means of alternate current transformers, which convert the 2,000 volts contained between the street mains into 100 volts in the houses; and this London Electric Supply Company have arranged for a vast extension of this system to be worked from Deptford.

In America alternate current transformers are due to the remarkable enterprise of Mr. Westinghouse, used to light 120,000 incandescent lamps in 68 towns. In fact, the electric lighting of a whole town from a central station begins to excite less astonishment than the electric lighting of a single house did ten years ago.

The efficiency of a well-made alternate current transformer is very high, being no less than 96·2 per cent. when the transformer is doing its full work, and 89·5 per cent. when it is doing one quarter of its full work, according to the experiments made by our students. It certainly does seem most remarkable, and it reflects the highest praise on the constructors of electrical machinery, that motor power can be converted into electrical power, electrical power at low pressure into electrical power at high pressure, or electrical power at high pressure into electrical power at low pressure, and lastly, electrical power into motor power in each case with an efficiency of 94 per cent.

As a further illustration of the commercial importance of this electric transformation, I will show you some experiments on electric welding, one of the latest developments in electrical engineering. To weld a bar of iron one square inch in section requires a gigantic current of some 13,000 ampères. To convey this current even a few yards would be attended with a great waste of power, consequently while an enormous current is passed through the iron to be welded, only a comparatively small current is transmitted along the circuit from the dynamo to the welding apparatus. Mr. Fish, the representative of Professor Elihu Thomson, of America, to whom this apparatus is due, will be so kind as to first show us the welding together of two bars of square tool steel, the edge of each bar being three-quarters of an inch, and the operation is entirely completed in some fifteen seconds. For this experiment an alternate current of 20 ampères will be produced by the dynamo at the other side of the lower Bristol road, and this current will be converted by the transformer on the platform into one of 9,000 ampères, large enough for 12,000 of those incandescent lamps, if these were placed in parallel and the current divided among them. He will next try welding some thicker bars; and lastly, he proposes welding together two pieces of aluminium, which it is extremely difficult, if not impossible, to weld in any other way. The bars, as you see, are in each case pressed together end on, and, in consequence of the electric resistance of the very small gap between the bars being much higher than that of the bars themselves, the current makes the end of the bars plastic long before it softens the whole bar. Hence a very good weld indeed can be made by end pressure.

Did time allow, I should like to describe to you what perfection the system of economical distribution with accumulators originally proposed by Sir William Thomson in 1881, and shown in its very simplest form in the wall diagram, has been brought by Mr. King, the engineer to the Electrical Power Storage Company, how the cells when they are fully charged are automatically disconnected from the charging circuit and electrically connected with the discharging circuit, how the electric pressure on the discharging or house mains is automatically kept constant, so that the brightness of the lamps is unaffected by the number turned on, and how cells that are too energetic have their ardour automatically handicapped and not allowed to give more current than is being supplied by the less active ones.

During the last few months fierce has been the battle raging among the electricians, the war-cry being alternate current transformers *versus* accumulators, while the lookers-on with that better view of the contest that they are proverbially said to possess, have decided that the battle is a drawn one. Neither system is the better under all circumstances; if the district to be lighted be a very scattered one, use alternate current transformers by all means, but if the houses to be lighted are clustered together at a distance from the supply of power, then the storing property possessed by accumulators, which enables the supply of electric power to far exceed the capacity of the dynamos and engines in the busiest part of the twenty-four hours, will win the battle for accumulators. Any direct current system of distribution such as is furnished by accumulators has also the very great advantage that it lends itself to the use of the very efficient electro-motors which I have been using this evening. Alternate current motors do exist, but they are still in the experimental stage and are not yet articles of commerce.

Secondary batteries have caused much heart-burning for their uses, from the apparent fickleness of their complex chemical action, yet but imperfectly understood. But we have at length been taught what is good and what is bad treatment for them, and after years of brave persevering application on the part of the Electrical Power Storage Company, that forlorn hope, the secondary battery, has become one of the most useful tools of the electrical engineers, and secondary cells, some of which, thanks to the kindness of that company, I am using here to-night to supply power for lamps and motors, may now be trusted to have a vigorous long life. That company, I learn, undertake henceforth to keep their cells in order, when used for central station works, for 12½ per cent. per annum, and I understand that they have such confidence in them that they anticipate making no little money by incurring this insurance office responsibility. It is not then surprising that the Chelsea Supply Company have decided to use secondary batteries on a large scale for the economical distribution of light and power in their district.

Oliver Goldsmith said more than 100 years ago in his life of Richard Nash, Esq., "People of fashion at Bath. .... when so disposed attend lectures on the arts and sciences, which are frequently taught in a pretty, superficial manner so as not to tease the understanding, while they afford the imagination some amusement." I want not to be superficial, yet I must not tease your understanding, and so we will not lose ourselves in technical details. If, however, my remarks have led you to appreciate the vast economical importance of using very large electric pressures, and to grasp that by substituting 2,000 volts for 50 volts when transmitting a certain amount of electric power the current can be reduced to one-fortieth part, and the waste of power when transmitted along a given length of a given wire to the 1-40th of the 1-40th, that is to the 1-1600th part, your imagination will have been kindled as well as amused.

With a loss on the road of only 11 per cent. M. Deprez has, by using 6,000 volts, transmitted 52-horse power over a distance of about thirty-seven miles through a copper wire only 1-6th of an inch in diameter. A piece of the actual conductor he employed I hold in my hand; the copper wire is coated with an insulated material, and then with a leaden tubing, so that the outside may be touched with perfect impunity, in spite of the high potential difference employed. M. Deprez's dynamo and motor were not nearly as efficient as he could make them now, so that his terminal losses were unnecessarily great, and the efficiency of the whole arrangement, wonderful as it was, was not so startling as it would otherwise have been. I have told you that the loss in dynamo and motor has actually been reduced to only 12½ per cent., so that if a dynamo and motor of this efficiency had been used by M. Deprez the total loss in the whole transmission over thirty-seven miles would have been under 25 per cent. Indeed, by using only 1,250 volts Mr. Brown has succeeded in transmitting 50-horse power supplied by falling water at Kriegstetten to Solothun in Switzerland, five miles away, with an entire loss in the dynamo, motor, and the five miles of going and returning wire of only 25 per cent., so that ¾ of the total power supplied by the water at Kriegstetten was actually delivered to machinery at Solothun, five miles away.

In less than twenty years then from Gramme's practical realisation of Pacinotti's invention we have power transmitted over considerable distances by electricity with only a total loss of 25 per cent., whereas the combined loss in an air pump and air motor, or in a water-pump and water motor is 40 per cent., irrespective of the additional loss by friction or leakage that occurs *en route*. We cannot help feeling that we are rapidly arriving at a new era, and that it will not merely be for the inauguration of the quick transmission of our bodies by steam, or the quick transmission of our thought by telegraph, but for the economical transmission of power by electricity, that the Victorian age will be remembered.

I showed you a little while ago an electric fire. Was that a mere toy, or had it any commercial importance? To burn coal, to work dynamos, and to use the electric current to light your houses and your streets is clean and commercial; to use the current to warm your rooms clean but wasteful, on account of the inefficiency of the steam engine. But when the dynamos are turned by water power which would otherwise be wasted, the electric current may be economically used not merely to give light, but also to give heat. And when the electric transmission of power becomes still more perfect than at present, even to burn coal at the pit's mouth, where it is worth a shilling a ton, may, in spite of the efficiency of the steam-engine being only one-tenth, be the most economical way of warming distant towns where coal would cost twenty shillings a ton. Think what that would mean, no smoke, no dust, a reform effected commercially which the laws of the land on smoke prevention are powerless to bring about, a reform effected without the intervention of the State, and, therefore, dear to the hearts of Englishmen.

I am aware that this idea of burning coal at the pit's mouth and electrically transmitting its power has quite recently been stated to be commercially impracticable. But is that quite so certain? for in 1878 it was stated that, although telephones may do very well for America, they certainly would never be introduced into Great Britain, as we had plenty of boys who were willing to act as messengers for a few shillings a week. The phonograph was also declared to be worked by a ventriloquist, and electric lighting on a large scale was proved to be too expensive a luxury to be ever carried out.

To-day the electric current is used for countless purposes; not only is it used to weld, but by putting the electric arc inside a closed crucible, smelting can be effected with a rapidity and ease quite unobtainable with the ordinary method of putting the fire outside the crucible. If one had pointed out a few years ago that it was as depressing scientifically to put a fire outside a crucible when you wanted to warm the inside, as Joey Ladle, the cellarman, found it depressing, mentally, "To take in the wine through the pores of the skin instead of by the convivial channel of the throttle," who would have believed that, in 1888, a 500-horse power dynamo would be actually employed to produce an eletcric arc inside a closed crucible in the manufacture of aluminium bronze? Putting a conservative drag on the wheels is a good precaution to take when going downhill, but it is out of place in the uphill work of progress.

But of all the many commercial uses to which the electric current may be put, probably, after the electric light, electric traction has most public interest. The English are a commercial people, but they are also a humane people, and when, as in this case, their pockets and their feelings are alike touched, surely they will be radicals in welcoming electric traction, whatever may be their political sentiments on other burning topics of the day. It is not a nice thing to feel that you are helping to reduce the life of a pair of poor tramway horses to three or four years; it would be a very nice thing to be carried in a tramcar for even less fare than at present. Now, while it costs 6d. or 7d. to run a car one mile with horses, it only costs 3d. or 4d. to propel it electrically. Indeed, from the very minute details that have recently been published of the four months' expenses of electrically propelling thirty cars at seven and a half miles an hour along twelve miles of tramway line in Richmond, Virginia, it would appear that the total cost, inclusive of coal, oil, water, engineers, firemen, electricians, mechanicians, dynamo and motor repairers, inspectors, linemen, cleaners, lighting, depreciation on engine, boiler, cars, dynamos, and line work has been only 1¼d. per car per mile. This tramway is no doubt particularly favourable for propelling cars on the *parallel* system (that is the system in which the current produced by the dynamo is the sum of the currents going through all the motors on the cars) without a great waste of power being produced by a very large current having to be sent a very long distance, because the tramway track is very curved and the dynamo is placed at the centre of the curve with feeding wires to convey the current from the dynamo to all parts of the track. But even in the case of a straight tramway line with a dynamo only at one end, it is quite possible to obtain the same high economy in working by employing a *large* potential difference and by sending a small current through all the trains in *series* instead of running the trains in *parallel* as is done on the Portrush, Blackpool, Brighton, and Bessbrook tramways.

This *series* system of propelling electric trains was, oddly enough, entirely ignored in all the discussions that have taken place this year at the Institution of Civil Engineers and at the Institution of Mechanical Engineers regarding the relative cost of working tramways by horses, by a moving rope, and by electricity; and yet this series system is actually at work in America, as you will see from an instantaneous photograph, which I will now project on the screen of a series electric tramway in Denver, Colorado; and a series electric tramway 12 miles long, on which 40 cars are to be run, is in course of construction in Columbus, Ohio. The first track on which electric trams were run in *series* was the experimental "Telpher Line," erected in Glynde in 1883, under the superintendence of the late Professor Fleeming Jenkin, Professor Perry, and myself, for the automatic electric transport of goods. The large wall diagram shows symbolically, in the crudest form, our plan of series working; the current follows a zigzag path through the contact pieces, and when a train enters any section the contact piece is automatically removed and the current now passes through the motor on that train instead of through the contact piece. The Series Electrical Traction Syndicate are now developing our idea, but it has received its greater development in the States, where the Americans are employing it instead of spending time proving, *à priori*, that the automatic contact arrangements could never work.

In addition to the small waste of power and consequent diminished cost of constructing the conductors that lead the current into and out of passing trains, the series system has another marked advantage. Some years ago we pointed out that when an electric train was running down-hill, or when it was desired to stop the train, there was no necessity to apply a brake and waste the energy of the moving train in friction, because the electric motor could, by turning a handle, be converted into a dynamo, and the train could be slowed or stopped by its energy being given up to all the other trains running on the same railway, so that the trains going downhill helped the trains going uphill—the stopping trains helped the stopping trains. At that time we suggested detailed methods of carrying out this economical mutual aid arrangement, whether the trains were running on the parallel or on the series system. But there is this difference, that whereas on the parallel system it is only when a train is running fairly fast that it can help other trains, the series system has the advantage that, when a motor is temporarily converted into a dynamo by the reversal of the connections of its stationary magnet, the slowing train can help all the other trains even to the very last rotation of its wheels.

Brakes that save the power instead of wasting it are purely English extraction, but their conception has [re]cently come across the Atlantic with such a strong [Y]ankee accent that it might pass for having been born [an]d bred on the States.

Economy is one feature that gives electric traction their [ri]ght to claim your attention, safety is another. This [mo]del telpher line worked on the *post head contact* [sys]tem is so arranged that no two trains ever run into [on]e another, for in addition to each of the three trains being provided with an automatic governor which cuts off electric power from a train when that train is going too fast, the line is divided into five sections connected together electrically in such a way that as long as a train is on any section A no power is provided to the section B behind, so that if a train comes into section B it cannot move on as long as the train in front is on section A. Whenever a train—it may be even a runaway electric locomotive—enters a blocked section it finds all motive power withdrawn from it quite independently of the action of signalmen, guard, or engine driver, even if either of the latter two men accompany the train, which they do not in the case of telpherage; no fog, nor colour blindness, nor different codes of signals on different lines, nor mistakes arising from the exhausted nervous condition of overworked signalmen can with our system produce a collision. Human fallibility, in fact, is eliminated while the ordinary system of blocking means merely giving an order to stop, and whether this is understood or intelligently carried out is only settled by the happening or non-happening of a subsequent collision, our automatic block acts as if the steam were automatically cut off, nay, it does more than this, it acts as if the fires were put out in an ordinary locomotive and all the coal taken away, since it is quite out of the power of the engine driver to re-start the electric train until the one in front is at a safe distance ahead.

The photograph now seen on the screen shows the general appearance of the Glynde line, which has recently been much extended in length by its owners, the Sussex Portland Cement Company, and a telepher line with automatic blocking on the principles I have described is about to be constructed between the East Pool tin mine, in Cornwall, and the stamps. There will be four trains running, each consisting of 33 skeps containing 3 cwt. each, so that the load carried by each train will be about five tons.

It may be interesting to mention that the last difficulty in telpherage, which consisted in getting a proper adhesion between the driving wheel of the locomotive and the wire rope, has now been overcome. The history of the telpher locomotives is the history of steam locomotives over again, except that we never tried to fit the electric locomotives with legs, as was proposed in the early days for steam locomotives. It is a tedious, discouraging history, but it is so easy to be wise when criticising the past, so difficult to be wise when prospecting the future. Gripping wheels of all kinds, even the india-rubber tires used for the last three years have all been abandoned in favour of simple, slightly loose, cheap iron tires, which wear for a very long time, and give a very perfect grip when the bar supporting the electro-motor is so pivoted, pendulum wise, to the framework of the locomotive that the weight of the motor no longer makes the locomotive jump in passing the posts as it did until quite recently.

After several years of experimenting, we have in telpherage, I venture to think, at least a perfectly trustworthy, and, at the same time, a most economical method of utilising distant steam or water power to automatically transport our goods, and in time it may even be our people, over hills and valleys, without roads or bridges, and without interfering with the crops or the cattle, or the uses to which the land may be put, over which the telpher trains pursue their snakelike way; we have, in fact, the luxury of ballooning without its dangers.

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents, nor can he take notice of anonymous communications. All letters must be accompanied by the name and address of the writer, not necessarily for publication, but as a guarantee of good faith.

EXTINCT BRITISH BUTTERFLIES.

Your interesting article on this subject (SCIENTIFIC NEWS, vol. ii., pp. 124 and 160) raises some questions to which I must beg to call attention. Our climate is admittedly less favourable to butterflies (and indeed to many other insects) than is that of Continental districts under similar latitudes. But such as it is, it has not, to our knowledge, undergone any changes within historical times. Now, if the lack of sunshine be a leading factor in the extirpation of, *e.g*, *Papilio podalirius* and *P. machaon*, how, it may be asked, did these species ever establish themselves in Britain at all?

Drainage must, of course, tell against the existence of species which feed upon fen vegetation. But this is certainly not the case with *P. podalirius* and *machaon*. The caterpillar of the former feeds upon sloes, plum, apple, and pear trees, and upon oaks. *Machaon* feeds upon the leaves of carrots, which are certainly more abundant than they were formerly. Further, on the Continent *machaon* is not a fen insect.

I must beg to express doubts concerning the following passage: "In our British climate thistles and kindred plants die early in the autumn, and before the larvæ can feed on them the chilly nights have withered the food plants." So far as I remember, the autumn frosts in northern and central France, Germany, etc., set in quite as early as with us, and the thistles will therefore be cut off quite as early.

The chief causes of the decrease or disappearance of the larger and more striking British butterflies are, I submit, the "British mania," to which you have referred from time to time, and the "ravages of the picture-makers," which you mention on p. 174. It is just possible that some of your readers may not know what is here meant by the expression "picture-makers." These people obtain by any means a quantity of butterflies, and arrange them in a glass case, not according to their structural affinities, but in concentric circles, in squares, triangles, crosses, or other patterns. The case is then hung up on the wall as a decoration. The extent to which this freak is indulged in is perfectly alarming. I have seen such cases form a prominent feature in exhibitions got up by country societies; and on one occasion, when stopping at Leeds, I saw an announcement that a collection of 50,000 beautiful insects was being exhibited in the Roundhay Park, and that the owner was willing to sell. On going there I found several rooms lined with these "pictures," in which more butterflies had been used up than a hundred genuine entomologists would have sacrificed in a life-time. To such follies, more than to climate, drainage and cultivation, I think that the decrease of our finer butterflies must be traced.

F. E. S.

THE MULTIPLICATION OF SPARROWS.

A correspondent in your issue of July 6th concludes, from certain observations which he has made, that "the sparrow is not so prolific as it is generally supposed to be." I should like to ask how does he, then, account for the fact that in most districts the sparrow is more common not only than any other bird, but often than all other species put together? I do not think that killing down, or even, were it possible, the extirpation of this marauder, would be injurious to the farmer and gardener, since scope would thus be given for the multiplication of the swallow and other true insectivorous birds which the sparrow persecutes and drives away.

As to the food of this bird, Mr. S. A. Forbes, writing in the *American Naturalist* for 1881, gives the following decisive evidence (p. 393): "I add a few notes on the food of twenty-five sparrows shot in and around Aurora, Ill., in the years 1879 and 1880. At a time when 30 per cent. of the food of the (American) robin, 20 per cent. of that of the cat-bird, and 90 per cent. of that of the blue-bird consisted of insects, no insects were found in the stomachs of the sparrows, except traces of three grasshoppers, making, perhaps, 6 per cent. of the food."

ARUSPEX.

FOOD OF THE LEECH.

Replying to "J. P. P.," in your issue of 5th inst.: In a small aquarium I had some time since, I found a young leech, inadvertently introduced, feasting on a small snail, which it was moving to and fro in the water, its other end being fastened to the glass, some distance from the bottom of the aquarium.

8th October, 1888. F. M.

RECENT INVENTIONS.

The following list has been compiled especially for the SCIENTIFIC NEWS *by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents, 234, High Holborn, London, W.C; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester; and 6, Lord Street, Liverpool.*

EXTINGUISHING FIRES.—Means for extinguishing fires in ships' holds and places in which furnaces are employed have been patented by Mr. H. C. Carver. This invention uses the waste gaseous products of combustion in furnaces for extinguishing fires. These products are conveyed through pipes and discharged on to the fires to be extinguished, thus rendering the atmosphere incapable of supporting combustion, and so extinguishing the fire.

VENTILATORS.—An exit ventilator has been patented by Mr. J. W. Gibbs. The object is to form the ventilators so that they have not the rattling noise noticeable in the ordinary mica-flap ventilators when variations of draught occur. This is attained by forming the surfaces which come in contact of a soft, non-inflammable material, which cushions the blow and obviates the noise. The material employed is asbestos, which works well simply fastened like an ordinary mica-flap.

MUSICAL INSTRUMENTS.—A mechanical musical instrument has been patented by Mr. J. M. Draper. It consists of a reed box containing a double set of reeds of different tone, each of which sets of reeds can, by means of opening and closing shutters covering the outlets of the reed box, be played at will, either alone or with other sets. By opening and closing the shutters the volume of sound is also controlled. Arrangements are made for providing this instrument with bells, cymbals, etc., which may be sounded at will.

DISINFECTING.—A disinfecting machine has been patented by Mr. T. P. Hollick. This invention dispenses with the means usually employed for disinfecting a house, such as sprinkling, or exposing the disinfectant in a basin, and is carried out by means of an endless cotton or flannel band, which passes round rollers arranged above a trough containing the disinfectant. The lower part of the bands rests in the disinfectant. As the top roller is revolved the band is moistened and raised, and exposed to the air in the room, thus disinfecting it.

TIDAL POWER.—A means of utilising the rise and fal of the tides for raising water for supplying baths, stree watering, etc., has been patented by Mr. W. Green. A reservoir is provided which fills at high water; a float i also provided, in an enclosure constantly open to th tidal water. On this float is mounted a hydraulic ram which communicates with the tidal reservoir by flexible pipe, as also with an elevated reservoir. As the tide falls it operates the ram by means of a valve, and continuously raises the water until the tide again rises.

ELECTRIC LAMPS.—An electric arc lamp has been patented by Mr. F. C. Phillips. The invention relates to the adjustment of arc lamps. On a spindle are rigidly mounted two wheels, to which are attached chains. To the free end of each of these chains is fixed an electrode. The chains are so arranged on the wheels that the electrodes suspended on the chains counterbalance each other, and by this arrangement the electrodes approach or recede from each other simultaneously, and at a relative speed, depending on the relative diameters of the two wheels to which the chains are attached.

MUSICAL INSTRUMENTS.—A tension-regulating device for the strings of musical instruments has been patented by Mr. W. Fischer. It consists essentially of an angular block for each string, pivoted upon its vertex in the framing of the instrument. The rear shank of this block is screwed down on to the framing, so as to move radially the other shank, which is provided with a pin, to which the string is secured. This pin consists of a screw, fastened in the block, by means of which tension is given to the string, being finally adjusted and tuned by the screw in the rear shank of the angle lever.

VARNISH.—An improvement in the manufacture of varnish, paint, etc., has been patented by Mr. A. G. Wass. The object is to utilise the waste products evolved in the refining and distillation of mineral oils and in the manufacture of gas. In the first case the waste product is an acid tar, and in the other case a tarry residue. These products are subjected, in a vessel, to a certain heat, and a proportion of rosin added. The products so treated are then thinned down with turpentine until the desired liquid state is attained, when it is allowed to cool, and the product can be used as a varnish, paint, enamel, etc.

CHAIRS.—A chair with an adjustable back and foot-rest has been patented by Mr. F. Vogel. The invention consists in the means by which the adjustment may be varied by the sitter without leaving the chair. The back is hinged at the rear of the seat, and the foot-rest to the front of the seat. These rests are connected by cords passing through the arms of the seat, in such a manner that by depressing the foot-rest the back is raised, and by depressing the back the foot is raised. At the passage of the cord through the arm is arranged a friction-brake, acting automatically, for securing the back and foot-rest in the position given to them.

ELECTRICAL MEASUREMENTS.—An apparatus for measuring electric currents has been patented by M. A. de Khomistry. The invention is based upon the unequal expansion of different metals, the essential part consisting in fixing together two or more strips of different metals to form a compound conductor, through which the current to be measured is then passed. This conductor thus becomes heated, and its unequal expansion will cause a curvature of same. If one end be fixed the other end will move according to the heat developed in the conductor. This motion is transmitted to a pointer on a graduated scale. The same method may be applied to making and breaking contacts and such-like purposes.

TECHNICAL EDUCATION NOTES.

SCHOOL OF ART WOOD-CARVING.—The School of Art Wood-carving, City and Guilds Institute, Exhibition Road, South Kensington, has been reopened, after the usual summer vacation, and we are requested to state that one or two of the free studentships in the evening classes, maintained by means of funds granted to the school by the institute, are vacant. To bring the benefits of the school within the reach of artisans, a remission of half-fees for the evening class is made to artisan students connected with the wood-carving trade.

THE GOLDSMITHS' COMPANY AND TECHNICAL EDUCATION.—The Goldsmiths' Company have made a proposal to the Charity Commissioners which, subject to the approval of Parliament, has been accepted by that body, whereby the buildings, with seven acres of land, at present occupied by the Royal Naval School at New Cross, will be acquired by the Commissioners out of the surplus funds of the City parochial charities. From the same source the Commissioners will set apart an endowment of £2,500 per annum, which will be met by the Goldsmiths' Company by the appropriation out of their corporate funds (not trust funds, but funds over which they have absolute control) of an annual endowment of a similar amount. The institute is intended to be called the Goldsmiths' Company's (New Cross) Institute. As soon as possible after the vacation a scheme will be prepared for the establishment of the institute upon the above basis, with provisions for the constitution of a governing body and for defining the work of the institute. This scheme will have to be laid before Parliament for approval, and the arrangement between the Charity Commissioners and the Goldsmiths' Company is necessarily made subject to that approval.

THE PEOPLE'S PALACE.—On October 5th the Master of the Worshipful Company of Drapers (Mr. J. H. Daniell) performed the ceremony of opening the new technical schools of the People's Palace for East London. These schools have been erected and will be equipped at the expense of the Drapers' Company, which has made a donation of £20,000 for that purpose. The class-rooms and workshops are not yet fully equipped, but in some cases work has been already begun, and before long the whole building will be utilized for the various purposes for which it has been erected. It embraces, among other apartments, engine rooms, electric and chemical laboratories, workshops for pattern-making and moulding, and for brickwork and masonry, an admirable lecture-room (which will be used on every week night), a mechanical drawing room, a building construction drawing room, a photographic studio, and a printing room. There will be two departments of education in this school—a day school in which the courses of instruction are arranged to extend over a period of two years, and an evening school in which classes will be held for apprentices, artisans, and foremen, in the scientific principles connected with the special industries in which they are employed, together with practice in the laboratories and instruction in the workshops. In the day school there will be courses of mathematics, mechanical and industrial drawing and science, with laboratory practice and the use of tools. Special efforts will be made to give those pupils who intend to follow the engineering, building, or other constructive trades, a thorough practical knowledge of drawing, construction, and mechanics, together with sufficient workshop instruction to enable the lads leaving school at the age of fifteen to understand and execute an ordinary working drawing. To those who are to be trained especially as engineers, the course of study will include drawing, the principles of pattern-making from drawings and to measurement, metal turning and lathe work, and construction of models from drawings of their own execution. The object of the school is to develop the faculties of the pupils by means of a systematic course of technical and manual training. It is not, however, intended to teach a trade, but simply to provide each pupil with an education which will fit him for making ready progress in any trade which he may subsequently be engaged in.

SALES.

The Charge for Advertisements in this Column is Sixpence for the first sixteen words, and Sixpence for every succeeding eight words. Advertisements for this Column should be received by first post on Tuesday to insure insertion in the following number.

Electrical Apparatus.—Special batteries for cautery, require no attention, plates remain in the liquid, no acids.

Electrical Apparatus : Special hand, foot, and power dynamos, for cautery, incandescent lighting, etc., wound with silk-covered wire.

Electrical Apparatus : Electromotors, dynamos, galvanometers, resistances, batteries, etc.—G. BOWRON, 97, Crawford Street, London, W.

Wanted.—Trap-Door Spiders and Nests; Larvæ and image of Ant Lion (Myrmelion); "stick" and "leaf" insects; for cash or exchange. State price or desiderata.—MARK SYKES, Adelphi Street, Salford.

Zuccato Typograph.—Cost 7 guineas; will take £3 10s., or offers.—Address, B., SCIENTIFIC NEWS, 138, Fleet Street.

Amateur Mechanics supplied with Lathes, Drilling, Planing Machines, Castings, etc. Cash, or easy payments.—Britannia Company, 100, Houndsditch, London.

Britannia Co. *Bona-fide* makers of 300 varieties of lathes, and other engineers' tools. Prize medals. Makers to the British Government.

Practical Hints on Electro-Plating, etc. One stamp.—Address HENRIC, 234, Great Colmore Street, Birmingham.

Amalgamating Brushes, Scratch-brushes, Polishing Sand, Calico Mops, Rouge and Crocus Compositions, Nickel Salts and Anodes.—HENRIC, 234, Great Colmore Street, Birmingham.

Do your own Electro Plating and Gilding. System inexpensive. Particulars one stamp.—PERKS, 47, Alexandra Road, Richmond, Surrey.

Watts' Gas Engines, all sizes, from 1½ bore, slide explodes charge, simple. Lists, 3 stamps.—Below.

Watts' Gas Engines, work without noise, are easily made up. Castings supplied. List, 3 stamps.—Below.

Dynamos for plating and lighting, experimental dynamos, electro motors, separate parts, wire, punchings, etc.—Below.

Dynamos, highest efficiency, castings or finished. List, 2 stamps.—WILLIAMS, WATT, AND Co., Belshaw Street, Homerton, E.

Mica or Talc cut for all purposes. Mica chimneys, Mica covers, etc.—C. JOHNSON, 87, New Oxford Street, W.C.

EXCHANGES.

Exchange Notices will be inserted in this Column at the rate of Sixpence for the first twenty-four words, and Threepence for every succeeding eight words.

Advertisements for this Column should be received by first post on Tuesday to insure insertion in the following number.

Powerful Electro-Motor, Grigson's pattern, on polished mahogany stand. Exchange for lantern slides, chromatropes, etc., to value 30s.—G. HARRIS, 17, York Street, Nottingham.

Student's Microscope, 2 achromatic powers, in mahogany cabinet, with 2 dozen best mounted slides. Exchange lantern slides to value £2.—G. HARRIS, as above.

SELECTED BOOKS.

The Principles of Agricultural Practice as an Instructional Subject. By J. Wrightson, M.R.A.C., F.C.S., etc., Professor of Agriculture in the Normal School of Science and Royal School of Mines, etc. With Geological Map. London: Chapman and Hall, Limited. Price 5s.

The Building of the British Islands. A Study in Geographical Evolution. By A. J. Jukes-Browne, F.G.S., of the Geological Society of England and Wales. London: Bell and Co. Price 7s. 6d.

Kirke's Handbook of Physiology. Twelfth edition. Thoroughly revised and edited by W. Morrant Baker, F.R.C.S., and Vincent Dormer Harris, M.D. London: J. Murray. Price 14s.

The Industrial Self-Instructor in the leading branches of Technical Science and Industrial Arts and Processes. With practical, useful, and technical notes, facts and figures for ready reference. Profusely illustrated by working drawings, designs, and diagrams. In five volumes. London: Ward, Lock and Co. Price 7s. 6d. each.

A Text-Book of Physiology. By Michael Foster, M.A., M.D., LL.D., F.R.S., Professor of Physiology in the University of Cambridge, etc. With illustrations. Fifth and thoroughly revised edition. In three parts. Part I. comprising Book I., Blood—The Tissues of Movement—The Vascular Mechanism. London: Macmillan and Co. Price 10s. 6d.

DIARY FOR NEXT WEEK.

Saturday, Oct. 13.—Chesterfield and Midland Counties Institution of Engineers, at 2·45 p.m.—*The Dumb Fault;* Mr. G. Elmsley Coke. *Stanley's Coal Heading Machine;* Mr. R. Stanley. *Past and Present Methods of Banking Coal at Annesley;* Mr. J. Timms. *A Double-Acting Wedge for Getting Coal;* Mr. [illegible] C. Cox.

NOTICES.

The Title Page and Index to Vol. I., now ready, price 3d.

Binding Cases for Vol. I., price 2s. each.

Cases and Binding, Vol. I., including Title Page and Index, price 3s.

Vol. I., bound in cloth, with Title Page and Index, 9s. 6d.—by post 10s.

The Back Numbers of SCIENTIFIC NEWS can be obtained from all Booksellers and Newsagents, or direct from the Publisher, 138, Fleet-street, London, E.C. Price 3d. each, or by post 3½d.

METEOROLOGICAL RETURNS

for the ten weeks ending on Monday, Oct. 1st, 1888. Specially prepared for SCIENTIFIC NEWS from official reports.

	Mean Temperature.	Rainfall.	Duration of Sunshine.

Scientific News

FOR GENERAL READERS.

Vol. II. OCTOBER 19, 1888. No. 16.

CONTENTS.

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

On page 262 of Scientific News is an abstract of a note read at the British Association by the Rev. A. Irving, D.Sc., on the "Relation of the Percentage of Carbonic Acid in the Atmosphere to the Life and Growth of Plants." According to experiments there referred to, the vigour of plant life is increased by increasing the supply of carbonic acid in the air up to about an equality of the oxygen, *i.e.*, to about 600 times as much as the air at present contains, provided the roots are freely supplied with water.

This is a rather startling result, and so much opposed to those of other experiments, that I am not surprised to read on page 288 that Professor Seeley expressed some scepticism, and referred to the fact that the surroundings of lime kilns are not remarkable for luxuriant vegetation. To this example I may add that of the celebrated Grotta del Cane, from which there is a continual overflow of carbonic acid pouring down the slope of the valley towards the lake below. This is shown by immersing a torch in the pool of carbonic acid. The torch is thereby extinguished, but its smoke adheres to the heavy gas and accompanies its overflow, thus rendering its course plainly visible if the experiment be so performed as to produce a good supply of smoke. There is another similar outflow of carbonic acid shown in the same valley, which, when I was there, bore the name of "the fountain of natural beer," a name based on the experiment of standing knee-deep in the gas and scooping draughts to the mouth by the hand, thereby obtaining a taste similar to that of the effervescing beverage known as "birra" to the Neapolitans. The carbonic acid overflows abundantly from this and other places in the neighbourhood. If Dr. Irving is right, the course of all these streams should be indicated by specially luxuriant vegetation, but such is not the case.

Another subject was opened by this paper, viz., the assumed or supposed excess of carbonic acid in the carboniferous age. This supposition includes another, which in spite of its wide and free acceptance, appears to me to be a very superficial one. I refer to the matter-of-course assumption that at the time when our particular coal seams were in the course of deposition, all the rest of the world was engaged in just the same kind of geological business.

We know that in certain areas certain deposits were formed later than those upon which they rest, and earlier than those above them; but we have no evidence to prove that similarity of composition of any particular deposit, or even similarity of fossils, proved simultaneous deposition *all over the world*.

We do know, for example, that the fauna and flora of Australia and New Zealand actually living there prior to the interference of British colonisation, differed more widely from the simultaneously existent fauna and flora of Europe, Asia, and Africa, than do those revealed by the fossils of the post-pliocene and pliocene, and even earlier periods, and that they were more nearly allied to these than to living species on our side of the world.

At the present time the lithological character of current deposits varies with the rocks from which the depositing rivers obtain their material, or those of the shores which the sea waves are wearing down. Besides these variations we have glacial deposits and volcanic rocks simultaneously in the course of formation, and we have great peat bogs growing and ready for submersion in some places but none in others.

As I have shown (see "The Formation of Coal" in "Science in Short Chapters"), we have coal seams now in course of formation in the Aachensee and the fjords of Norway, that have come under my own observation, and doubtless in a multitude of other places where similar conditions prevail.

In the interesting account of the inhabitants of the Canary Islands, by Mr. J. H. Stone (Scientific News, page 355), we have an example of the so-called "stone age" ("*stone stage*" would be better) flourishing in modern times. The same occurs in New Guinea.

The deep sea explorations of the *Challenger* and other expeditions have inflicted serious thrusts on the established practice of determining geological *time* periods by fossil fauna, living creatures having been fished up from the deep sea which, had they been found as fossils, would have been referred to palæozoic periods rather than to recent life. But these thrusts are mere skin wounds compared to what is likely to follow, when we consider how very narrow is the scratch on the ocean bottom that has yet been made by the dredge compared with the enormous area that remains unexplored.

We are evidently moving in the direction of a general inference that physical conditions, not chronological eras, determine the course of geological evolution, both as regards the physical constitution of rocks and the fossils they contain. At the recent International Geological Congress, Dr. Sterry Hunt stated his belief that the action by which the old granites as well as the basic gneisses were formed "had continued since the most remote period, and was going on at the present day with diminished intensity" (see report, SCIENTIFIC NEWS, page 347); and Dr. Hicks, who followed, though differing with Dr. Hunt on the Wernerian and Plutonic controversy, "admitted that rocks of volcanic origin could change at any period of the world's history into crystalline schists under favourable conditions." It would be difficult to find two higher authorities on this particular part of the subject than these.

Many who are not experts in geology have been, and still are, deceived by the manner in which the term "carboniferous group" or "strata" is used in geological treatises. They imagine that coal is only found in the "carboniferous strata." As a matter of fact, all the strata of all ages, from the lowest of the palæozoic to the recent, are more or less carboniferous. The strata which have received the distinctive title of "carboniferous" are simply those which in the British Isles and some other places are specially rich in one particular kind of coal. This kind of coal and other kinds of coal abound in other countries both above and below *our* coal measures, and even in our country good workable coal is found below this and below the millstone grit (or "farewell rock," as our *local* miners call it, from their experience of the hopelessness of finding coal when it is reached). Coal is found and worked in the mountain limestone and limestone shales of Durham, Northumberland, and Scotland.

Returning to the idea of an era of carbonic acid excess in our atmosphere, it should be remembered that even in our "carboniferous group" there is no indication of a *general* excess of vegetable growth at that period; the coal seams are partial deposits found here and there in lake basins or long estuary troughs.

Besides this we must remember that if at that period the whole world were immersed in an atmosphere containing any great excess of carbonic acid beyond that now prevailing, all terrestrial animal life would have been destroyed, the chain of evolution broken asunder in such a manner that the course of creation of land animals and birds, if not of the marine vertebrata also, would have to start afresh. This is directly contradicted by the geological record.

SOME PHOTO-MICROGRAPHIC APPARATUS.

(Continued from p. 379.)

ANOTHER form of apparatus made by Messrs. Swift is shown in the woodcut, fig. 4. In this case the whole apparatus is mounted on a table, which is supported on three legs, which, to add to the portability of the instrument, are made to unscrew.

The microscope supplied with the apparatus has rackwork motion to the internal draw-tube for use in the adjustment of an amplifier, when such is required. A stop is placed across the claw-foot of the microscope, to ensure the tube being brought correctly to the horizontal position.

A slot traverses nearly the whole length of the top of the table, along which the illuminator apparatus, the board upon which the microscope is fixed, and the camera are made to slide.

The camera is constructed to take plates up to $6\frac{1}{2}$ in. by $4\frac{3}{4}$ in., and has a range of from 6 in. to 30 in., and a double rack-work arrangement for effecting this extension.

Focussing with the fine adjustment can be done from the back of the camera by means of a rod carried along the side of the table, at the end of which is a pulley, over which a fine cord passes to the milled head of the fine adjustment.

Specially corrected objectives are supplied for use with this instrument, by the aid of which the object to be photographed can be definitely focussed upon the screen, since the actinic and visual foci are identical.

With this apparatus excellent work can be done.

Fig. 5 shows a very perfect apparatus designed by Dr. Crookshank, and made for him by the last-named firm. The instrument was specially designed for use with very high power objectives, for the photography of Bacilli. How excellent are the results obtained, can best be judged by reference to Dr. Crookshank's work, "Photography of Bacillus," the photo-lithographic illustrations in which were produced from negatives procured by means of this instrument.

Owing to the small amount of light passing through the lenses of high power objectives, illumination by means of paraffin would necessitate very long exposures; the oxy-hydrogen limelight is therefore used as the illuminant, a special series of lenses for condensing the light on to the object being arranged in front of the lantern. The heat arising from the condensation of a powerful light on the object under examination would probably injure it by melting the medium in which it is mounted; to obviate this, a glass trough containing a strong solution of alum is inserted between the condensing lenses, the action of the alum being to absorb most of the heat rays in the illuminating pencil.

Fig. 5 shows the apparatus in the position in which it is most generally used, but in case it is desired to photograph liquids, the apparatus can be brought to the vertical position. This is done by removing the two bars which act as ties between the legs which support the instrument, folding the leg at the lantern end of the table beneath the board, and traversing up the back legs by means of the screw provided for the purpose. A slab is provided, which, together with these legs, supports the instrument very securely.

A few words descriptive of the arrangement of the apparatus may be found of interest. The oxy-hydrogen lantern and the microscope are mounted on a table which rotates on metal centres, thus enabling the microscope to be turned to one side for centering, etc. The lantern can be moved to or from the sub-stage, as may be found necessary for the adjustment of the illumination. The camera is very similar to that before described in Swift's apparatus, having a range of 30 in.

The fine adjustment is done from the back of the camera by means of the usual rod carried along the table, but the arrangement differs considerably from any before described.

The fine adjustment to the microscope is connected by means of a fine cord to a small pulley keyed to a pinion, carried on a bracket secured to the revolving table, upon which the lantern and microscope are fixed. At the end of this pinion is a grooved pulley, which, on the microscope, etc., being brought into the central position in front of the camera, gears with a small rubber-tyred pulley, fixed at the end of the rod which extends to the back of the camera.

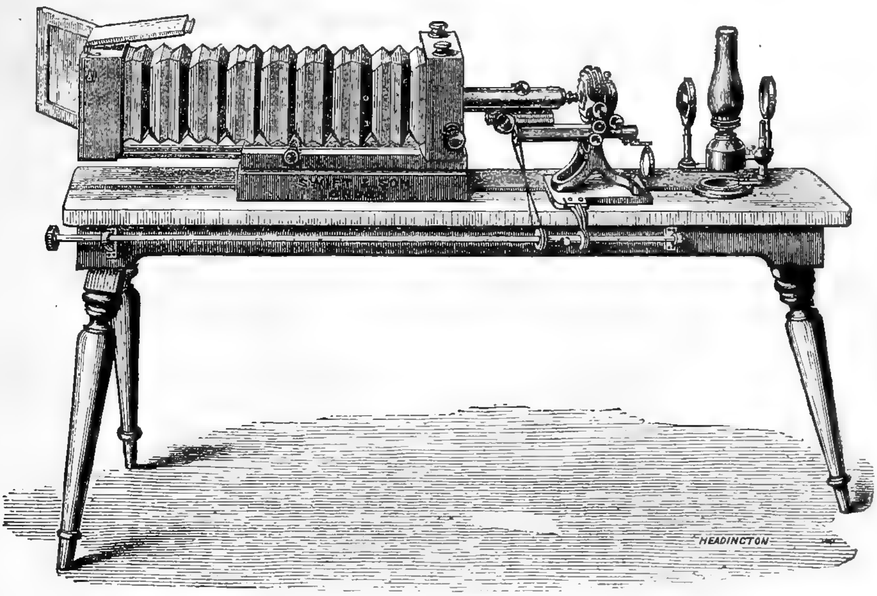

FIG. 4.

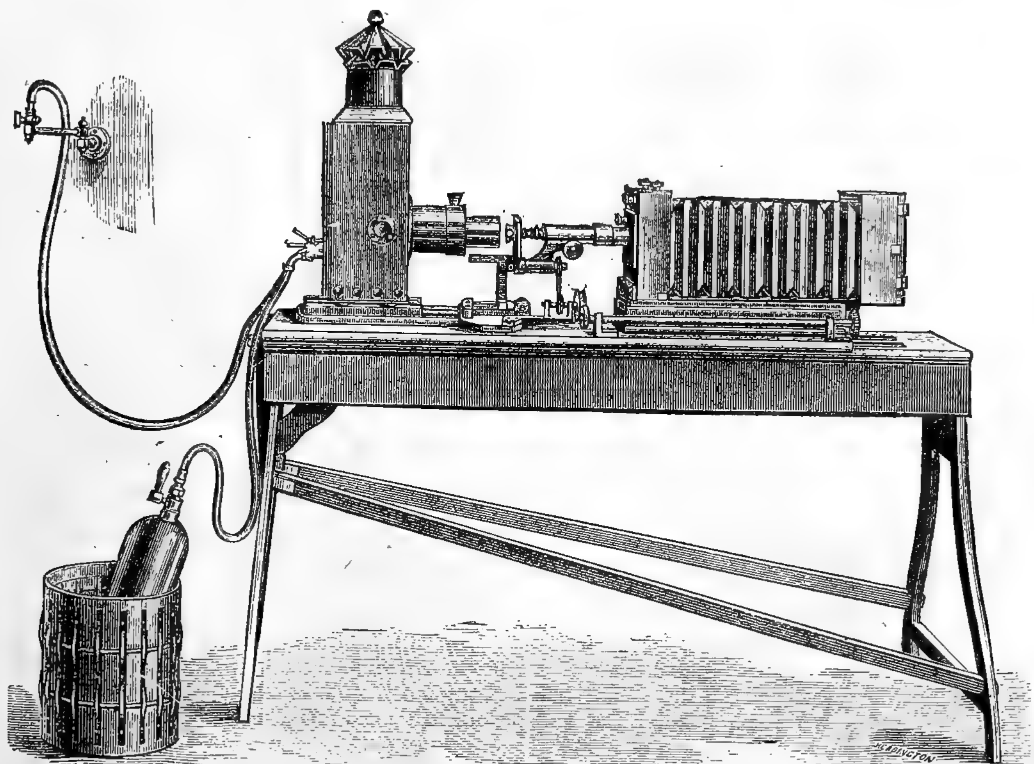

FIG. 5.

This method will allow the lantern and microscope to be turned to one side without disconnecting the cord, a matter sometimes forgotten when the fine adjustment screw is worked direct from the pulley on the rod, to the great detriment of a delicately constructed instrument.

THE ANCIENT INHABITANTS OF THE CANARY ISLANDS.

A Paper read by Mr. J. Harris Stone, M.A., before the Anthropological Section of the British Association.

(Continued from page 381.)

IN Gran Canaria I saw a number of what, for want of a better name, may be called seals, some of which are shown in fig. 4. Their purpose is unknown. They are made of baked pottery and deeply marked in various patterns. Some are circular, others square and triangular, varying in size from one inch to four. Perhaps a more realistic description of them would be to say that they are like small butterprints, as used at the present day. Somewhat similar articles are found in Egypt, whose use, like these Guanche things, is also unknown.

The natives were moderately expert in making and baking vessels of pottery which were of simple, but what would now be termed artistic shapes, and marked, like those in figs. 5 and 6, with various patterns.

Some few stones with what are said to be inscriptions have been found, but none yet have been deciphered. It is thought that some of the characters are Phœnician. One of these stones is said to be bilingual, being graven in the same character as the Tougga stone, with a translation in Punic letters, which would make the date not later than the second century B.C.

Their staple food was *gofio*, roasted grains ground to powder, and eaten mixed with water. Several *gofio* hand-mills have been found, both rotatory, and those with a simple backward and forward movement, a round stone being rolled in a narrow trench cut in another oblong stone. They obtained fire by the friction of wood, and I saw in Gran Canaria a piece of wood about eight or nine inches in length scooped out by friction, and a pointed stick which was found by it.

They shaved with sharp stones, and according to Galindo, when they were troubled with acute pains they drew blood from the part affected with lancets made of tabonas or sharp stones.

The natives were great wrestlers, and exhibitions of wrestling, and fighting duels seem to have been of frequent occurrence. These spectacles were considered to make a great impression on the minds of the youth, exciting them to healthy emulation and gallant deeds. A famous wrestler called Adargoma, was captured and taken to Spain, where a celebrated wrestler of that country challenged him to a trial of skill. Adargoma accepted the Spaniard's challenge, and said to him, "Brother, since we are to wrestle, we had better first have a drink together," then taking a glass of wine in his hand, he said to the Spaniard, "If you can, with both your hands, prevent my carrying this glass of wine to my mouth, and drinking it, or cause me to spill one drop of it, then we will wrestle together, but if you cannot do this, I would advise you to return home." Then drinking off the wine in spite of the other's utmost efforts to prevent him, the Spaniard, amazed at the Canarian's prodigious strength, prudently took his advice and sneaked off.

Their religion had more of a spiritual than material character. They had no idols.

In Palma the natives held the sun and moon in great veneration; keeping an exact account of time in order to know when it would be new or full moon, and for recording their days of devotion. They seem to have worshipped one God in the heavens who was greater than all.

In Tenerife the natives adored one God, whom they worshipped by the names Achguarergenan, Achoran, and Achaman, which signify the Sustainer of the Heavens and the Earth. He was also called by other names, the Great, the Sublime, and the Sustainer of all.

A favourite method of disposing of the dead was to lay them on the rough volcanic ground near the sea, and cover them with pieces of lava. Two of these cemeteries I have explored in Gran Canaria. There possibly may be more than these two ancient burying-places, and if so, it is to be hoped that other travellers will pay particular attention to them. Those I have examined are at Agaete and on the Isleta. Figure 7 is from a photograph of the Isleta cemetery looking towards Confital Bay. These cemeteries agree exactly in situation and character of the ground. The *antiguos Canarios* must have liked to be buried close to the sea. The choice of this unpromising-looking ground, composed entirely of the roughest of rough stones found in a volcanic country, without a particle of mould, might perhaps be due to the singularity of the spot, to the great difference existing between it and the neighbouring country. These outbursts of past volcanic fury not unlikely assumed religious importance in their eyes. It may of course be urged that, owing to the value of pasture land, such would not have been used for burial purposes, or that, the ancient inhabitants possessing no digging tools, this lava-block-covered land afforded the easiest mode of burial for the mass of the population. The first theory for the origin of these singularly placed cemeteries is that which I think most accords with what we know of the race. There is one difference I should note between the cemetery at Agaete and that on the Isleta. The covering mounds of stone at Agaete over the largest graves contain red stones. I noticed none on the Isleta graves. It would be interesting to know who were the persons dignified by having red stones in their burial piles, and why in regard to this custom the *Canarios* of the north differ from those of the west.

The mounds are of various sizes and shapes, the only uniformity being that the sides, for a height of about 4 feet, are wall-like, composed of large cinder stones, whose more or less flat surfaces are carefully ranged upon the exterior. The top is formed by smaller stones thrown on and allowed to settle in any order, but naturally assuming more or less of a flattish pyramidal shape.

On the Isleta two partially dismantled graves were measured. One was chosen for its unimportant appearance, and the other because it was one of the, if not the, largest on the ground. The former was 15 inches wide and just 1 foot below the level of the ground, the topping stones which covered in the body resting their ends on the ground on either side. Its length was 6 feet 6 inches, and it was rudely squared at the ends. The other grave had been covered by a large, circular mound, and lay due north and south. The stones had been pulled down at the north end exposing the grave, from which the skull had been taken, though there remained the ribs, vertebræ, femurs, and a few small bones, all of which, from their great size and very marked eminences for the attachment of muscles, showed that the man had been tall, well-built, and very powerful.

The inside of the grave formed a chamber, lined with immense pieces of flat lava stones, and roofed with others of a concave shape. The grave was therefore dome-shaped, but 7 feet long, and rounded off at the ends, not squared, as in the smaller grave. The height

Fig. 4.—Seals.

fflth more at floor to the highest point of the roof was 3 feet 9 inches, and in width the grave was 22 inches.

I noticed the direction in which the bodies had been laid in the ground, and had expected to find that the old Canarios buried east and west; but such was not the case, for the first narrow trench ran due north and south. The next lay north-east and south-west, and of the fifty or sixty graves which were examined, more lay north and south than in any other direction. It must have been from mere cursory examination or mere hear-say evidence that Gaptain Glas, in 1764, asserted that the Canarios buried their dead with their heads towards the north, and that later Messrs. Berthelot and Webb said that they buried east and west. Together, these assertions are correct; singly, undoubtedly they are incorrect. If they intended to bury in any particular direction, they were most careless in the way they did it. The inspection of the cemeteries of Agaete and the Isleta, the disposition of the mounds, and a close examination of the open graves, forced the conviction upon me that no particular direction was followed. At the Isleta cemetery, where there must have been several hundred mounds, the marked difference in the size of the lava piles was most noticeable. The largest were quite six times as big as the smallest. Some of the large ones, instead of following the usual oblong shape, were circular.

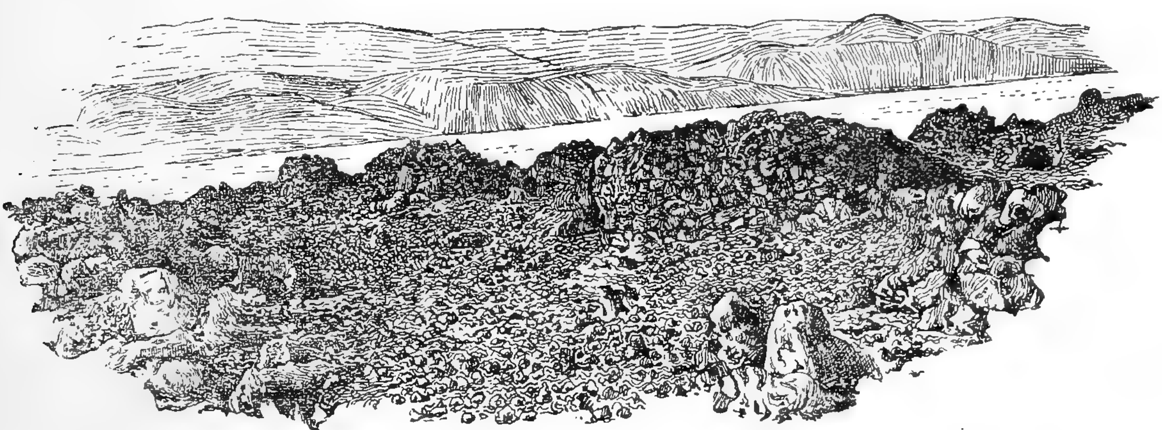

Fig. 7.—Guanche Cemetery.

Position of their Women.

A significant sign of the character of a people is

Fig. 5.—Guanche Pottery.

always the social and political position of its women. Whether they are used merely as beasts of burden, as valueless appendages to the men, or as worthy of consideration in the nation's deliberations and councils, whether, in short, they are looked down upon or looked

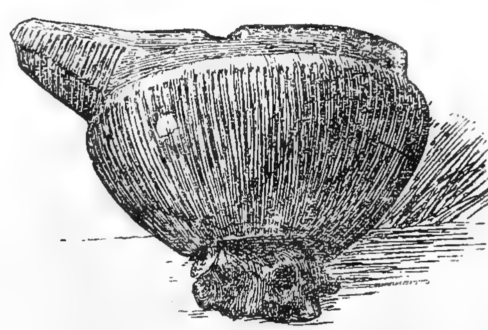

Fig. 6.—Guanche Pot.

up to and honoured, are questions well worth attention when investigating the character of a nation, whatever may be the race, whatever the time in which it lived. The position of women among the ancient inhabitants of the Canary Islands was unusual when compared with other old races. The matter has not been before, so far as I am aware, ever separately considered. It must be confessed that the actual facts we have to go upon are scanty, but by dint of careful reading between the lines of the narratives which have come down to us, a fair estimate of the position of women is obtainable. For this purpose our main reliable sources of information may be reduced to two, although we obtain a few hints from the remarks of casual travellers, the MS. of the two priests who chronicled Bethencourt's conquest, and the Spanish MS. of Father Juan de Abreu de Galindo (or Galineo according to Glas) a Franciscan Friar. I have already alluded to the former. The latter MS. was translated and published by George Glas as far back as 1764, but was only published in Santa Cruz de Tenerife as late as 1848. Galindo wrote the narrative in the year 1632, some 130 odd years after the conquest, in the island of Palma, the island, be it remembered, which was sharply and quickly conquered in about six months without any serious depopulation. There the customs and habits of the old inhabitants would be still readily traceable and more prominent than if studied in an island which had been slowly decimated, and therefore almost solely by the uncertain light of tradition. Even to this day the conservatism of Palma is most noticeable, more custume for example, being preserved there than in any of the other islands.

Unlike s[illegible]vage nations, the women do not seem to have [illegible]rtake tasks of laborious toil. In Tenerife the [illegible]pared the ground for seed by hoeing it with wooden hoes, and then the women did the lighter task of scattering the seed in the hollows. The women helped, as they still do in most civilised countries, in gathering in the harvest and in winnowing the ears. When the men, women, and children waded into the sea to drive a shoal of fish towards the shore, we are particularly told that an equal division of the prize was made, every woman receiving a share and one for her children. In the incidents and occupations of domestic life the women doubtless played their usual part. We are told nothing to the contrary, and therefore may fairly presume that if the conquerors and travellers had noticed anything unusual in this respect they would have recorded it. We are told that in Canaria the women did the painting and dyeing, and in the proper season gathered the flowers, shrubs, etc., from which they extracted the several colours. In battle they waited on the men, succoured the wounded, and removed the dead.

They were treated with respect. In Tenerife they had a custom that when a man by chance met a woman alone on the road or in a solitary place, he was not to look at or speak to her, unless she first spoke to or demanded ought of him, but to turn out of the way; and if he made use of any indecent expression or behaved in an unbecoming manner he was severely punished. Even in their wars among themselves it was held to be base and mean to molest or injure the women or children of the enemy, "for they considered them as meek and helpless, therefore improper objects of their resentment." Though this relates specially to Canaria, from what we know generally of the other islands, the same noble sentiments may fairly be attributed to their natives also. The men were careful to protect their women from the enemy. When the Spaniards once unexpectedly came upon a body of some fifty natives near a wild pass in the centre of Fuerteventura, they at once rushed to attack the invaders of their islands, in order to hold them in check till their wives and children were in safety. For rudely armed people to thus take the initiative against an enemy armed with weapons of iron and clad in mail shows a great amount of courage.

The women, too, were not deficient in bravery. Rather than fall into the dreaded hands of the licentious conquerors, we read of two women throwing themselves down a precipice in Canaria. Another woman strangled a child at her breast for fear that its cries might inform the enemy of the presence of her companions. When driven to bay, the women could fight, and did fight well.

The heroic king Benhearo, who with Benchomo made the name of Guanche renowned and celebrated in Europe, was accompanied by his daughter Guacina, who, it is said, rode at the head of the troops.

The diplomatic capability of the ancient Canario women of high rank is well illustrated in the following story: "Before the advent of Bethencourt there lived in Galdar a young and beautiful woman, of noble birth, who was as wise and good as she was beautiful. At that time Canaria was governed by many nobles in different districts of the island, who met together and formed a council for general matters. They had much trouble in keeping peace, and Andamana, by her sage advice to the people, aided them much. The nobles or chieftains were, however, jealous of her influence, and not liking a woman's interference, they persecuted her and her followers in Galgar, and persuaded the people not to listen to her. This hurt her much, as she had given the best part of her life to them. She did not rest satisfied with complaints, but took to action. Going to Guimidafe, one of the chieftains who was considered the 'most valiant and prudent of all the nobles in Canaria,' and who lived in a cave, she told him her grievances, and proposed an alliance with him. It is not the only occasion in the world's history that the women of royal blood have been obliged to be suitors. Guimidafe seems to have consented readily to espouse the princess and her cause. Accounts differing slightly render it uncertain whether she fought and conquered the island before marrying Guimidafe or whether they married first and fought—their enemies—afterwards. The latter is the more probable. At any rate, Andamana and Guimidafe reigned over a united Canaria. They had one son, Artemi, famous for his courage and virtue, who became king, and it was during his reign that Bethencourt landed at Arguineguin, where he was repulsed with loss."

This cave of the beautiful Andamana at Galdar is the one that we had cleared out of its rubbish, and where were found the paintings which have been already alluded to

(To be continued.)

A Plague of Aphides.—During the fine weather of September, there occurred in certain Midland districts a perfect plague of *Aphides*, lasting for about a week. So numerous were they, that persons walking or riding found their mouths, noses and eyes constantly filled with these troublesome insects. This fact is the more remarkable since during the spring and summer *Aphides* were exceptionally scarce, as were also their principal enemies.

General Notes.

Pollax Island.—According to advices received at New York from Yucatan, this island, on the coast of that Republic, disappeared during the recent cyclone in that region.

The Propagation of Cholera.—Dr. Otto Riedel, in a recent work, admits that insects—he should have stated more precisely two-winged insects (*Diptera*)—constitute an important agency in the distribution of the cholera-bacillus.

The Chlorides of Iridium.—M M. Nilson and Petterson have communicated to the *Comptes Rendus* an account of three well-defined chlorides of iridium. They remark that a metal of the third group of the natural system of the elements is thus found capable of acting either as a univalent, divalent, or trivalent body in definite compounds.

Frozen Milk.—According to *La Nature*, M. Guerin, of Grandvilliers, has devised a practical method of freezing milk, so that it may be kept for weeks unchanged, and transported to any distance in the solid state. It may then be re-converted into a liquid by a simple rise of temperature, and is fit for consumption, not having lost any of its natural properties.

The Fertilising Effects of the Nile.—Prof. A. Müntz recently undertook to show that the perennial fertility of Egypt was due not so much to the mud deposited by the Nile as to the properties of the water. But on analysis he found that the water of the Nile was poorer in nitrate of potash than that of the Seine. The Nile conveys only 3 to 7 milligrammes per litre of nitrate of potash, whilst the Seine contains 11.

Formation of Hair-Silver.—Opificius (*Chemiker Zeitung*) shows that on igniting powdered sulphuret of silver in a current of hydrogen, the silver is obtained in the form of fine hairs, which shoot up out of the mass, forming a dense thicket of fine threads of metallic silver. Sulphuret of silver yields the same product in a current of carbonic acid. Copper may also be obtained in the form of hairs or threads on heating the sulphuret of copper in a current of hydrogen.

A Lunar Rainbow.—M. de Valois, Mayor of Aumâtre, writes in *La Nature*, that on Monday, September 24th, he observed at Aumâtre, about 9.45 p.m., during stormy weather, and whilst a slight rain was beginning to fall, a well-marked lunar rainbow, having the appearance of a very luminous halo on a dark ground, and which extended in the form of the arc of a circle over about 100 to 110 degs. It rose at first almost vertically in the north-west and terminated at the west near its highest point.

Chemical Reactions between Solids.—A Belgian chemist, M. W. Spring, finds that certain solid bodies, if submitted to intense pressure, can act upon each other and enter into combination. Thus, when a mixture of sulphate of baryta and carbonate of soda was exposed to a pressure of 6,000 atmospheres 11 per cent. of the sulphate was transformed into carbonate. Hence the old adage of the chemists, "Substances act upon each other only when in solution" (*Corpora non agunt nisi soluta*), no longer expresses an exact truth.

Effects of Petroleum upon Health.—M. Wiecyk has studied the effects of petroleum vapours upon the workmen in the Carpathian oil region. These men have to breathe an atmosphere tainted with hydrocarbons, ethylene, carbonic acid, carbonic oxide, and sulphuretted hydrogen. Cases of asphyxia are not rare. The affections ordinarily incident to long-continued work are tinglings in the ears, dazzling, throbbing of the arteries in the head, syncopes and hallucination, palpitations and general weakness. Consumption and epidemics are rare.

Glacier Dust.—The holes with which the great interior glacier of Greenland is studded (*Le Siècle*) were found by Prof. Nordenskiöld and his companions to contain each a quantity of mineral dust, to which their origin, on well-known physical principles, is supposed to be due. As to this dust, the question arises whether it has come from the realms of space, or whether it has been projected from volcanoes. The similarity of the composition of this dust with that of meteorites causes the majority of eminent authorities to incline to the former opinion.

Profits of Timber Growing.—Mr. G. Cadell (Macmillan) shows that the revenue of the Government forests in India in 1886-87 showed a profit of 41,017,000 rupees. This has been built up "from not only an entire absence of income but from a rapidly decreasing capital." The means used have been simply "restraining the destruction of the forests by the wood merchants, guiding, without checking, the cutting of trees by the peasantry for their farming and building necessities," and taking a middle course between reckless waste and oppressive restriction.

The Speed of Light.—The following figures, quoted by *La Nature* from the results of independent observers, show that there exists comparatively little disagreement on this important point. The velocity, in kilometres per second, is given by

Foucault, in 1862	298,000
Cornu, 1874	298,500
Cornu, 1878	300,400
Cornu, according to Listing	299,920
Young and Forbes, 1881	301,382
Newcomb, 1882	299,860

Influence of Aluminium upon Cast-Iron.—Messrs. Keep, Mabey, and Vorce give an account, in the *Journal of the Franklin Institute*, of the value of small proportions of aluminium as an addition to cast-iron. It appears from their experiments that fused wrought-iron, a mixture of cast-iron and steel, or steel alone, either of which would yield castings full of blow-holes, will make solid and homogeneous castings if as small a quantity of aluminium as $\frac{1}{10}$th of a per cent. be added just before pouring. Great benefit is promised to the iron-founder from the rapidly falling price of aluminium.

Influence of Drinks upon Digestion.—Dr. A. Heneynoki, assistant at the Rostock Medical Klinik, has recently, according to the *Naturwissenschaftliche Wochenschrift*, made experiments on this question. Water in quantities up to 22 to 23 fluid ounces has no appreciable effect

Alcohol diluted down to 4 per cent., and in quantities of about 8 fluid ozs., if it does not assist digestion certainly does not impede it. At the strength of 10 per cent. it has a perceptible, and at 20 per cent. a very decided, impeding action. Beer, up to about 26 fluid ozs., has the same action as highly diluted alcohol. Red wine, up to 17 fluid ozs. ($\frac{1}{2}$ litre), has the same action as beer. White wine assists digestion. The most favourable action is that of coffee and tea.

Fluorine and Vegetation. — Among the principles found in the ash of many vegetables, especially cereals, fluorine has not yet attracted the attention of agriculturists. What part does it play? Is it necessary to examine if it could be usefully added to the soil like the phosphatic and potassic manures? These are questions which, says *La Nature*, we cannot answer. It is, therefore, with much interest that we have read a pamphlet on calcium fluoride and its use as a manure, published by M. Dussan, a farmer in the *Basses Pyrénées*. M. Dussan informs us that in experiments carried on for three years upon wheat, maize, potatoes, clover, and lucern, calcium fluoride, along with phosphates and salts of potash, confer a remarkable energy upon vegetation. We may here remark that many of the phosphatic minerals employed in the manufacture of superphosphates contain an appreciable quantity of fluorine, all of which is scarcely expelled in the process.

A Dearth of Frogs.—It happens this year that frogs are scarce. Perhaps the sharp night-frost of October 2nd has driven them earlier than usual to bury themselves for the winter. No general lament is to be expected for the reduced numbers of a rather unpopular creature, but the directors of our now numerous physiological and biological laboratories are much bothered to get a sufficient supply of the "martyr of science." This leads us to ask why the dealers do not adopt a simple precaution which would enable them to collect frogs at any season, and keep them till wanted. Frogs become torpid at a moderately low temperature, and by sinking them to the depth at which the earth possesses an invariable degree of warmth, they may be kept almost indefinitely without consciousness or wasting. A pit about 4 ft. deep, covered by a stout wooden lid at the surface, and another near the bottom, answers very well. The frogs should be placed twenty or so together in boxes lined with dead leaves. Anyone who tries this plan may count upon a supply whatever the state of the weather.

Literary Announcements.—An important new work, entitled "Practical Surveying," by George W. Usill, A M.I.C.E., will shortly be issued by Messrs. Crosby Lockwood and Son, London. It will form a text-book for students preparing for examinations or the colonies. The same publishers also announce for immediate publication—"Antiseptics: a Handbook for Nurses," by Annie M. Hewer, diplomée of the Obstetrical Society of London; "The Mechanical Engineer's Office Book," by Nelson Foley, second edition, much enlarged; "Turning," a text-book on the elementary principles and practice of using the lathe, with numerous engravings and diagrams, by P. N. Hasluck; "The Model Engineer's Handybook," by P. N. Hasluck; "The Clock Jobber's Handybook," by P. N. Hasluck; "The Cabinet Worker's Handybook," by P. N. Hasluck; and also the following works in their popular "Weale's Rudimentary Series":—"The Art of Practical Brick Cutting and Setting," by Adam Hammond, author of "Practical Bricklaying," with ninety engravings; "Plumbing: a Text-Book to the Practice of the Art or Craft of the Plumber," by William Paton Buchan, fifth edition; "Modern Workshop Practice," by J. G. Winton.

A Mysterious Illumination.—The White Star steamer *Britannic*, which arrived at Queenstown on October 11th, *en route* for New York, reports that at 9.30 on Wednesday night, when off South Arklow, a most singular phenomenon was observed in the heavens by the captain, officers, and passengers who were on deck at the time. The sky to the westward, which was perfectly dark, no stars being visible, became suddenly illuminated with a brilliant light of a pale yellowish hue, which lasted for fully fifteen minutes, gradually changing into a fiery red colour, which appeared to be the reflection of a large ship in flames. The captain and officers, who had never witnessed such a strange sight before, and not knowing but that they were in the vicinity of a burning vessel, altered the course of the *Britannic* somewhat, so as to bring her more in the direction of the place from which the glare seemed to arise. In a few minutes the fiery red colour became divided into two sections, which appeared disturbed by flutterings, and gradually diminished into a small clear white light resembling that of a steamer's masthead light, which faded into darkness, and the entire illumination disappeared.

The Public Health.—The Registrar-General's return for the week ending October 6th, shows that the deaths registered during that period in 28 great towns of England and Wales corresponded to an annual rate of 18·2 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The six healthiest places were Oldham, Nottingham, Wolverhampton, Bristol, Huddersfield, and Birmingham. In London 2,413 births and 1,352 deaths were registered. Allowance made for increase of population, the births were 300 and the deaths 106 below the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had been 15·8 and 16·0 in the two preceding weeks, further rose last week to 16·5. During the 13 weeks of last quarter the death-rate averaged 16·2 per 1,000, and was 3·4 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,352 deaths included 39 from measles, 24 from scarlet fever, 35 from diphtheria, five from whooping cough, one from typhus, eight from enteric fever, 72 from diarrhœa and dysentery, and not one from smallpox, ill-defined forms of continued fever, or cholera; thus 184 deaths were referred to these diseases, being 21 below the corrected average weekly number. In Greater London 3,190 births and 1,680 deaths were registered, corresponding to annual rates of 30·1 and 15·9 per 1,000 of the estimated population. In the outer ring 23 deaths from diarrhœa, seven from fever, seven from whooping cough, six from diphtheria, and six from measles were registered. The deaths from diarrhœa included five in West Ham, four in Croydon, and three in Walthamstow sub-districts. The 20 deaths in Tottenham sub-district included three from fever, and three from whooping cough. Three fatal cases of measles occurred in Epsom, and two of diphtheria both in Godstone and in Walthamstow sub-districts.

FLINT INSTRUMENTS COLLECTED IN TUNISIA BY M. F. MOREAU.

THIRTY years ago flints intentionally wrought had scarcely been remarked. Now they are found in numbers in the most varied forms and in all regions of the globe where it has been possible to search for them, and thanks to them we are able to reproduce an entire past age of humanity. Hence their importance to the anthropologist and the archæologist. Man, in however savage a state, must have quickly comprehended the utility of the stones lying at his feet, both for the purpose of attack and of defence. He learnt to point them and to give them shapes best suited for his purposes. Everywhere these flints, sometimes split by fire or coarsely wrought, sometimes polished by persevering toil, present an analogy which strikes even the most hasty observer. "They are found," says an American scientist, "underneath the mounds of Siberia, in the tombs of Egypt, on the soil of Greece, among the rude monuments of Scandinavia; but from whatever region they come they are so identical in form, in material, in workmanship, that they might easily be taken for the work of the same artificers."

Does this similarity allow us to suppose ancient relations of which we can scarcely seize the traces? Or has man simply obeyed innate instincts, as do the other animals daily before our eyes? The former solution seems to the author the more probable, though we should incline to the second, adding that this is one of the numberless questions which it is easy to put, but which our present knowledge does not permit us to answer with the necessary certainty. We therefore follow with a lively interest the new discoveries, all destined to facilitate the examination of the grand problem which has occupied the philosophers of the past, as it will doubtless still engage those of the future.

M. F. Moreau, in the course of a recent voyage in Tunisia, has traversed a little known country between Gafoa and Tamerza. Dr. Collignon, whose researches on the pre-historic past of the region are well-known, has not been able to visit it. It is inhabited by a scattered population living in tents or under shelters constructed of branches, and migrating according to the weather. It was not thus formerly. M. Moreau has found in many parts true workshops where raw materials, fragments, nuclei, articles, just sketched or completed, lie in confusion on the ground, as they happened to be on the day when the workman, driven by circumstances of which we know nothing, forsook them for ever.

The climate in those days was probably more hospitable than at present. The remains of fossilised trees, and the remnants of more recent forests, attest that these regions, now so desolate, were formerly wooded. The disappearance of the trees has brought about that of the water, and has transformed fertile tracts into barren sands.

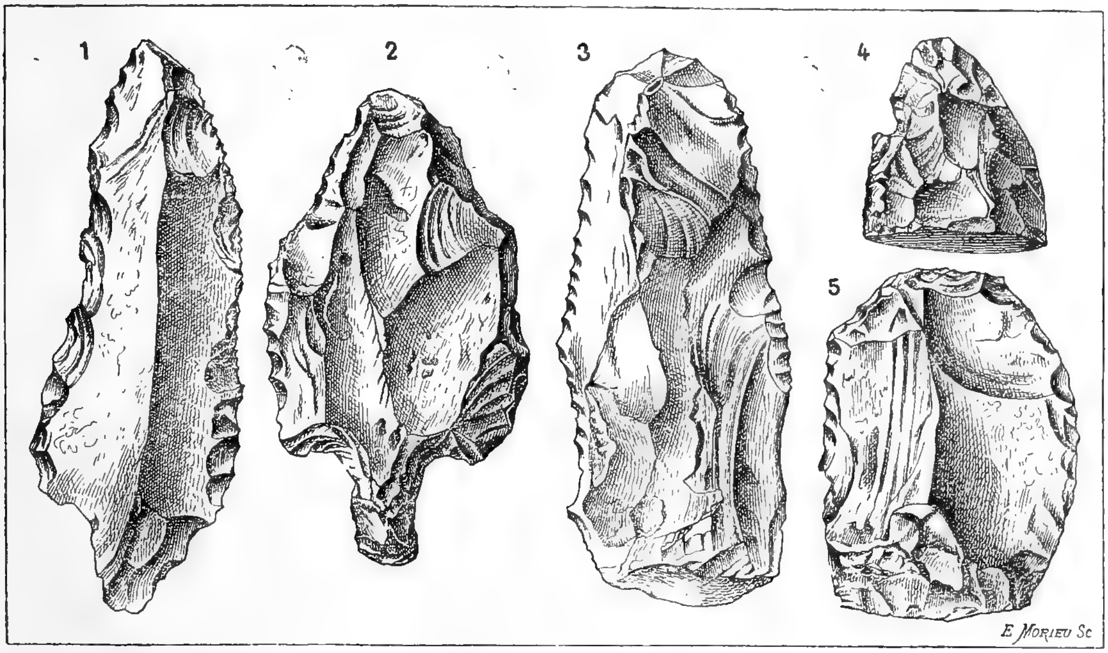

FIG. 1.—POINT OF JAVELIN FOUND AT TAMARZA. FIG. 2.—POINT OF A LANCE, FROM THE GORGES OF OUED-SELDJA. FIG. 3.—THICK AND MASSIVE BLADE FOUND AT BIR-SAHAD. FIG. 4.—FRAGMENT OF A LANCE-POINT DISCOVERED AT BIR-SAHAD. FIG. 5.—SCRAPER FROM BIR-SAHAD.

The cut flints brought by M. Moreau and shown in figs. 1 to 5, borrowed from *La Nature*, belong to an epoch to which no certain date can be assigned. Particular notice is due to a javelin-point derived from Tamerza; a lance-head with a stalk (for insertion in the shaft), found in the bed of a streamlet in the deepest of the gorges of Oued-Seldja; a massive blade, found at Bir-Sahad; a fragment of a fine point, carefully retouched on both surfaces, found at two kilometres from Bir-Sahad. This is, of all the specimens which he has collected, the one which M. Moreau considers the most remarkable in workmanship. All belong, as far as it can be judged from the figures, to "Mousterian" type, though we cannot pretend to prove them contemporaneous with the same type in Europe. M. Moreau has not found any fragment of pottery nor any characteristic bone which might permit of a more exact classification.

The discoveries of M. Moreau are not the only ones which have been made in Tunisia in the last few years. Those of Dr. Collignon have already been spoken of, and in 1844 the Marquis de Nadaillac presented to the Society of Anthropology numerous flint implements found by his son (then a captain in the 101st Regiment of the Line), in the neighbourhood of Cabes, several of which present a type very similar to those just described. They consist especially of arrow-heads, and, judging from their number, it is probable that there must have been a numerous population. There were also found hatchets, or at least fragments from the ancient bed of the Oued-Gabes, where they lie in a stratum of sand humus, covering a bed of gypsum. We may also cite a number of flints in the form of a crescent, very small, but bearing traces of careful workmanship. These crescents cannot have been for any use; they must have been amulets or votive stones deposited in sepulchres. M. Rivett-Carnac announces that flints of similar shapes have been found in the province of Banda, in India, and others are known as coming from the Caucasus. It is curious thus to find the same designs recurring in all latitudes and in all parts of the globe.

THE FORMATION OF PETROLEUM.

THE hypothesis of an inorganic origin of petroleum, advanced at one time by Professor Mendelejeff and others, is at present scarcely taken into consideration, whilst the question whether it has been derived from plants or from animals, must still be regarded as open. Both these have found their advocates down to the present day. Whilst the geologists, especially since Leopold Von Buch, assume the animal remains of earlier geological epochs—especially those of fishes, saurians, corallines, sepias, shell-fish, etc.—as the primary material of petroleum, the adherents of the other theory seek for the origin of these fossil hydro-carbons in the plant-world of those ages. Both parties agree, both on chemical and on geological grounds, that the formation of petroleum must have ensued under high pressure, but not at a very high temperature.

In consequence of experiments on the decomposition of animal fats, Herr C. Engler (*Deutsche Chemische Gesellschaft* and *Naturforscher*) has made observations which may serve as contributions to the theory of the formation of petroleum from animal matter.

By the distillation of 500 kilos. (about 1,000 lbs.) of fish oil from the Menhaden (*Clupea menhaden*) a large kind of herring caught off the east coast of North America, at pressures from 4 to 10 atmospheres, and at temperatures of 320 degs. to 340 degs. Cent., he obtained, along with gases and a watery liquor, about 300 kilos., or 60 per cent., of an oil which was resolved into three main fractions, boiling respectively at 150 degs., between 150 degs. and 300 degs., and above 300 degs. Cent. The portion boiling below 150 degs. Cent., consisted of a mixture of non-saturated and saturated hydro-carbons. Check experiments with the glycerides of oleic and stearic acid (artificially prepared), as well as with these fatty acids, alone gave analogous results. It may therefore be regarded as proved that animal fats under strong pressure are capable of conversion into hydro-carbons, as it is also the case with vegetable fats.

But though the conditions of the formation of petroleum from vegetable and animal matter may be regarded as identical, Engler points out certain facts which are strongly in favour of the latter source. There is, above all, the absence of any considerable deposits of plant remains in connection with oil-regions, and inversely, the absence of any abundant discoveries of petroleum among coal-beds. On the other hand, where oil is found in a primary deposit, animal remains can be regularly pointed out. Thus in the shelly limestone (*muschelkalk*), in the Carpathian fish shales, and in coral reefs, the occurrence of petroleum has been observed. Particularly interesting are the orthoceratites in the Trenton limestone at Packenham, in Canada, whose former living-cells sometimes contain several ounces of petroleum. Bituminous rocks display, as a rule, considerable quantities of animal remains.

The absence of nitrogen and its compounds in petroleum seems at first sight striking, and not in favour of their formation from animal matter. But the same fact might with almost equal justice be urged against their vegetable origin; for the remains of plants contain considerable quantities of nitrogen, as is proved by the extraction of ammonia from coal on a commercial scale. But, even disregarding the circumstance that nitrogenous compounds occur in many petroleums, we must consider the very unequal stability of the non-nitrogenous oils and of the nitrogenous muscular substance of the animal body. Engler recalls many observations on the formation of adipocire, "fat-wax," a product of the transformation of the fats during the decay of animal remains. This substance, which often contains as much as 98 per cent. of fatty acids, is still found even when the nitrogenous matter and the very bones have disappeared. Thus in the accumulated animal remains of the primitive world the decomposition may have proceeded in two main phases. The nitrogenous compounds were decomposed, the nitrogen escaped either in the free state, or in that of ammonia and other compounds. The fat remained behind or was transferred to secondary localities, where it was finally converted into petroleum.

The absence of carbonaceous residues in mineral oils must be interpreted as militating against a vegetable rather than an animal origin. The poverty of cellulose in hydrogen, in case of a decomposition at a low temperature (whereby the formation of carbonic acids is trifling, as compared with the formation of water), must necessarily involve a more abundant liberation of carbon. It is different in animal fats or in the fatty acids thence resulting. If in these all the oxygen with an equivalent proportion of hydrogen be eliminated as water, there remains carbon and hydrogen in an approximate proportion of 87 per cent. carbon and 13 per cent. hydrogen. But this is, as Engler shows, very near the general composition of crude mineral oils. His experiments have also shown that fats and fatty acids under pressure in a sealed tube are often resolved into gases and volatile hydrocarbons without any important separation of carbonaceous residues. Engler, therefore, maintains that petroleum is essentially of animal origin, especially as the ancient marine flora was very small in quantity in comparison with its fauna.

THE BUFFON CENTENARY.—At a commemoration of the hundredth anniversary of the death of Buffon, discourses were pronounced by M. Guillaume, a connection of the Buffon family, and by M Grandidier, on behalf of the Academy of Sciences.

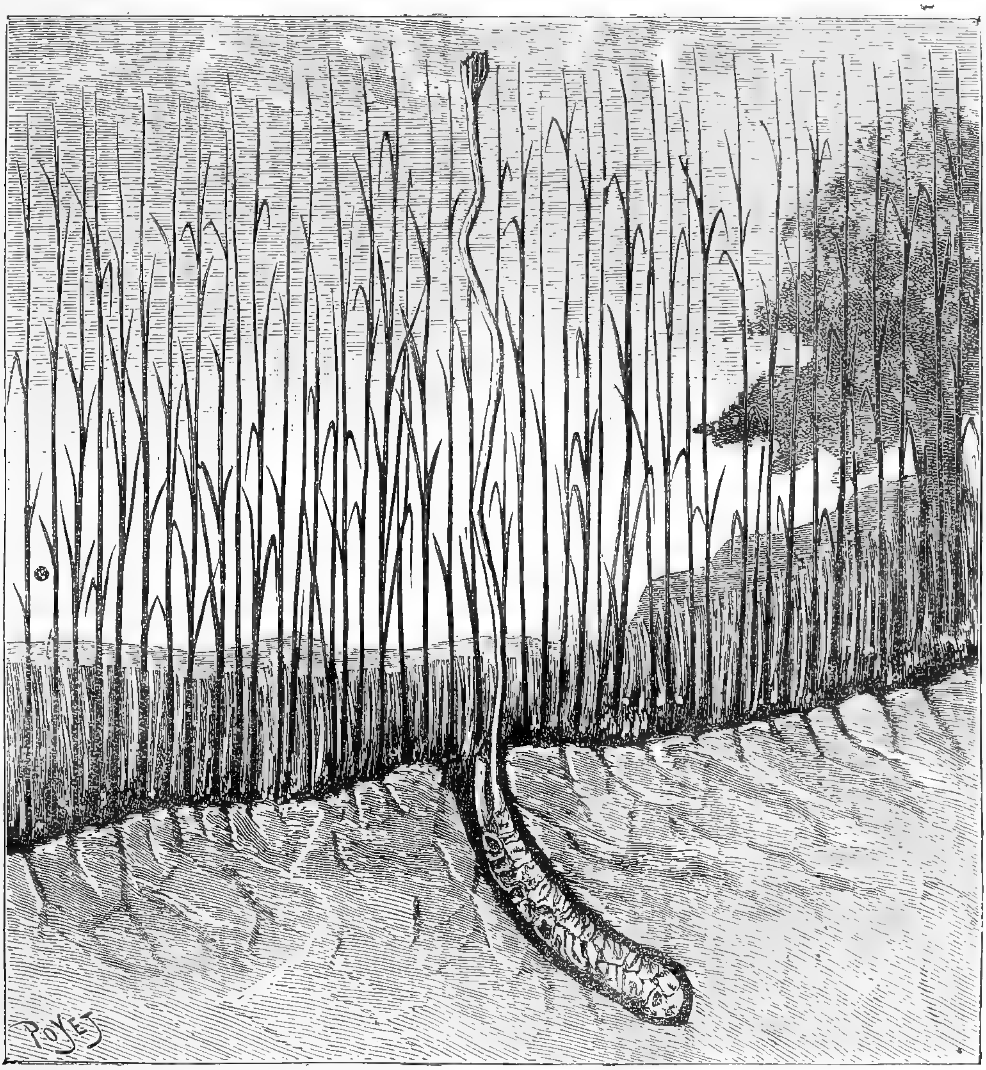
Natural History.

A CURIOUS FUNGUS.

THE dietetic relations of animals and plants are not yet thoroughly known. Every one is aware that there are animals which seize upon some other animal or some plant and devour it entirely an open, straightforward manner. We are equally familiar with the fact that other animals live parasitically; they introduce their ova into the bodies of other animals or of plants, these ova, when hatched, preying gradually upon their host, absorbing its juices, and in many cases destroying it outright. Such parasites are the intestinal worms which haunt man and the lower animals, the "warbles" which perforate the hides of cattle, the ichneumons which insert their eggs into caterpillars, the weevils which in like manner oviposit in the buds of plants, so that the young grub may prey upon what should have been the fruit.

But it is less generally known that there are plants which turn the tables upon the animal creation. The late Charles Darwin, as well as other naturalists, has called attention to the so-called "carnivorous plants" which capture insects and consume them bodily. But a less known case is that of a plant, generally of very humble rank, which lives parasitically upon some animal, and appropriates its body.

One of the simplest instances of this kind of parasitism is when an ordinary mould attacks some living insect in the larval or pupal stages. Entomologists, in searching for the pupae of moths, whether in the earth or among decaying vegetation, not unfrequently find them invaded by mould; such specimens, of course, come to nothing.



Cordyceps Robertsii, GROWING FROM THE PUPA OF *Charagia virescens*.

A much more decisive and instructive case is that of the "fly-fungus" (*Empusa muscae*). In autumn we may occasionally perceive sitting on the window-pane a common house fly, with which there is decidedly something amiss. Its movements are feeble and sluggish, and at last it seems to become fixed to one spot, where it dies. The glass around it appears to be covered to the extent of perhaps a quarter of an inch with a whitish film. If the observer can persuade such a fly—as we have done more than once—to die upon a slip of glass that can be placed under the microscope, he will see that its body and the glass around is covered with the fungus, which has, in fact, fed upon the fly and destroyed it as decidedly as a spider might have done, though more gradually, and without any conspicuous mark of violence. If this fungus be applied to the body of other flies, especially near the spiracles, the latter become infected, and perish in like manner.

Attempts which we made some years back to impart this disease to blow-flies, gnats, and to the blood-sucking *Stomoxys calcitrans*, did not prove successful. But there are cases of other plants taking root in or upon living animals with a fatal result.

A certain species of wasp is said to be occasionally thus attacked. The botanical journal *Flora* reports that the fungus *Torrubia cinerea* has been found growing upon a mature *Carabeus*.

Count d'Ursel, in a recently-published work on South America, asserts that in Bolivia, Peru, Chili, La Plata, and Brazil he has met with an insect which, after its death, is "transformed" into a plant. He describes and figures this creature as a "thick, hard grub, with distinct articulations." When about to die it buries itself a couple of inches in the earth, and then gradually increases in bulk until it presents an appearance very like that of a potato. A stem is then put forth, which in the spring months bears a crop of blue flowers. We do not accuse the Count of dealing in romance, but we suspect that he has misunderstood the phenomena which he has witnessed.

A somewhat similar case is that of the so-called "Bull-rush caterpillar" (*Cordyceps Robertsii*) of New Zealand. A specimen of this insect and of the plant which issues from its remains has been lent to us, and is shown in the accompanying figure.

The plant, which is called by the Maories "Awheto," and which is by no means rare, grows chiefly at the root of the "rata" (*Metrosideres robusta*). The body of the caterpillar, which is found underground, is in some instances as much as $3\frac{1}{2}$ inches in length. The one which has been submitted to us is of a brownish colour, hard to the touch, and of a shrivelled appearance, like that of a caterpillar which has perished from want of food, or which, though fully fed, is unable to effect its transformation into a pupa. The horny portions of the head, the jaws, and some of the feet can be distinctly identified. From the nape of the neck—speaking in non-technical language—proceeds a stalk which may reach the length of six inches. At its summit is a fructification resembling the "club-headed bull-rush" on a reduced scale. There are no leaves, and if the stem be accidentally broken off, a second stem shoots up at its side. The natives eat the plant, which when fresh has, they say, the flavour of a nut. It is also burnt, and in that state is used as a colouring-matter in the tattooing process.

We are far from considering this ill-named phenomenon as a link between the animal and the vegetable kingdoms, or as the transformation of a caterpillar into a plant. The facts as described to us must be interpreted as follows: the caterpillar, burrowing in the soil to undergo there its transformation into a chrysalis—as do many species—encounters some of the spores of a fungus. One of these takes root in its body at a part which the caterpillar, even if lively, cannot reach to free itself from the intruder; it there nourishes itself on the juices of the body, which perishes as it vegetates. Whether the same fungus attacks any other kind of caterpillar is a question not yet decided.

The fungus in question is said to be nearly related to the "ergot," which is parasitic upon rye and sometimes upon other kinds of grain.

Ants and Butterflies.—In the last number of the journal of the Bombay Natural History Society, Mr. Lionel de Nicéville describes the manner in which the larvæ of a species of butterfly (*Tarucus theophrastus*, Fabricius) are cultivated and protected by the large common black ants of Indian gardens and houses. As a rule, ants are the most deadly and inveterate enemies of butterflies, and ruthlessly destroy and eat them whenever they get the chance, but in the present case the larvæ exude a sweet liquid of some sort, of which the ants are inordinately fond, and which they obtain by stroking the larvæ gently with their antennæ. Hence the great care which is taken of them. The larvæ feed on a small thorny bush of the jungle, the *Zizyphus jujuba*, and at the foot of this the ants construct a temporary nest. About the middle of June, just before the rains set in, great activity is observable on the tree. The ants are busy all day running along the branches and leaves in search of the larvæ, and guiding and driving them down the stem of the tree towards the nest. Each prisoner is guarded until he is got safely into his place, when he falls off into a doze and undergoes his transformation into a pupa. If the loose earth at the foot of the tree is scraped away hundreds of larvæ and pupæ in all stages of development, arranged in a broad, even band all round the trunk, will be seen. The ants object to uncovering them, and immediately set to work to put the earth back again; if this is taken away again, they will remove all the chrysalids and bury them lower down. When the butterfly is ready to emerge in about a week it is tenderly assisted to disengage itself from its shell, and, should it be strong and healthy, is left undisturbed to spread its wings and fly away. For some time after they have gained strength they remain hovering over their old home. In one case a butterfly fell to the ground before its opening wings had dried, and a soldier-ant tried to rescue it. He carried it back to the tree with the utmost care, and made several attempts to assist the butterfly to hold on again, but finding his efforts unavailing he left the cripple to recover himself. On his return, seeing no improvement, he appeared to lose all patience, and, rushing in, bit off both wings and carried the body into the nest. But high-handed proceedings of this kind are very unusual. It is said to be a curious sight to watch the fragile and delicate butterflies wandering about, all feeble and helpless, among the busy crowd of coarse black ants, and rubbing shoulders in perfect safety with the ordinary fierce, big-headed soldiers. A larva of another species thrown down among them as an experiment was immediately set upon and torn to pieces by the ants.

Intelligence of a Cat.—M. G. Vayssié de Veragne gives, in *La Nature*, the following curious incident, referring for confirmatory evidence to M. Palmaroli, Director of the Academy of the Fine Arts at Rome. An old convent on the Janiculum is covered with convex tiles, which advance to the edge of the roof. and project over. This arrangement is favourable for the construction of nests, and accordingly a flock of pigeons have established themselves there. One day a stray, half-starved cat, which had taken up its quarters at the Academy, was seen on the roof. Quite near it, and close to a nest, two pigeons were resting, quite ignorant of the danger. But instead of seizing the birds, pussy waited till they flew away, and then advancing very carefully she reached the edge of the roof, thrust her paw under a tile, raised it gently, and looked down into the nest. With our opera-glasses we could see the eggs, and expected that she would break the shells and devour the contents. Not at all; she made a conscientious review of all the nests, and went away very philosophically. For a week, at sunset, this proceeding was repeated; the cat arrived punctually, made her visit of inspection, and departed. One fine day we could see young pigeons in most of the nests. The visitor came as usual, examined everything, and again departed. One of us said, laughing, "She is waiting until they are in good condition." Such was the case. In a few days the marauder lifted up a tile, and did not replace it; she thrust her head into the hole, and reappeared, holding a young pigeon, which she devoured forthwith. This is not all; so methodical was the cat that she never took more that two pigeons, but one evening, when she was about to seize her dinner, the coveted prey sprung from the nest and flew away. The cat took an attitude of indefinable stupefaction, but soon recovering she made a complete raid under all the tiles, and in the morning we found in the bell-tower the remains of ten young pigeons.

COCKCHAFERS IN AUTUMN.—M. Dufeu (*La Nature*) states that he has this year found cockchafers during the month of September, their usual time of appearance being in May. When digging in his garden at Varenne-Saint-Hilaire (Seine), he has just found one at the depth of eight inches.

THE SHEEP FLY (LUCILIA SERICATA).

SEVERAL instances are known of a change, gradual or sudden, in the diet of an animal species not by any means due to a deficient supply of what the older zoologists would have called its "natural food." Semper relates in his work on "The Conditions of Existence of Animals," that sea-gulls have been known to cease preying upon fish and feed upon grain. On the contrary, bats have in South America taken to fishing instead of pursuing moths.

The New Zealand parrot (*Nestor mirabilis*), formerly nourished itself on the juices of plants and flowers, but has now developed an amazing propensity for sipping the blood of sheep. The blue-nosed baboons of South Africa are occasionally guilty of killing and devouring sheep.

Similar changes of habit are met with more frequently in insects. Considerable attention has been latterly attracted to a small carrion-beetle (*Silpha atrata*) which has turned vegetarian, and proves very destructive to the mangel wurzels and sugar beets. A very curious case of this kind is described by Ritzema Bos, in the *Biologisches Centralblatt* and the *Naturforscher*. A well-known fly (*Lucilia sericata*) has become a dangerous parasite of sheep, by a change in its food during the larval stage.

Like the maggots of many *Muscidæ* the larvæ of *Lucilia sericata* generally lived in dung, or in the flesh of dead animals. Karsch considers the species in question as a genuine blow-fly, whilst Ritzema Bos has found its larvæ able to live in sheep's dung. In many districts of the Netherlands, the maggot now infests the flesh of living sheep, and in seasons favourable to its development, it occasions a really formidable epidemic among them. This new plague is most to be dreaded in the luxuriant marsh-pastures of North and South Holland, Friesland, and Groningen, whilst on poor, sandy, and heathy soils the sheep suffer little. According to Ritzema Bos the flies are induced to deposit their eggs in the excrement which often adheres to the wool of sheep. Less frequently do they attack parts of the animal which are free from such impurity. In ovipositing, the fly alights upon the body of the sheep and fixes its eggs to the wool in groups of ten to twenty, until about 500 have been deposited. Their development depends on the weather, but it takes from twenty to forty hours, when the maggots, closely resembling those of the blow-fly, creep out and reach their full growth in from fifteen to twenty-four days. The larvæ then leaves the body of the sheep and falls to the ground. Here it remains lying among the grass of the pasture, and is transformed into a pupa. Several generations succeed each other in the course of the summer, and the larvæ of the last generation probably creeps into the ground and pass the winter their as pupæ.

The symptoms of the disease produced in sheep by these larvæ depend firstly in the irritating action of the larvæ upon the skin. The skin then secretes a serum-like, offensive liquid, which gives the wool a bad colour, and makes the hairs adhere together. The skin, in consequence of the grubs creeping over it and boring into it, becomes hot, of a blood-red colour and swollen. When the mature parasites have left the sheep, the superficial inflammation heals, though the wool falls off in consequence of the elimination of the thickened layers of the epidermis. Most commonly, however, the injury occasioned by the first brood of maggots is intensified by those of the following generations, and as there are flies all the summer which deposit their eggs, the disease grows constantly worse. It extends not merely forwards from the hind-quarters of the sheep, but the larvæ penetrate deeper and deeper, not merely into the subcutaneous cellular tissues, but into the muscles, which they mine and consume.

The occurrence of this maggot-disease in the Netherlands cannot be traced with certainty, though it seems to have been first observed about 1860. An alleged introduction from England (!) cannot be demonstrated, as the disease attacks all races. It is rather to be assumed that the fly, which is a native of the continent of Europe, has assumed parasitic habits in the Netherlands in the manner already described. Hitherto sheep have not been attacked in this manner in Germany. This deserves notice, as the fly, which is described as rare by Karsch, is now very common in North Germany, Whilst the zoological collection in Berlin till lately possessed only two specimens from Styria, it is now caught freely on putrid flesh laid as a bait. Hence the question arises whether *Lucilia sericata*, as well as *Sarcophila wohlfahrti*, may not be concerned in the numerous cases of *Myasis* in man which have been observed in Europe.

The common lurid green *Lucilia cœsar* and *Lucilia sericata*, likewise of a green colour, are distinguished chiefly by the position of the eyes in the male. In *L. cœsar* they almost touch on the head, whilst in *L. sericata* they are separated by a black line. The females are distinguished by the frontal line, which in *L. cœsar* is black, but in *L. sericata* grey-brown and narrower.

WORK FOR NATURALISTS' CLUBS.

IV.—Leaves.

COLLECT a number of leaves of various kinds, deciduous and evergreen, long and round, simple and cut. Elder, laurel, hyacinth, lilac, tropæolum, ash, horse-chestnut, and grass will make a good selection.

Notice the effect of situation upon the *form* of the leaves. Social plants, such as grasses and daffodils, have often narrow leaves, which do not shade one another too much. Here and there a masterful intruder, like the daisy, dandelion, or shepherd's purse forces its way in among them, forming the selfish arrangement known as a rosette. A circle of broad leaves pressed tightly against the ground keeps a clear space which competitors cannot enter, If you cut out the root you will see how effectually the rosette-forming plant keeps its little patch of ground to itself. Leaves carried upon the boughs of trees are often much divided, so as to bend and fold together in a high wind. Floating leaves and leaves of marsh-plants are usually of very simple outline, for they have few competitors, and are little liable to get in one another's light. Submerged leaves are generally cut into narrow segments, but the reason is not very clear. Some naturalists suppose that they need to expose as large a surface as possible, in order to extract the minute proportion of carbonic acid dissolved in a vast bulk of water. Lubbock ("Flowers, Fruits, and Leaves") and Grant Allen have discussed the shapes of leaves in a very interesting and profitable way.

The *surfaces* of leaves give a wide scope for observation and discussion. How much there is to tell about hairs! There are glandular hairs to catch or deter small creeping insects; hairs set in weels, as effectual a protection against young animals as a spiked palisade against roving boys; hairs which keep off browsing quadrupeds, like the hairs on some common grasses, which cattle never touch; then there are hairs which keep the little drops of moisture (dew-drops, for example) from dispersing, and force them to run together into big drops, which roll down the channelled leaf-stalk, and so wet the earth about the roots; lastly, there are hairs which, like those of the nettle, are poisoned stings. We forget the vexation of the nettle-rash when we observe the ingenuity of the mechanism by which it is caused. The nettle-hair is provided with a brittle and pointed siliceous cap, which breaks off in the wound. Then the poison is able to flow out through the tubular hair from a reservoir at its base, and aggravate the tiny puncture. We cease to wonder that nettles are let alone by nearly all animals except jackasses, when we consider how admirably it is protected. The success of the invention is attested by the number of fraudulent imitations. Ever so many "dead nettles," plants with the outward form of the nettle, but innocent of offence, profit by their artful resemblance to the dreaded stinging-nettle.

But we must get away from the hairs of leaves, if our article is to keep within any reasonable limits. Kerner, on "Flowers and their Unbidden Guests," is well worth looking into on the subject of defences against gnawing insects. The leaves of evergreens are protected by their glossy surface from rain and dew, which might freeze upon them, to the great injury of the tissues within. Half-melted snow cannot be kept off so easily, and this, followed by frost, is sometimes very deadly.

The *stomates* of leaves are easily found. Notch the surface of a succulent leaf, say hyacinth, with a razor or sharp knife. Then catch the edge of the surface between the blade and the thumb. Strip off a small piece of the epidermis, and mount in water. If the air-bubbles are troublesome, momentary warming over a spirit-lamp, or the addition of a drop of alcohol, will be useful. Common books describe the structure of the stomates, but they often give a mistaken account of their use. The stomates serve for the regulated escape of water-vapour, not for the absorption of gases. It has been experimentally proved that the upper surface of the leaf absorbs quite as much carbonic acid as the lower, and yet it is the lower which carries nearly all the stomates. The mechanism for regulating the orifice of a stomate depends upon the power which the guard-cells possess of rapidly absorbing water when stimulated by sunlight, and upon the ease with which they give up their water in the dark. A simple model will make the action of turgidity in opening the stomate quite obvious. Fix to an upright board a loop of good indiarubber tubing. One end of the tube is to be clamped to the board, so as to hold and close it at the same time. Secure the top of the loop by a hook and pass the other end of the tube through a brass tube, tight enough to prevent it from slipping, but not so tight as to choke the passage. The two limbs of the tube should be drawn into a parallel upright position, when they will roughly represent the guard-cells of a closed stomate. Now pass the open end over the nozzle of a water tap (if a good pressure is at command) or of an oxygen bottle. Apply the pressure gradually, and observe how the two limbs of the tube separate from each other as they become distended.

Then *sections* through leaves and leaf-stalks will, of course, be studied. Bower and Vines' "Practical Botany" may be recommended as a useful guide to the demonstration. The epidermis, with its hairs and stomates, the palisade cells towards the upper surface (in "bifacial" leaves), the spongy tissue towards the lower surface, the air-spaces, and the vascular bundles, will easily be made out in a good, thin section of the leaf. The palisade-cells, set at right angles to the surface, permit the chlorophyll-corpuscles to avoid exposure to an over-intense light by ranging themselves along the side walls of the cells. If we were troubled with a light too intense for our eyes, and had no notion of making window-blinds or curtains, we should probably alter the shape of our rooms, especially if bricks were semi-transparent, like cell-walls. We should build long and narrow rooms, lit only at one end, and take care not to sit facing the light. This is what the chlorophyll corpuscles do, and the palisade-cells give them every facility for executing the manœuvre. Observe that upon the very same tree, leaves fully exposed to the light become thickened, while those that are half-shaded remain thin as fine paper. The difference is very apparent in the beech. By thin sections, it can be shown that the thick leaves have three or more rows of palisade cells, the thin leaves often only one. Where a leaf is exposed to full light on both sides, as is the case with the erect leaves of the hyacinth or daffodil, it becomes "centric," *i.e.*, palisade-cells are formed on both sides.

In the *leaf-stalk*, notice the vascular bundles, the tough and elastic collenchyma (cells with thickened angles), and the air-spaces. If a good section is got, it will be vastly improved by treatment with Schultze's

Fluid (iodised zinc chloride). Observe that the air-passages extend continuously through the leaf and leaf stalk. Gather a long-stalked leaf, *e.g.*, of buttercup; put the leaf into the mouth, close the lips upon it, and pass the cut end into a beaker of water. Blow hard, and a stream of small bubbles will issue from the end of the stalk. At the base of the leaf stalk may often be seen a pulvinus, or cellular cushion, which causes the daily movements of erection and drooping. Under the stimulus of light the cells become turgid, and erect the leaf. In the dark, water is given off, and the leaf droops. The interesting chapter on the "Sleep of Leaves," in Darwin's "Movements of Plants," should be consulted on this point. In the sensitive plant, large pulvini are found, not only at the base of every leaf, but of every leaflet, and mechanical irritation, as well as darkness, can excite the unequal turgescence which makes the whole arrangement collapse.

The different sorts of *specially modified leaves* cannot be described in our brief notes, but we may at least enumerate the leaves which serve as traps to digestive organs (pitcher-plants, sundews, pinguicula, utricularia), and the leaves which become transformed into tendrils, spines, or glands. Leaf-arrangement, leaf-folding, leaf-colours are mentioned only to show how inexhaustible is the subject.

Reviews.

Planetary and Stellar Studies; or, Short Papers on the Planets, Stars and Nebulæ. By John Ellard Gore, F.R.A.S., M.R.I.A., F.R.G.S.I. London: Roper and Drowley.

Mr. J. E. Gore, who must not be identified with another scientific author, Dr. Robert Gore, F.R.S., has here furnished us with an exceedingly able account of the heavenly bodies, and certain collateral subjects.

In the brief Introduction the author refers to the accuracy of the observations of the ancient Chaldean and Egyptian astronomers, who, though not possessed of telescopes, had the advantage of an atmosphere far more transparent than that of Western Europe. He then proceeds to a description of the planets. When speaking of Venus, he refers to the strange notion prevalent in November and December, 1887, that this planet was a return of the "Star of Bethlehem." He concludes that Venus has no satellite of a size sufficient to be visible with our telescopes. On the alleged mountains of Venus the author is silent.

Next comes Mars, a planet which has lately excited much attention on account of his "canals." On their nature Mr. Gore gives no opinion. He mentions that the areas of land and water on the surface of this planet are about equal, and he is of opinion that from the close proximity of the satellites to the body of the planet they will have little efficacy as illuminators, and from their small size they can produce but feeble tides in the seas.

In considering the planet Jupiter we find mention of the probable high temperature of this planet, of the red—possibly incandescent—spot on its disc, of the enormous depth of its atmosphere, and of the coincidence in time of occurrence between its spots and those of the sun.

Saturn, Uranus and Neptune are all noticed in due course, but there is no mention of the suspected existence of one extra-Neptunian planet if not more.

It will be noticed that in his account of the solar system, Mr. Gore makes no mention of the two, to us, most conspicuous bodies, the sun and the moon.

In his eleventh chapter the author examines the double, triple and multiple stars, the number of which is now found greater than it was formerly supposed. The phenomena of the variable stars are next considered, and the current explanations are mentioned, none of which the author thinks fully satisfactory. Under "nebulæ" the author recognises the fact that spectroscopic observation proves many to be accumulations of glowing gas, thus giving strong confirmation to the celebrated "nebular hypothesis."

In speaking of the distance of the fixed stars, the author refers to the opinion of the late Mr. Proctor, that the brilliancy of a star is no test of its distance, and that the more conspicuous of these bodies owe their greater brightness, not to relative proximity to the earth, but to real superiority in size.

One of the most interesting sections of this work is that dealing with the "Great Pyramid and the Precession (erroneously written *procession* in the Table of Contents) of the Equinoxes." Certain "astronomers and physicists, including the Abbé Moigno (the late distinguished editor of *Cosmos* and Mr. Piazzi Smyth), contend that the builders of the pyramid ascribed to Cheops, embodied in this vast structure a number of the most important scientific data. Among other things, it is said that the precession of the equinoxes is indicated by certain of the measurements of the pyramid. This phenomenon, *i.e.*, the rotation of the pole of the equator round the pole of the elliptic in a period of 25,000 years, is due to the revolution of the sun around some central body in that period of time. This supposition the author shows to be erroneous.

Under "Changes in the Stellar Heavens," Mr. Gore treats of the observed motions of the so-called fixed stars, and also of the appearance, often sudden, of stars periodically unnoticed. Thus, that observed by Tycho Brahé in 1573, was visible even in daylight, but within five months it disappeared to the naked eye. Its light was at first white and extremely bright, then in succession yellowish red, and lastly, of a pale-livid colour. Similar, if less striking, cases have repeatedly been observed by eminent astronomers.

We regret that we cannot, on account of space, prolong our examination of this most interesting work. We must regard it as at once readable and accurate, and we most commend especially the author's judicial reserve on points not proven.

Proceedings of the Bristol Naturalists' Society. New Series, Vol. V., Part 3 (1887-8). Bristol: The Society.

This volume contains much matter which was well worth putting on record. Professor C. Lloyd Morgan contributes an interesting memoir on "Elimination and Selection." *A propos* of Mr. A. R. Wallace's critique of the phrase "natural selection," Professor Lloyd Morgan suggests provisionally the use of the phrase "natural elimination." He remarks that "too little importance has, perhaps, been attached of late years to the mental element in evolution. In Lamarckism it took a foremost place. In the reaction against Lamarckism the mental element fell into the background. But those naturalists who have kept abreast of philosophy are more and more coming round to the view that mind and body are indissolubly connected; that the mind does not act *ab extra*, but is an integral and essential part of the organic whole." He admits that we are still in the dark about origins. Elimination originates nothing. Selection originates nothing. We are thrown back upon variation, bodily and mental, as the origin. But how originates this variation? In response to surrounding conditions. True; but how?

Mr. A. J. Harrison, M.B., furnishes a paper on "Seals and their so-called Ballast Bag." He proves that the alleged "ballast-bag" is merely the stomach, and he gives us very satisfactory evidence that the stones swallowed are not to serve as ballast, but to aid in the comminution of the food in the stomach. "Seals seize their prey greedily, and swallow it rapidly, their trenchant teeth not being adapted for much mastication; but the presence of a number of round smooth bodies in the stomach, such as these pebbles, would assist very materially in breaking up the food."

"The Crossing of Ferns," by Colonel Arthur M. Jones, is also an important paper as containing definite evidence on the fertility of hybrids. It was indeed pronounced "an established fact" by Sir Joseph Hooker in a letter to Mr. E. J. Lowe, written in 1884. The latter gentleman succeeded in raising a hybrid between *Polystichum angulare* and *P. aculeatum.* The hybrid has been proved by Col. Jones and others to be easy of reproduction from spores.

At a meeting of the Entomological Section of the Society there was exhibited a hermaphrodite specimen of *Odonestes potatoria*, one side being male and the other female. The contrast between the two antennæ was remarkable. We find, however, no indication that the insect was dissected. Another exhibit was a hybrid between two well-known hawk-moths, *Smerinthus populi* and *S. Ocellatus.*

The Midland Naturalist. September, 1888.

This issue contains a very interesting paper by the Rev. H. H. Slater, entitled "Insularity," though its bearings would scarcely be inferred from the title. It is substantially a condemnation of that peculiarity among our naturalists which we have elsewhere felt bound to protest against as the "British mania." Our readers are, of course, aware that a multitude of ornithologists, entomologists, and botanists confine their collections and their studies to the fauna and flora of the United Kingdom. For a British or alleged British specimen of some rare bird, or egg, or insect, they are willing to pay considerable prices, whilst an identical specimen, caught or found on the other side of the Channel, they will scarcely accept as a gift. It has often been shown that no similar feeling prevails in any Continental country. A French entomologist may be exceedingly careful to put on record the locality of any specimen which comes into his hands, but he will not attach a higher value to it for having been caught in France rather than in Belgium, Germany, Switzerland, Italy, or Spain. It has also been pointed out that this same craving for British specimens is one of the main causes contributing to the extirpation of our finest birds and insects.

Mr. H. H. Slater argues against the British mania on the ground that Great Britain does not form anything like a natural zoological or botanical region. Had Britain been separated from the Continent by a deep sea, as is Madagascar from Africa, we should have had an independent fauna and flora the peculiarities of which, in contrast to those prevailing on the European mainland, would probably have been most instructive. The author adds, most justly: "We should undoubtedly have a far higher claim to the possession of true scientific knowledge if we were to confine our attention to one moderate-sized genus of mammalia, birds, insects, mollusca, or plants, and work out the distribution of that genus in the world zoologically (or, in the case of plants, botanically) and palæontologically, and familiarised ourselves with every member of that genus, its area, economy, habits, and uses, than by ever so general a study of the whole class as exemplified only in Britain."

Will any of the younger naturalists included among our readers take this advice?

The author asks, further, why, in these days of easy and cheap travelling, we hear of so few botanical, entomological, and geological trips on the Continent? We might further ask, why do the multitudes, whom business or pleasure call to the Colonies, not do something there for natural science?

Forest Culture and Eucalyptus Trees. By Ellwood Cooper. San Francisco: Cuberry and Co.

This little work consists of several district portions, very unequal in their value. The author's lecture on the cultivation of the Eucalyptus, in California, may be of great interest to the inhabitants of the United States, but will excite little curiosity elsewhere. At the same time we cannot help asking whether the sanitary value of these trees is quite as high as is popularly supposed.

It is said that the experiment tried in the Pontine Marshes has given very doubtful results.

The three essays, or lectures, delivered by Baron Müller, F.R.S., the Government Botanist for Victoria, one on "Forest Culture in its Relations to Industrial Pursuits," another on the "Application of Phytology to the Industrial Purposes of Life," and the third on "Australian Vegetation," are of great importance, especially as in their original form they are not easily met with. We have never seen the policy, or rather, the necessity of maintaining the forests enforced at once so practically and so philosophically. The two other lectures show the resources and the capabilities of Australia, and explain how they may be developed.

The concluding portion of the book, an account of the Santa Barbara College, in California, derives its sole and slender connection with the rest of the contents from the circumstance that Mr. Ellwood Cooper delivered his lecture on the Eucalyptus before this college.

Abstracts of Papers, Lectures, etc.

YORKSHIRE ASSOCIATION OF SANITARY INSPECTORS.

At the quarterly meeting held Sept. 27th, at Bradford, Mr. William Warner (Nottingham) read a paper on "Destructors and Refuse Furnaces," in which he said the development of this burning method had been no easy matter, and at the present time it had to fight many severe battles. If they analysed the opposition in the council chamber, at public meetings, or in the House of Commons, they could not find any just or reasonable cause to stop its progress; indeed, a careful study of the points raised would show to the unprejudiced mind that all these objections were raised without foundation. It had been proved beyond doubt by competent authorities that the method was the best and only safe one to prevent the propagation and spread of infectious diseases. Yorkshire was one of the first to enter the field and show the world the shrewdness of its inhabitants. Leeds had its first destructor built in 1877, and it appeared to have sufficiently satisfied the Corporation of that town, as a second was built in 1879. In 1881 the system was taken up with great spirit, but in 1883 no new destructors were adopted, a circumstance probably accounted for by threatened injunctions in some of the towns where the furnaces were in operation. After an examination of the evidence of the best medical authorities, one was led to imagine that it could not be possible to obtain a verdict against the use of furnaces for burning refuse if constructed upon experienced principles. At a recent Local Government Board inquiry Inspector Tidy stated he considered the destructor, with the cremator, an enormous advantage in sanitary work. Professor Wanklyn, in a report on the subject, gave the results of his investigation, and stated that "at these temperatures, and in presence of the accompanying air, all septic poisons are destroyed, and organic compounds are resolved into carbonic acid, water, and nitrogen gas; only the minutest traces of empyreumatic products could survive and pass away through the shaft into the general atmosphere. No harm to the health of the community is to be expected or feared from these products." Considering the valued opinion of medical authorities, why did they hear objections to the system on sanitary grounds? Why did they have agitation and threatened lawsuits? He attributed the objections to reasons which might be summed up as follows:—1st. Supposed depreciation of property in the neighbourhood where destructors are erected. 2nd. The traffic in refuse to the destructor depots. 3rd. Prejudice and individual causes. The first objection might be explained in assuming that people would not live where they were subjected to a nuisance or injury to health caused by noxious gases emitted from the burning; but it had been proved by experience that houses were equally well let in the neighbourhood of such furnaces, and that people who lived near them did not leave their homes to find a more ozonised atmosphere. The second objection might be formed with substantial reason in some towns, where the collection of refuse was let by contract. But the contract could be let under stringent regulations or even with more satisfaction done by the local authorities themselves. They could show by the evidence of medical men that where destroyers had been started the death-rate had been reduced. He described destructors which had been patented, and the cost of some of those which had been constructed. Taking the results generally, a chimney 160 ft. high was found very suitable, and its internal dimensions should be determined in accordance with the number of cells employed, and the probable rate of refuse treatment. A chimney this size with moderate foundations and good levels on site, could be built with a 6-cell destructor for about £3,000; but if they took the cost of several which had far exceeded proportionately that expenditure, the system would show itself favourably against other methods. Another important financial feature was formed by the high temperature produced in burning refuse, where sufficient power was found to do useful work after leaving the cells. At Leeds, Bradford, and Heckmondwike it was utilized during the daytime to grind the clinker into mortar, which was a good source of revenue to the Corporations. Batley proposed to work their sewage machinery as done at Ealing. There was no town, with the exception of Warrington, that used its power to the fullest extent. The amount of power available depended upon the construction of the furnaces, the quality of refuse, and regular method in working. Taking an average basis, Leeds was capable of producing 120-horse power from their 20 cells in winter, or if they calculated the consumption of 3lb. of coal to each horse and coal at 10s. per ton, they saved the actual value of £500 per annum in heat alone. He had shown how they had collected and burnt the refuse, and utilised the products of combustion, but there was another part of the system which must be taken into account. The refuse consisted of mineral and organic matter, with moisture; the former was not combustible, and would not reduce in bulk, but when acted upon by the heat it changed its form, and was fused into hard clinker. The organic matter with carbon, left a small residue of ash, and the moisture was evaporated entirely during the process. The component parts of the clinker were naturally hard, and when in a fused state were serviceable for many purposes. When broken up and mixed with lime or cement, it would stand as concrete for the best foundations; it was used extensively for forming road bottoms, and some towns obtained good saleable mortar by grinding it with lime and water in a mortar pan. In the year 1886 Leeds received £394 for mortar, Bradford £1,204, and Bolton £1,757. The fine ashes produced from refuse furnaces were extensively used for bedding granite stones in roadways and pleasure ground foot paths, and the fine dust from the flues had found a market with farmers. If a town could utilise the whole of the clinkers, fine ashes, and flue dust, it would not only pay for the cost of burning and the repayment of capital expended on the plant, but would also produce a revenue to aid the necessary cost of collection. He did not see why this point of perfection should not be reached. Referring again to the question of situation, he observed it was said that destructors should be erected outside a town, and some distance from dwellings, but his experience was that the greater number of complaints were received in those towns where the furnaces were thus situated. He believed that if a destructor of the latest type could be built during a night, unseen, and put to work without the knowledge of the surrounding inhabitants, no one would detect any difference, and no one would complain. Would health towns like Buxton and Bournemouth tolerate anything said to approach a nuisance? At the latter town it was considered a support to health, and a sight to be seen by its visitors. The destructor was erected within a stone's-throw of houses whose rents were from £400 to £500 per annum, and worked without inconvenience to the occupiers. In conclusion he advised them to induce their committees to select a site where there was ample space, not only for the furnaces with their probable extension, but have sufficient ground to enable the workmen to perform their duties with the best results, and due consideration for their comfort. Let them also provide good stores and ample water supply, and prevent as far as possible, sanguine inventors from experimenting with them, either at their own cost or the Corporation's, and thus miss the probable chance of failure.

WOOLHOPE NATURALISTS' FIELD CLUB.

At the last meeting, the Rev. M. G. Watkins, M.A., read a paper on "The Migration of Birds," in the course of which he said :—This subject is best divided into two parts ; first, the history of and the views which have been held on migration ; secondly, the phenomena of migration and the general laws connected with it.

The least observation showed men from the earliest times that certain birds arrived and departed at certain seasons. The first writer to take a scientific interest in migration, whose speculations indeed were not superseded for more than 2,000 years, was Aristotle. He notes the analogy between the migration of fish and of birds, and is the earliest writer to name the double migration of birds, from the autumnal cold into warmer regions, and from summer warmth again to colder countries. Cranes, he says, fly facing the wind, which is now found to be more or less the case with all birds. He has discernment enough to pronounce that the fable of their carrying a stone with them for ballast is untrue. Quails cannot fly with ease in showery weather, hence they utter their call to each other as they fly, being in difficulties. On their outward journey they have no leaders, but on their return they take with them the quail-mother (probably the landrail), the long-tongued bird (perhaps the greenshank), the night owl, and the ortalan. The latter calls to them through the night. Cranes, too, choose a leader, and rest all night on the ground during their migrations, with their heads under their wings, and standing on one leg in turns, while the leader, with eager neck, listens and looks out and gives notice in case of alarm.

The Roman Pliny, 300 years afterwards, is much more credulous. He repeats these stories of the crane. "Some birds," he states, "make voyages over sea and land to see strange countries." Quails settle at times in great numbers on sails and masts, thus bearing down the ships and sinking and drowning the sailors. They choose companions to go with them, especially the "glottis." "This bird," says Pliny, in his quaint fashion, "is very forward at the first setting-out (as being desirous to be a traveller, to see far countries and to change the aire), and the first daies journey he undertaketh with pleasure, but soone finding the tediousnesse and paines in flying, he repents that ever he enterprised the voiage. To go backe again without company he is ashamed, and to come lag behind he is as loth ; howbeit for that day he holdeth out so-so, and never goeth further ; for at the next resting-place that they come unto, he faire leaveth the company and staieth there, where lightly he meeteth with such another as himselfe, who the yere before was left behind. And thus they do from time to time, yere by yere."

The first author to examine bird migration with a scientific eye was undoubtedly Gilbert White, just a century ago. He gives lists of summer and winter migrants, with the times when the birds arrive or depart, shows that food supplies are not the only cause of migration, and that birds cross usually at the points which give the shortest sea-voyage. But his sight was clouded by the tenacity with which he clung to his belief in the hibernation of birds. Many theories have since his time been enunciated by Weissman, Palmen, and others, but the first requisite on which to found a safe judgment, abundance of varied observations on migration, was wanting. The influence of Darwinism, too, has rendered it almost necessary for his disciples to assume that not instinct, but experience, not indeed the experience of the individual but of the species, compelled and guided migration. Ten years ago, therefore, it might be said that our scientific horizon with respect to migration was almost where it was in the time of White of Selborne ; that is, our knowledge of the subject had practically not advanced for a century.

In 1879 a conviction had entered the minds of many bird students that without more accurate observations and abundance of them from all quarters of Great Britain, no definite conclusions respecting the phenomena of migration could be reached. A committee was in that year appointed by the British Association (which soon obtained the aid of the Trinity Board) to investigate and register the phenomena of migration round our coasts. The plan adopted was to issue circulars inviting lighthouse-keepers to note and forward to the committee any particulars of birds coming or going by day or night, and especially of any which accidentally killed themselves by striking against the lanterns. Sometimes as many as 200 birds in a night are killed on a lighthouse, chiefly land birds ; marine birds seem to have acquired more experience. Starlings strike in the greatest numbers, woodcocks usually one at a time. Many of the lighthouse men have now become expert in identifying birds, and enjoy registering them. At the close of the year the schedules are sent back to the committee, who then proceed to tabulate, and, if possible, draw conclusions from them. The annually published volumes containing these deductions are of deep interest to all lovers of birds.

Birds, as a rule, it is found, follow the coast-lines in their migrations. One common route is across the Straits of Gibraltar, thence along the western shores of the European continent. Another route leads by Malta and Sicily to the shores of Italy and thence by the Riviera. A third leads over the Alps into Austria and Germany. Birds come across to England either from the North Sea or by the shortest way across the Channel. In the former case they generally fly over and sometimes halt at the little island of Heligoland, and there some of the most unexpected captures have taken place, while careful watch has been kept upon all birds which pass over. In a favourable season the number of these is very great. A competent ornithologist, Herr Gätke, fortunately lives there, and science owes much to his observations. Almost all the birds of Europe and Northern Asia migrate more or less, and, says Mr. Seebohm, "we may lay it down as law, to which there is probably no exception, that every bird breeds in the coldest regions of its migrations." He too regards migration as "a fact in the history of birds of comparatively modern date." It has often been debated what is the true home of migratory birds, whether the country in which they breed or the land they adopt as their winter quarters. The preponderance of evidence is, Mr. Seebohm thinks, largely on the side of the former theory ; and he adds, "the cause of migration is want of food, not want of warmth. The feathers of a Siberian jay or a Lapp tit are proof against any cold." Yet the autumnal emigration from us depends partly on temperature, partly on the period when young birds are able to shift for themselves. Migration usually takes place at night, but larks have been seen on the Channel migrating by day. Heligoland is probably not a hundred acres in extent, and its resident birds do not appear to exceed a dozen species, but its value to migratory birds as a resting place is so great that 150,000 larks have been caught there in a single night.

"On the night between October 28th and 29th, 1882," Mr. Gätke remarks, "we have had a perfect storm of goldcrests, poor little souls, perching on the ledges of the window-panes of the lighthouse, preening their feathers in the glare of the lamps. On the 29th, all the island swarmed with them, filling the gardens and over all the cliffs—hundreds of thousands; by 9 a.m. most of them had passed on again" ("Migratory Report," 1882, p. 49). Birds when migrating dislike a favouring as much as an absolutely contrary wind, preferring a wind from the side. They appear to fly at a high elevation, and when they arrive at Heligoland to drop down as it were from the clouds. Mr. Seebohm supposes that they migrate by sight and not by instinct, but the gravest difficulties appear to me to beset the former theory. In the spring migration (of course I take for granted a knowledge of our spring and autumnal migrations) the adult males usually come first, then the adult females, next the birds of the year, then wounded or crippled birds. On their return various stragglers first come, then the young birds, and finally the old birds. "The conclusion I came to," says Mr. Seebohm, "was that desire to migrate was an hereditary impulse to which the descendants of migratory birds were subject in spring and autumn, and which has during the lapse of ages acquired a force almost, if not quite, as irresistible as the instinct to breed in spring." Here again allowance must be made for the prepossessions in the writer's mind. "Among true migratory birds," he continues, "it appears to be a general rule that the farther north a species goes to breed the farther south it goes to winter."

During the land migration, the same author thinks that birds travel slowly during unfavourable weather, and rest at night, but for a sea journey they wait for a favourable wind and then come over *en masse*. Mr. Cordeaux, a member of the Migration Committee, agrees with this. "In the Cheviots," he says, "I have observed for two years in succession that the streams of small migrants from Scotland follow those main valleys which run nearest north and south, sticking closely to the lowest levels, where the brushwood and bracken beds offer greater privacy and security than the bare fell sides. Birds also, when migrating, follow from choice low-lying tracks of land and river-courses in preference to elevated plateaus and the summit-line of mountain ranges" ("Migration Report," 1886, p. 52). When birds cross the German Ocean, if fine they fly at a great height; if wet and cloudy they keep but a little distance above the waves. There is doubtless much mortality in bad weather, even among the larger birds, during their migration. The Lincolnshire coast during a gale has been found strewn with the dead bodies of the hooded crow. When countries are over-crowded with birds some appear to migrate for good and all into distant lands. The curious irruptions of the sand grouse into England in 1863, and again in the present summer, appear to be migrations of this nature.

Migration, then, among British birds may be considered as of three kinds. First, the regular stream of birds which come here in spring to breed and which leave us again in autumn, and again that similar stream which appears in October and leaves in February or March; next, the continuous migration of our common birds, blackbirds, jays, etc.; and thirdly, exceptional immigrations, such as that of the sand grouse just named.

As for the continuous migration of common birds, it may be noticed that this movement has only been discovered of late years, and that the reports from the different lighthouses show constant examples of it. Thus a migration of the same kind of birds frequently occurs, but in opposite directions, across the North Sea. Crows, rooks, jackdaws, starlings, larks, sparrows, buntings, and finches, have been noticed there crossing each other. Indeed, Professor Newton says, "Hence we are led to the conclusion that every bird of the northern hemisphere is to a greater or less degree migratory in some part or other of its range." Mr. Cordeaux takes blackbirds as an example of this tendency, and says: "In the autumn, during September, the young of the year leave their summer quarters, and their place is shortly taken by others, likewise young birds, coming in October and November from districts which lie directly east or south-east of Great Britain. Should an English winter prove severe, or even partially so, our old birds will also leave, and in their place we have an influx of old blackbirds from the Continent, pushed forward from similar causes. In the spring the Continental visitors disappear, and our so-called resident blackbirds come back to their nesting quarters. As far as our knowledge extends the normal conditions of locality and climate over the whole area are such as do not necessitate a regular interchange of the members of their respective *avi-faunas*. There is apparently no reason why our rooks, starlings, skylarks, and blackbirds should not be able to winter in England just as well as abroad;" and he adds: "Such are the ordinary phenomena of migration; a movement which is as regular and persistent as the flow and ebb of the tide." And once more: "Practically such birds as the lark and the starling are migrating all the year round." The robin, too, seems almost always moving from woods to the vicinity of houses and back again, and even to far distant countries such as Africa.

With regard to the third kind of bird migration—that which is local, occasional, and exceptional—it must be remembered that it is only so because we do not as yet see the full purpose which thus stirs so many birds at once. Doubtless, want of food is one great cause, or abundance of food in an unusual locality. Thus in 1885 the abundance of Arctic ice brought down mollusca, entomostraca, etc., to more temperate seas, and so vast quantities of gulls were observed in the Firth of Forth feeding on them. Again, the sand grouse (*Syrrhaptes paradoxus*), which visited our shores this summer, "from the short time necessary for incubation," says Mr. Tegetmeier, "and the rapid growth of the young, increases so rapidly that it may have been compelled to seek new pastures and to extend its range. It could not traverse northward for climatic reasons; eastwards its range is limited by the Pacific, southward is the larger bird of the same genus (*S. Thibetanus*), and it therefore proceeded westward." Cold is another cause of abnormal migration. Birds are pushed on as it were by it from a bleaker into a more sheltered district. A large and unusual influx of ring-ousels appeared at Spurn Point, Yorkshire, in May this year, and at the time of writing an abnormal migration of crossbills (*Loxia curvirostra*) is taking place from Germany. Some have appeared on the coast of Holderness, in Yorkshire, and one was captured and kept on board the light-ship at the Spurn for a week before it escaped. In a letter to Mr. Cordeaux, dated July 1st, 1888, Mr. Gätke sends the following interesting notes of the occurrence of the crossbill on migration in Heligoland:—"Have you seen any crossbills (*Loxia curvirostra*)? We are swarming here with them. Since the 16th of June there have been flights from ten, twenty, fifty—and sometimes all the hawthorns in my garden you know so well are crammed with them. There must, during some days, have been hundreds dispersed amongst the foliage. When they are feeding they remain quite dumb, and only when taking wing the whole chorus begins, calling 'cüt, cüt, cüt.' I have just mounted an old male, almost as red all over as a male *Fringilla erythrinus*; a few with white bars have been reported but I have not seen one. They are of all shades, from lemon to orange scarlet, and almost carmine, but the greater number, as you may fancy, are grey birds, but not a single striped young one amongst them. These birds are rather out of date; they are not regular visitors to this island, years intervene without any being seen, and when they do appear it has almost invariably been in August, with boisterous north-westerly winds and rain; this year flight has been two months too early, and came with fine sunny weather. All are in excellent plumage—wings, tail, and all."

In conclusion, it may be noticed that what I have said refers merely to the phenomena of bird-migration. The motives in the little wanderers' minds are still, and are long likely to be, an inscrutable mystery. We can only affirm that they proceed from a divinely-planted impulse, an ἐνέργεια, which in truth must underlie both use and wont on long experience in directing these hidden irresistible journeys over wide continents and waste seas. How this instinct or impulse works is a proper question for investigation by naturalists. Thus Darwin supposes that migration is due to long habits, originally awakened by the need of a distant search for food. Mr. A. R. Wallace's view, however, holds that migration is one of the means of getting rid of the enormous surplus of bird population, as only a small number, he thinks, survives out of the vast crowds which seek to pass from one region to another. What this instinct is in itself is as fruitless a question as similar inquiries in human psychology. The more a lover of birds attempts to understand the motives which bids them change their skies or pass from the ken of man to the comparative obscurity of the woods, the more he is foiled. But the attempt to penetrate this great secret of bird life will assuredly fill him with ever-increasing wonder as he reflects on the resolution shown by even the feeblest birds in carrying out this law of their being—how such feathered atoms as the golden crested wren brave the rough nights and severe weather of the North Sea in October to reach our shores; how the sand martins, the smallest of the British swallows, do not scruple to commit their delicate forms at the same time to wastes of sea and leagues of land, in order to arrive at their winter homes.

Cheltenham Natural Science Society.—The annual meeting took place on October 4th, when the President, Mr. Francis Day, C.I.E., read the annual address, and the election of President and Council for the ensuing year took place. Mr. Day was again chosen President. Mr. Day, in his address, reviewed the work of the past session. At the conclusion of the business of the annual meeting the first regular meeting was held, when a paper was read by Dr. Drew on "Flight of Birds and Insects."

Liverpool Microscopical Society.—At the meeting held on October 5th, Mr. J. C. Thompson, F.L.S., F.R.M.S., was elected President for the year 1889. Mr. J. C. Thompson exhibited under the microscope and made some remarks upon some remarkable and little-known *Cladocera*, a genus of the *Crustacea*, which he had recently found at various depths in the Cumberland lakes. One of these—the *Leptodora hyalina*—is an exquisitely transparent creature about a quarter to half an inch in length, and has the appearance when alive of a minute fragile glass canoe rapidly beating its way through the water. He had found it in Grasmere, Easedale, and Thirlmere lakes, its presence in the latter possibly possessing some interest in the near future to Manchester water-drinkers. The other forms Mr. Thompson exhibited were *Bythostrephes cederstromis*, *Bosmina longirostris*, an animal not uncommon in London drinking-water, and *Hyalodaphnia kathlbergensis*, a most eccentric-looking microscopic crustacean, with an immense eye, surmounted by a long pointed head. An interesting discussion followed, in which the President, the Rev. H. H. Higgins, Dr. Carter, and others took part.

Penrith Literary and Scientific Society.—The annual meeting and *conversazione* in connection with this Society were held on October 4th, when there was a large attendance of members and others.

Bristol Naturalists' Society.—At the first meeting the Hon. Secretary showed a specimen of *Staphylea pinnata*, the bladder or bag nut, which he had seen growing in the neighbourhood. Dr. G. Munro Smith gave a demonstration of apparatus used in physiological research. He first said that one of his objects in giving the demonstration was to call attention to the fact that the Bristol Medical School possessed a laboratory and apparatus for physiological research, and he expressed a hope that Bristol would help generously in the contemplated increase of the medical school.

TOTEM CLANS AND STAR WORSHIP.

A Paper Read by Mr. George St. Clair, F.G.S., before the Anthropological Section of the British Association.

(*Continued from p.* 393.)

It has been stated already that the word "totem" appears to mean crest, mark, or sign; the Rev. Lorimer Fison says, a badge of fraternity. In Queen Charlotte Islands, the Huidas are universally tatooed, the design being in all cases the totem, executed in a conventional style. It is of practical use to prevent wrong marriages.

Next, it may be observed, that if the totem-crest has an astral origin, we need seek no other origin of the worship of the totem animal. Plutarch long ago suggested that the worship of animals may have arisen from the custom of representing them on standards.* He was not far wrong if the animals were figured on the standards, because they were star-gods. The worshipper was created by his god. Prof. Sayce finds that a common phrase in Assyrian texts is this: "The man the son of his god"; † and of these deities, one is represented as a fish, another as an antelope, etc. As a parallel to the phrase, "The man the son of his god," we have, in the Hebrew Scriptures, the Moabites called "sons and daughters of Chemosh" (Num. xxi. 29), and even Malachi calls a heathen woman the daughter of a strange god (Mal. ii. 11). Among the Arabs, the Kalb tribe consists

* Lubbock's "History of Civilisation," 252.
† Sayce's "Hibbert Lectures," 244, 284.

of the Beni Kalb, *i.e.*, sons of the dog.* In Peru, the Incas were descended from the sun, which was their god; and so, if the Indians of Peru, before the Incas, claimed descent from the fox, dog, llama, condor, eagle and puma, besides the serpent and several species of fish, it is no very violent supposition that these also were the names of celestial bodies; in fact, we are told on the best authority† that each of these species was supposed to have a representative or archetype in heaven. There were Greek houses descended from Zeus the eagle, and from other gods, while many of the gods had close association with animals, as Athena and the owl, Dionysus and the dolphin, Apollo and the mouse. I have no doubt that some of the gods of the Egyptians, such as the ram-headed Ammon, were zodiacal; and there is a passage in Plutarch which connects these gods with the military standards or crests.

Since then the totem animal was the representative of a stellar god, who was the progenitor and creator of all his worshippers, we can readily understand how the animal came to be reverenced, even to the degree of being worshipped.

It becomes a principle that the totem animal is not to be injured, much less killed and eaten. The Australian will not kill the kangaroo, emu, or black snake, which is his totem, lest it should be his own protector, being, in fact, in the form of his god, and an incarnation of the deity. In New Caledonia, when a child tries to kill a lizard, the men warn him to "beware of killing his own ancestor?" The Osages believe themselves to be descended from the beaver, and therefore will not kill that animal. Everywhere it is the same; a man does not eat the animal which gives name to his clan, does not clothe himself in its skin, and, if compelled by circumstances to kill it, asks pardon for the offence and purifies himself from the sacrilege. He will eat freely of the sacred animal of another clan, but the incarnation of his own particular god he would consider it a crime to injure. Thus, in ancient Egypt, at Apollinopolis, men hated crocodiles and never lost a chance of killing them, while the people of the Arsinoite nome dressed geese and fish for these sacred creatures, adorned them with necklaces and bracelets, and mummified them sumptuously when they died. The crocodile here takes the place of the python, the enemy of Apollo, and therefore it is hated by the men of Apollo's city; while every student of Greek mythology will allow that Apollo was a celestial god.

It is a very natural arrangement that totem clans should be found localised in nomes or districts; and it follows from this localisation that the special god of the clan becomes the chief god of the district, while other deities of the country are not altogether ignored. We start with a small community, all of whose members reverence all the gods of the Zodiac. We see them divide into twelve companies, which become totem clans, each especially associated with the worship of one deity out of the twelve, but they will retain for a long time a lingering regard for all the rest.

Chæremon and the wisest priests of Egypt quoted, in support of their own opinions, those of the oldest Egyptians, whom they understood to acknowledge as gods, only the sun, moon and planets, the stars of the Zodiac, and those decans which are subdivisions of each zodiacal sign into three. These, they said, were the sovereign arbiters of destiny, which their fathers had honoured by sacrifices, and to which they had erected images.‡ It was an ancient opinion that the division of Egypt into thirty-six nomes or provinces, was in imitation of these thirty-six decans, each of which had its protector. The heavenly guardians became the protecting deities of the Egyptian nomes, which took the names of the animals there revered,§ as the lion of Leontopolis, the crocodile of Crocodilopolis, the wolf in Lycopolis, etc., while some of the deities were worshipped universally. In some places triads of gods existed; for example, Amen, Mut, and Chonsu, composed a triad at Thebes; and this may possibly have arisen through there being three decans to the sign. The connection between the gods and the beasts has been a puzzle

§ Dupuis, quoted in S. Wake, 261; Frazer 12, 37.

to writers on Egyptian religion,* but I think this was its simple origin; the living animals were symbols of the stellar gods, and the constellations may perhaps have received their animal names from their connection with the seasons and months of the year. In each nome the worshippers refrained from eating their own sacred animal.

The tendency to separate clannish development, distinct forms of worship, and internecine religious wars, was sought to be met, as I conceive, by the strict enforcement of the rule that children should never belong to the same clan as their father. There were two ways of achieving this object, and it may be difficult to say which would answer best; one would be the Australian system of classes, in which *Ippai* and *Kapota*, for instance, being man and woman of one class, marry together, and pass their children over to the class of *Murri* and *Mata;* the other, which, in fact, is more prevalent, would be for a man to take his wife from outside the clan, and the children to be reckoned to the same clan as their mother. This view brings the Australian system of classes into such consistent relation with the more widely spread system of the gens, that I venture to think it favours the explanation I offer of the reason for exogamy; especially as the Australian system is generally supposed to present peculiar difficulty.

This rule of exogamous marriage would operate to bring into each local tribe an increasing number of women and children belonging to every other, and in ordinary times the tribes might regard themselves as one people. But all the time the wife had a different god from the husband, the children were of the gens and blood of their mother, and when a blood feud sprung up, the father was bound to be the enemy of his own children. The only safety for the children was to go to their mother's blood relations, and remain with the clan from which she had been drawn; and thus there would come about a local concentration of the clans, which largely neutralised the good effect of exogamy.

The views which I am putting forward receive remarkable confirmation from the doctrine of metempsychosis. The curious connection between the institution of totemism and the doctrine of the transmigration of souls, has been noticed by several writers, but their explanations of the connection are not satisfactory.

Opinions might be quoted, but I must hasten to state my own—which is this, that the soul of a deceased person goes beneath the horizon with the sun, performs the same journey as the sun, and therefore necessarily passes through the signs of the Zodiac in succession, and becomes identified with one animal form after another.

"The doctrine of transmigration," says Sir Gardner Wilkinson,† "is mentioned by Plutarch, Plato, and other ancient writers as the general belief among the Egyptians, and it was adopted by Pythagoras and his preceptor Pherecydes, as well as other philosophers of Greece. Opinions varied respecting it; and some maintained that the soul passed through different bodies till it returned again to the human shape, and that all events which had happened were destined to occur again after a certain period, in the identical order and manner as before. The same men were said to be born again, and to fulfil the same career; and the same causes were thought to produce the same effects, as stated by Virgil. This was termed κυκδος αναγκης, "the circle (or orbit) of necessity."

This language is clearly borrowed from astronomy; it points to the revolution of the heavens, and the periodical recurrence of the same phenomena. It is confirmed by what we are told by Maspero.‡ "In the evening the soul follows the bark of the Sun and its escort of luminary gods into a lower world bristling with ambuscades and perils. . . . At midnight began the upward journey towards the eastern regions of the world. . . . The tombs of the kings were constructed upon the model of the world of night. They had their passages, their doors, their vaulted halls, which plunged

* S. Lang, "Myth and Ritual," ii. 107.
† "Ancient Egyptians."
‡ G. Maspero's "Egyptian Archæology," translated by Amelia B. Edwards, p. 154.

down into the depths of the mountain." The soul thus following the sun, of course traverses those constellations which, with some nations, were the Ram, the Bull, etc., with others the Hawk, the Crow, etc.; and thus the curious anomaly is explained that the clansman who has to do with only one totem animal while he lives, may have to do with several in succession after death.

It appears to be a half-forgotten tradition of the ancient belief which lingers among the various barbarous tribes that still believe in transmigration. The soul passing through the zodiacal signs, one after another, would arrive at length at its own clan-sign or totem; and there, perhaps, it would hope to stay, and enjoy felicity with its god. This is apparently the latent essence of that article of faith among Indians, that as the clan sprang from the totem, so each clansman at death reassumes the totem form. Thus the Moquis, believing that the ancestors of the clans were respectively rattlesnakes, deer, bears, sand, water, tobacco, etc., think that at death each man, according to his clan, is changed into a rattlesnake, a deer, etc.

Amongst the Black Shoulder (Buffalo) clan of the Omahas a dying clansman was wrapped in a buffalo robe with the hair out, his face was painted with the clan mark, and his friends addressed him thus: "You are going to the animals (the buffaloes). You are going to rejoin your ancestors. You are going, or your four souls are going, to the four winds. Be strong."* Frazer quotes the Australian ceremony at initiation of pretending to recall a dead man to life by the utterance of his totem name. An old man lies down in a grave and is covered up lightly with earth; but at the mention of his totem name he starts up to life.

I anticipate an objection to the views of my paper, that the theory seems to require a greater knowledge of astronomy on the part of Australians and Red-men than they or their ancestors are likely ever to have possessed; and perhaps a degree of religious culture, from which we should have to suppose they had fallen.

We have already heard witnesses to the fact that the Australian blacks are better acquainted with the stars than the average Englishman. They appoint men to study and to teach; and they find the knowledge useful on their journeys. Moreover they have a mythology, in which the eagle-hawk, and the crow are constellations. The Australians, then, appear to be elevated enough for our purpose. It must be allowed that they no longer carry out the religious and military duties, the rotational performance of which I imagine to be at the root of their class and clan distinctions, and they probably cannot give any intelligible reason of their present divisions, and their rules about marriage, totem animals, etc. But then neither did the Greeks of two thousand years ago understand the origin and meaning of their own mythology, and there is not a civilised nation in the world which does not retain some customs which it cannot explain, and which has not, in some things, become degraded in practice and belief. Besides, on any theory, the orgin of totemism appears to be forgotten. We might expect at least some obscure tradition of its origin to remain; and if I am right, we do actually find as much as this, in the idea that the totem animal is the creator, that the archetype is in heaven, and that men go to their totem god after death.

The zodiacal origin of totemism—if it be a fact—goes far to account for the widespread character of the institution. Measures of self-defence would be adopted instinctively by all tribes. The heavens are spread before all peoples; the seasons succeed one another in all continents; the moon divides the year into months universally. Thus Australian natives and North American Indians might get started on the same path independently; and ancient Greeks and Egyptians may have gone through similar stages of development in the early ages. What has been common to them all was so much observation of the star groups as to connect their periodical rising with the habits of animals, etc., and some kind of public duty to be performed by sections of the community in rotation.

* "Schoolcraft," Ind. Tr. iv. 86; Dalton, "Ethnol. of Bengal," p. 280. Quoted in Frazer, 36; Morgan, 179.

If there be truth in my general view, the theory I offer of the origin of totemism may not only be acceptable as an explanation of facts and arrangements which have appeared mysterious, but will indicate the following fresh lines of inquiry.

(1) What are the names of the constellations among barbarous and savage tribes?

(2) What is it that has led the families of men in all parts of the world to connect the constellations with animal and other symbols? I fancy the explanation may be that, according to the country or district, the abundance of wolves or hares, or of rain, would be the prominent feature of the month; and the sign of their coming would be the rising of the group of stars which marked the month. Thus the constellation which signalised the coming of the wolves would soon be called the wolf constellation, and a fancied resemblance to a wolf be traced among its stars, though it required a lively imagination to find it. Then the band of watchers gets named after the constellation; and all the rest follows.

(3) If the true origin of totem clans be actually found in the division of the year into seasons and months, and the corresponding division of the heavens, we have a new instrument in our hands for investigating the origin and significance of the castes of India, the *γενος* in Greece, and the *gens* in Rome.

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents, nor can he take notice of anonymous communications. All letters must be accompanied by the name and address of the writer, not necessarily for publication, but as a guarantee of good faith.

THE SPARROW.

Sir,—In reply to your correspondent "Aruspex," I will first say that I very much doubt if there are more sparrows in this country than other birds, but because they congregate where they can obtain food they are more conspicuous. I again repeat that "the sparrow is not so prolific as it is generally supposed to be," and I beg to offer "Aruspex" some figures for which I will vouch the accuracy. In the breeding season of 1887 I counted the young birds in 89 broods, and found 278 young birds only, or $3\frac{1}{8}$ to a brood. Again, if the sparrow is so numerous, how was it that out of 500 small birds massacred in two days whilst feeding at a corn stack, there were scarcely any sparrows amongst the slain, the carnage falling upon the buntings, several kinds of finches, and some starlings?

When "Aruspex" advocates the destruction of the sparrow to make room for the swallow, he must have forgotten that the swallow feeds only on flies and moths, which are the product of grubs and catterpillars, and it is from these pests that we receive the greatest damage; but if these are to be allowed to live and turn into food for swallows, woe to all our fruits and flowers!

I fear "Aruspex" cannot know what kind of bird the American robin (*Turdus migratorius*) is, or he would not have quoted from S. A. Forbes' writing. The American robin is a bird quite as large as our song thrush, and it appears to me to be absurd to draw any comparison between it and the sparrow.

Having had considerable opportunities of watching the habits of the sparrow, I must say that I have never seen or even heard of its molesting the swallow, although I know they will sometimes take possession of a martin's nest, and as for their driving away "other true insectivorous birds," it is all mythical. JOSEPH P. NUNN.

Royston, Oct. 13th, 1888.

SNAILS EATING STONE.—M. Bretenniers has found in Africa limestone rocks curiously perforated with cylindrical cavities, and in each there was a snail (*Limax*). M. Gaudry agrees that those holes are really the work of the mollusks. He has met with them a great many times on Mount Pelegrino, near Palermo.

RECENT INVENTIONS.

The following list has been compiled especially for the SCIENTIFIC NEWS *by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents, of* 234, *High Holborn, London, W.C.; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester; and* 6, *Lord Street, Liverpool.*

FOOD FOR CATTLE.—A food for cattle has been patented by M. J. A. F. Feuchères, Paris. For horses it consists of an admixture of sawdust or wood powder with leguminous plants and cereals, and for horned cattle and sheep it consists of an admixture of wood powder with oil-cake.

MUSIC.—A method of teaching music has been patented by Mr. A. Adamson. This system of teaching music consists in raising cards having marked on them the visible signs of the notes, by means of the movement of rods and levers from a portable hand key-board or key-board instrument placed in front of the teacher and facing the pupils.

ELECTRIC METER.—An electric meter has been patented by Mr. G. Forbes. This method of measuring electric currents is founded on the fact that an electric current passing through a conductor generates heat. This heat is applied to evaporate a liquid, and from the quantity of liquid so evaporated the quantity of electricity which has passed through the conductor is estimated.

DRAWING APPARATUS.—A drawing apparatus has been patented by Mr. H. Marle. It consists of a vertical blackboard ruled in squares of convenient size for displaying the contour of the model, and has an arrangement for supporting the model in front of the squares, consisting of an adjustable joint, projecting at right angles from the centre of the board, and having means to support the model.

FIRE EXTINGUISHER.—An apparatus for subduing or checking fires has been patented by Mr. T. R. Douse. The invention consists in the employment of a tank containing an alkali liquor and a small vessel containing an acid. When a fire occurs the small vessel is overturned automatically, and its contents mixing with the alkali forms carbonic acid gas, which is forced out from the tank into the building, which it fills and thus subdues the fire.

MARKING DEVICE.—A marking device for use in scoring at cricket has been patented by Mr. C. E. Clowes. This device consists of a small case resembling a watch-case, which may be carried in the pocket; this case contains dials and hands or indicators, moved by suitable train of wheels for showing upon the dials the scores or numbers. In the case are suitable projections which are pressed by the finger for the movement of the indicators. A gong may also be provided to be struck at certain intervals, to indicate the completion of an over.

VEHICLES.—An improvement in the means of communication between drivers and passengers in vehicles has been patented by Mr. J. Sax. This invention is applicable to cabs and the like, and provides an efficient means of communication independent of mechanical locking and releasing. The apparatus is operated solely by electricity, and the moving parts are by magnetic attraction maintained in the positions to which they are brought. The moving part is a disc having upon it such expressions as "Stop," "Left," "Right," and "Speak," or such like indications, which may be used as required.

WATCHES.—A compensating balance-wheel for watches and clocks has been patented by Mr. E. Golay. The invention consists in the combination of two alloys, which produces a non-magnetic and unoxidisable compensating balance-wheel, which produces perfect regulation. The interior ring of the balance-wheel is formed of an alloy composed of about 40 per cent. platinum, 35 per cent. copper, and 25 per cent. nickel; the external ring is formed of an alloy consisting of about 55 per cent. silver, 35 per cent. zinc, and 10 per cent. copper.

RAZORS.—Mr. W. S. Simpson has patented a razor sharpener. The object is to provide a sharpener whereby the blade is laid comparatively flat, and the edge sharpened with a long incline, thus producing a better cutting edge. Between two shoulders on a stem are arranged a couple of parallel surfaces, between which is formed a roughened surface as a sharpening medium, against which the flat side edge of the blade is brought into contact during a to and fro movement, the back of the blade bearing against the shoulder on either side as a guide.

PLANT SUPPORTS.—Mr. W. Hopwood has patented a plant support. This device is made of stout metal wire, bent to form a main leg constituting the vertical portion, while the upper end is curved horizontally in the shape of a semicircular arm. At the angle formed the wire is bent to form a circular eye, and at the end the wire forms a catch. The main leg is fixed in the ground to the required depth, as is also a similar appliance, the catch of the first one being inserted into the eye of the second, and the catch of the second into the eye of the first. Thus connected the two form a hoop, having two legs, and thus support the plant.

SAFES.—An improvement in safes or strong-rooms has been patented by Mr. D. R. Ratcliffe. The object is to protect them from being broken into by means of wedges applied at the angles or joints. Bars of angle metal are cut into lengths of the width, length, and height of the safe or strong-room. The angles of these bars fit together and form a cubical frame, the sides of which lap over each of the angles of the safe, and form a continuous metal covering, making the safe proof against the insertion of wedges. The sides of the safe may be flush with the inner sides of the angle bars, or they may have grooves into which the edges of the sides of the safe are inserted.

ARTIFICIAL MARBLE.—An improvement in producing inlaid designs in artificial marble has been patented by Messrs. J. B. Rottenstein and H. A. Cousins. Sufficient plastic material is placed in the proper position in a mould as will cover the design it is desired to produce. While still soft a templet of the design is placed thereon, and a cutter passed around the templet. When the material has partially set, the superfluous pieces are removed, leaving the designs alone in the mould. If the designs are to be bordered or shaded, the chosen material is filled in around them, and cut in the same manner, after which the ground is filled in, and the slab finished in the ordinary way.

SALES.

The Charge for Advertisements in this Column is Sixpence for the first sixteen words, and Sixpence for every succeeding eight words.

Advertisements for this Column should be received by first post on Tuesday to insure insertion in the following number.

EXCHANGES.

Exchange Notices will be inserted in this Column at the rate of Sixpence for the first twenty-four words, and Threepence for every succeeding eight words.

Cases and Binding, Vol. I., including Title Page and Index, price 3s.

Vol. I., bound in cloth, with Title Page and Index, 9s. 6d. —by post 10s.

The Back Numbers of SCIENTIFIC NEWS can be obtained from all Booksellers and Newsagents, or direct from the Publisher, 138, Fleet-street, London, E.C. Price 3d. each, or by post 3½d.

SELECTED BOOKS.

Planetary and Stellar Studies, or Short Papers on the Planets, Stars, and Nebulæ. By J. Ellard Gore, F.R.A.S. London: Roper and Drowley.

The Building of the British Islands. A Study in Geographical Evolution. By A. J. Jukes-Browne, F.G.S., of the Geological Society of England and Wales. London: Bell and Co. Price 7s. 6d.

The Metallurgy of Gold. A Practical Treatise on the Metallurgical Treatment of Gold-bearing Ores, including the processes of Concentration and Chlorination, and the Assaying and Refining of Gold. By M. Eissler, formerly Assistant Assayer of the U.S. Mint, San Francisco. With ninety illustrations. London: Crosby Lockwood and Son. Price 7s. 6d.

A Text-Book of Physiology. By Michael Foster, M.A., M.D., LL.D., F.R.S., Professor of Physiology in the University of Cambridge, etc. With illustrations. Fifth and thoroughly revised edition. In three parts. Part I. comprising Book I., Blood—The Tissues of Movement—The Vascular Mechanism. London: Macmillan and Co. Price 10s. 6d.

A Dictionary of Technical and Trade Terms of Architectural Design and Building Construction. Being practical descriptions, with technical details of the different departments connected with the various subjects: with derivations of, and French and German equivalents. Price 5s. London: Ward, Lock and Co.

DIARY FOR NEXT WEEK.

Wednesday, Oct. 24.—Institution of Mechanical Engineers, 25, Great George Street, Westminster, at 7.30 p.m.—Discussion of papers on *Description of Emery's Testing Machine*, by Mr. Henry R. Towne, of Stamford, Connecticut, U.S.A. *Description of the Compound Steam Turbine and Turbo-Electric Generator*, by the Honourable Charles A. Parsons, of Gateshead.

Thursday, Oct. 25.—Institution of Mechanical Engineers, 25, Great George Street, Westminster, at 7.30 p.m.—*Description of the Rathmines and Rathgar Township Water Works*, by Mr. Arthur W. N. Tyrrell, of London; *Supplementary Paper on the use of Petroleum Refuse as Fuel in Locomotive Engines*, by Mr. Thomas Urquhart, Locomotive Superintendent, Grazi and Tsaritsin Railway, South East Russia.

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

Good work is being done in the direction of so-called "Technical Education," which should rather be called *technological* education, to distinguish it from the true technical education which is given in the workshop. But my object now is not to discuss mere words, but to make a suggestion that I know from experience to be important.

During some eight or nine years I was the teacher of experimental physics and chemistry in the Industrial Department of the then infant Birmingham and Midland Institute, and pioneer of penny lectures to workmen. These were delivered regularly every week during about nine months of each year.

This, of course, brought me in contact with the most intelligent artizans of a town in which is included a greater variety of industrial avocations in proportion to its population than any other in the world. The friendly relations that I succeeded in establishing with my pupils enabled me to trace the effect of my teaching.

One of the directly useful results was that it enabled them to shift their occupations with far greater facility than was possible to the mere mechanical mechanic.

To those who are not practically acquainted with the condition of the modern artizan, such shifting of occupation may appear very undesirable. "The rolling stone gathers no moss," "Jack of all trades, and master of none," etc., may be quoted, but a further knowledge of what is daily occurring in our workshops would refute these proverbs and show that a large proportion of our most skilful artizans must be crushed by the progress of applied science, if only able to follow the particular trade or branch of trade to which they were originally apprenticed.

The trades of such men are being continually superseded or modified by such progress. The French platers and water gilders have been extinguished by electroplating and gilding; puddlers nearly so by Bessemer and other mild steels; bell-hangers by pneumatic and electric bells; engravers by photo-etching; and so on with a multitude of others. In Birmingham the gun trade is curiously variable, according to the prevalence of peace or war. Many others fluctuate with fashion. Thus the Coventry ribbon trade was ruined, but Coventry rose again to the surface by grasping at the bicycle.

But it is only the intelligent artizan or capitalist that can thus adapt himself to the rapid changes effected by modern invention and caprice.

Besides these who are thus liable to be improved out of existence, there is another class who should all start in their industrial career with at least two well-defined trades at their command. I allude to out-of-doors workers, who are dependent on the weather, or can only work at certain seasons. Masons, bricklayers, slaters, house painters, paper-hangers, gardeners, and many others are regularly out of work during a considerable part of every year. Some have a second occupation. A few understand the winter demand at gas works, for example. Some do a little snow sweeping, coal hauling, attendance on skaters, road making, etc , during winter; but a large proportion—a majority, I fear, are idle and worse. A very few understand the arithmetic of average income, live accordingly during the prosperous seasons, and keep a reserve for winter; but the usual bank is the pawnshop, with its ruinous usury, and the squalor of departed clothing and household goods just when they are most needed.

The demoralising effect of this enforced idleness and spasmodic prosperity is incalculable.

The possibility and advantage of varied occupation is strikingly demonstrated by the Norwegian peasant. His primary business is agriculture, the tillage of his own estate. But his summer has only a duration of three, four, or five months, according to the widely varying latitudes of that narrow strip of mountainous country. During the winter his fields are deeply covered with snow, and his only farm-work consists in the feeding of his cattle and horses, and working the snow plough over the share of national highway which the government compels him to maintain.

But he spends a merry, hard-working winter nevertheless. Though poorer as regards money income than the English bricklayer, he is prosperous and proud. He knows not the meaning of a pawnbroker, nor ever dreams of receiving charity visits from Lady Bountiful, or winter blankets or any other pauperising patronage —would scorn the suggestion of any such degradation. There are no workhouses in poor Norway, nor no demand for them, nor no claimants for out-of-door relief.

The Norwegian peasant is a Jack of all trades and a master of every one. He builds his own house, which for solidity and usefulness puts our jerry villas to shame. He is wheelwright, cartwright, blacksmith, farrier, cooper, cabinet-maker, carpenter and joiner, not only building his own house, but making all its fittings and solid furniture with his own hands. Some are shoemakers also, and many are wood-carvers of considerable artistic ability, some carving the hard ivory of the walrus tooth besides. The domestic cooperage is admirable. Those whose land comes to the shores of the fjords or lakes or rivers are also boat and ship builders, and knitters of fishing nets. Most of the agricultural implements are home made.

The watchmaking industry of Switzerland originated in an intelligent effort to provide a supplementary winter occupation for the peasant proprietors of the Cantons of Neufchatel and Vaud. In other parts wood-carving and similar domestic industries have been similarly adopted, and even the factory hands adjourn for harvesting.

Referring to the correspondence on the fecundity of sparrows that has lately appeared in these columns, I may mention a fact. I occupy a very old house, with a pair of old-fashioned wooden sun-blinds (*jalousies*) to each window. These were painted during the last spring, the work proceeding very slowly. The first step was to pull out the old sparrows' nests that were built in most of them. Considerable delay occurred—fresh nests were built and eggs laid—further delay—more nests and more eggs—and so on until I counted no less than five successive nests in each of the two places that I specially observed. In each of the fifth I destroyed four young birds. These vermin not only ravage our crops, but also drive away the useful insectivorous birds and the interesting song birds.

Some doleful paragraphs have lately "gone the round" of the newspapers. They relate to the colliers' strike for an advance of 10 per cent. on their wages, and the effect this will have on the price of coals in the course of the severe winter which is approaching. (Every coming winter is predicted to be severe in October, and as we have one or two severe winters in a decade, the prophets are sometimes triumphant.) Londoners have curious notions concerning the cost of coal, and many will be surprised to learn that an addition of 10 per cent. on colliers' wages will add about 3d. per ton to the price of coal. Colliers are paid by the ton of coal brought to the surface and screened into the waggons, usually by long weight, 22 cwt. to the ton. The price varies with the difficulty of working, but 2s. 6d. per ton is a full average. This should be understood, as we are threatened with a conspiracy to rig the market, and the advance of colliers' wages will be made a pretext for extortion by the conspirators.

THE UNSEASONABLE COLD.—In the night of Tuesday, October 2nd, a temperature of 22° F., *i.e.*, ten degrees of frost, was registered at Finchley.

THE ANCIENT INHABITANTS OF THE CANARY ISLANDS.

A PAPER READ BY MR. J. HARRIS STONE, M.A., BEFORE THE ANTHROPOLOGICAL SECTION OF THE BRITISH ASSOCIATION.

(Continued from page 406.)

THERE is one undoubted fact about the women, which stands out with greater prominence than any other—they were beautiful, very beautiful. When we remember that this description of them is frequently given by Spaniards who were accustomed at home to beautiful women of their own nation, we can confidently say that the women of this extinct race must have been exceptionally lovely. The priestly scribes of Bethencourt's expedition say, "The inhabitants of Canaria are tall, and look upon themselves as noble. They are handsome and well-formed people. Their women are very beautiful." Of Lanzarote, "The inhabitants are a fine race. The women are beautiful and modest." The women of Gomera were also noticeable for their beauty. We are told how Peraza, one of the Spanish leaders, became enamoured of a handsome Gomera girl, but who eventually betrayed him to her countrymen on account of his immoralities. At the present day, when travelling in Gomera, we were struck with the unusual beauty of the peasant women, especially in the centre of the island, where I strongly suspect much of the blood of the ancient race still lingers, though mixed with Spanish. In Valle Hermosa, for instance, the girls have perfect oval faces, generally dark eyes and a wealth of dark hair, fresh and delicate complexions, small well-poised heads, and shapely necks. Their figures are tall and well moulded, and carried with stately yet easy natural grace.

The marriage customs seem to have been different in the various islands. The Herreños were monogamous, and appear to have had no distinctions of rank, with the exception of the king, so intermarried freely. Every man wedded the woman he liked best, provided he could get her consent, and it was customary for the man when he chose a wife to make a present of cattle to her father, according to his ability, as an acknowledgment for his goodwill in letting him have his daughter. In this island the women worshipped a female deity, and the men a male. The ancient Gomeros, according to Azurara, regarded their women almost as common property, but this remarkable statement is not confirmed by the other narratives, and is contrary to what is elsewhere said ot the homely, domestic, and general moral character of the people. We must remember, too, that Azurara's account of this island was written before it had been conquered, and therefore it is unlikely that his informants knew much about the social habits of the natives.

According to Cadamosto, in Tenerife each man might have as many wives as he liked, and the same custom apparently existed which in England is said to have given rise to the curious tenure Borough-English. In Lanzarote, and perhaps in Fuerteventura, polyandry existed, a woman having as many as three husbands. In the other islands monogamy was maintained by law. None of the ancient Canarios had more than one wife, or the wife more than one husband, and the curious eastern custom existed of fattening the bride, here set apart for thirty days, with large quantities of milk and gofio.

ORIGIN OF THE RACE.

Whence came this singular race, the ancient inhabitants of the Canary Islands? Many have been the answers. Naturally they have been referred to the lost ten tribes. They are Assyrians, some of those who built the Tower of Babel. They are Jews specially banished to these Atlantic Islands for the purpose of being converted to Christianity. They are exiles from Africa, banished thence by the Romans, who cut out their tongues for blaspheming their gods—an explanation given as late as 1519, by one Thomas Nicols, who lived for seven years in the islands some thirty years after the conquest, and which is singularly enough mentioned by the Bethencourt chaplains as a tradition of the origin of the Gomeros. "This country is inhabited by a tall people, who speak the most remarkable of all languages of these islands, and speak with their lips, as if they had no tongues; and they have a tradition that a great prince, for no fault of theirs, caused them to be banished and had their tongues cut out; and, judging by the way they speak, one could well believe it."

There can be no doubt that the ancient inhabitants were highly civilised. Their customs, their habits, their traits, their laws, all indicate a civilisation that could not have sprung from a savage race, but must have been the gradual growth of ages.

The generally accepted opinion is that the natives found here at the conquest came from the neighbouring coast of Africa, and that their language and customs have affinity with those of the Berbers and Arabs. We know from Pliny's account of the travels of Suetonius Paulinus that there was a tribe called Canarii inhabiting a forest beyond the Atlas Mountains, and it may be suggested that members of this tribe, being the principal colonists, possibly named the whole group, and that consequently the inhabitants of the other islands were, for some time, called by tribal names, many of which survive to the present day. Mrs. Stone, in her "Tenerife and its Six Satellites," goes carefully into this subject of the names. She says, "Various are the constructions put upon these names, and the old names and modern are mixed in a manner difficult to unravel. Majo, which is said to be the ancient name of the people of Fuerteventura, has been converted into Majorero by the Spaniards, who also try to explain that Majo comes from a 'shoe,' referring to the curious foot-coverings of the natives. This is a poor explanation, for the shoes are similar to those worn in other islands. It is more likely to be from Majorata, the supposed ancient name of the island. Conejo, in like manner, is explained as a Spanish word, the inhabitants of Lanzarote being now called Conejeros, because of the number of rabbits in the island. It seems curious, if this explanation be true, that the Palmeros had not this name, as rabbits are said to be so plentiful in Palma. Titre-roygatra, which was the ancient name of Lanzarote, certainly does not seem to have any connection with Conejo. The names belonging to Tenerife admit of a tribal origin. Palma has quite lost its name of Benahoare, or Benehoave, and the present race are called Palmeros. As to Gomera, no one attempts an explanation, unless it be that it comes from Gumero, or Gomerita, a tribe mentioned by Leo Africanus as inhabiting the

HEAD OF GUANCHE MUMMY.

mountains of Mauritania. Numberless are the definitions of Hierro, already mentioned; but whether it comes from Hera, or Hero, the son of Gomer, according to P. Maestro Sarmiento, or Haoaros, another tribe mentioned in conjunction with the Gumeros, by Leo Africanus, or Hiero, who was a tyrant of Syracuse during the first Punic war, or none of these, is a matter not yet decided. But the signification of the names of the islands, renamed by the Spaniards as they are now known, is equally difficult of elucidation. There are no more palms in Palma than elsewhere. Fuerteventura is the least likely of all the islands to be considered as worthy of its name, 'fuerte,' strong or fort, 'ventura,' chance, luck, or, as some say, 'Buena-ventura,' good fortune. Viera states that Canaria is undoubtedly a Latin name, and draws certain deductions therefrom. This, however, is scarcely an argument, as, whatever names the islands or their inhabitants possessed, they would be Latinised by the conquerors."

While yet the islands are comparatively little known, let me, without laying myself open to a charge of pedantry, ask the public to call the islands by their right names. There is no reason for spelling Tenerife with two ff's. It is a four syllable word—Ten-er-i-fe. The large, round island is either Gran Canaria, or Great Canary, and not Grand Canary, as the daily papers have already barbarously started to call it in their "mails" list, since the cable to that island was opened. Still worse, however, is the mongrel appellation which is sometimes seen, "Grand Canaria."

From personal observation in the islands, it is probable that they were peopled originally by Berbers, but most likely by more than one tribe of that people, and I have little doubt that originally they were connected with the ancient Egyptians. The leaves of the laurel were placed on the head of a Guanche king at his coronation, and were similar to the lotus on the head of Isis. The "colocase," whose leaves are represented in Guanche designs, also are associated with the gods of Egypt. But there is a more forcible resemblance. There are only three nations known to have embalmed—the Egyptians, the Peruvians, and the people we are talking about. Many savage and semi-savage nations dried their dead, or smoked them, but the ancient people of the Canary Islands embalmed. "A judicious and inquisitive man," who lived twenty years in Tenerife, both as a physician and merchant, about the early part of the seventeenth century, says distinctly:—"The corps are sewed up in goats' skins. with thongs of the same, in a very curious manner, particularly as to the seams, which are incomparably even and exact." The mummies are embalmed similarly to those of the lower class of Egyptians, the incision for extracting the entrails being done with the "tabona," which, as in Egypt, was a stone of hard basalt. Galindo says their process was as follows:—"First they carried the body to a cave and stretched it on a flat stone, where they opened it and took out the bowels; then, twice a day, they washed the porous parts of the body, viz., the arm-pits, behind the ears, the groin, between the fingers, and the neck, with cold water. After washing it sufficiently, they anointed those parts with sheep's butter, and sprinkled them with a powder made of the dust of decayed pine-trees and a sort of brushwood, which the Spaniards called Bressos, together with the powder of pumice-stone; then they let the body remain till it was perfectly dry, when the relations of the deceased came and swaddled it in sheep or goat skins dressed, girding all tight with long leather thongs . . . . there were particular persons set apart for this office of embalming, each sex performing it for those of their own."

From other sources we gather that dragon's blood was an ingredient in the process.

I know of no Guanche mummy in England. At the British Museum, Mrs. Stone tells me she made inquiries and was shown as Guanche a mummy which was obviously Peruvian. In the museum of Tacoronte and Santa Cruz in Tenerife, there are several. Fig. 8 shows the head of one of the mummies in the latter museum. One at Tacoronte is in a very perfect condition, still encased in leather as it was found, with strips of hide, about an inch wide, tied and knotted round it. At the top, over the head, the mummy is tied up just as a sack's mouth is fastened.

Both the Egyptians and this nation used caves in which to lay their dead. The ornamental designs which I have seen—a good example of which are the marks on the painted cave at Galdar—are more Egyptian in character than anything else. Now, singularly enough, the Berbers lived in caves very similar to those used in the Canary Islands both formerly and now. Sir J. D. Hooker and Mr. Ball mention that when penetrating a defile known as Ain Tarsil, in Morocco, 3,000 or 4,000 feet above the sea, they saw caves some fifty feet above them, in the sides of the cliff, which they considered to be natural cavities enlarged by man. "The most singular point about these dwellings is the fact that they are all near the top of the cliff, where the rock is nearly vertical in position, that cannot now be reached without a ladder or other artificial assistance." This description would apply *exactly* to many caves in the Canary Islands, numbers of which are yet unvisited, owing to their inaccessibility. Messrs. Hooker and Ball did not enter any of these caves. I venture to suggest that some of them will be found to contain mummies similar to those of the Canaries. If so, the missing link between the ancient inhabitants of the Canary Islands and the Egyptians will have been found. Many points of resemblance are also noticeable between ancient Canarian words which have come down to us and similar Berber ones.

But going still further back we have good evidence that this people constituted part of the white dolichocephhalic race * which once extended through the British Isles, France, Spain, Northern Africa, Palestine, and Syria. The people of this aboriginal race, according to Professor Sayce, were distinguishable on account of their height and size, "and down to the time of David the gigantic descendants of the Anakim were still pointed out in the cities of the Philistines," whose height was "like the height of the cedars, and he was strong as the oaks" (Amos ii. 9). To this day in Tenerife the common expression for a tall, well-proportioned man is, "He is a regular Guanche." This race was a white-skinned, fair-haired people, which Professor Sayce says was characterised by the slightly retreating forehead and the peculiar nose, features certainly characteristic of the ancient inhabitants of the Canary Islands. Blue eyes and light hair are still to be continually met with in the most out-of-the-way spots.

* Upon the platform during the reading of the paper the author produced a Guanche skull. This Dr. Garson there and then measured and pronounced to be clearly dolicho-cephalic. He had not before seen the skull, and it had never before been measured

THE LAST OF THE GUANCHES.

The last we hear of the Guanches as a separate people is in the year 1532—thirty-six after the conquest —when Spanish delegates went to Spain to ask for the Inquisition to exterminate the remainder of those who were living, or rather merely existing in the inmost mountain recesses, and it is doubtful whether any pure-blooded survivor of the race now exist, for during my travels through the seven islands I came across none, though a sharp look out was kept. But it is very probable that in the natives now on the islands there is much of the old blood. During those thirty-six years, between the conquest and the advent of the dreaded Inquisition, there must have been much intermarrying between the two nations. The women of the ancient race were remarkable for loveliness; the Spaniards have never been pre-eminent for morality. An amalgamation of the two races has taken place. This admixture of Guanche blood in the islands to-day is evident from many plainly visible signs. The general character of the islanders struck me as being much softer, more simple, and more generous than that of the Peninsular Spaniards. There is a remarkable absence of bigotry and religious intolerance, and the peasants are imbued with a refreshing spirit of independence and love of liberty. That they have obtained from tariff-loving Spain the concession of free ports, is an example of their persistency and enterprise. Bethencourt found the Majereros "of large stature, powerful, and firmly attached to their form of government, very tall and difficult to take alive." Glas in his day noticed too that the natives of Lanzerote and Fuerteventura were of a noticeably large stature, and in my travels in those islands I observed the same. There is evidently more of the ancient blood in Hierro than in Tenerife. The old inhabitants of Palma were "a fine and tall people" and so they are to-day. As in the days of the Spanish conquerors, so now we found the Palmeros remarkable for their vivacity and wit, and some at any rate, of the quaint Palma costumes are very probably direct descendants of costumes worn by the ancient people.

The old inhabitants of Gran Canaria "are tall, and look upon themselves as noble. They are a handsome and well formed people. Their women are very beauful." A description generally applicable to the present inhabitants to-day. In this island it is recorded that the Spaniards slew a giant nine feet high.

The Conejeros are now, as they were before the conquest, "of a humane, social and cheerful disposition, very fond of singing and dancing." Many of the dances to be met with in the various islands are doubtless of Guanche origin.

The great inter-insular jealousy now existing between the islands reminds us very forcibly of the old days, and is perhaps a survival of the old feeling when there was no inter-communication among the islands, and when the natives of one island eagerly fought those of another when landed there by the Spaniards.

Beasts of burden were first introduced into the group by the Spaniards. Before that time all baggage must have been carried by men, probably on their heads. The pronounced development of the roughnesses and angularities for the attachment of the neck muscles, which I have repeatedly noticed on Guanche skulls, is confirmatory of this view. In the little-known island of Gomera the natives preferred to carry my portmanteau on their heads to trusting it to the baggage mule as in the other western islands, and this, too, for miles over very rough and laborious country.

A curious survival is the antipathy to blood-shedding. Butchers are looked upon as the lowest class of the com-

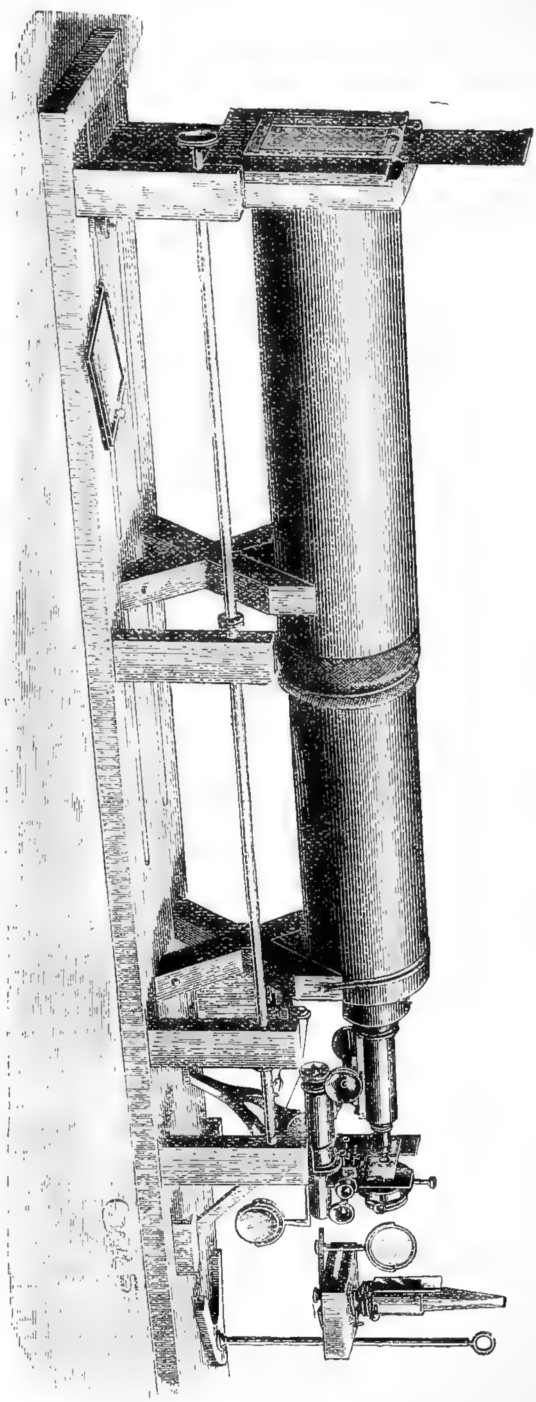

FIG. 6. (*See next page.*)

munity. Even the very criminals object to mix with them in prison, so that if convicted of misdemeanours they are whipped and not imprisoned. This horror of butchers, which is specially noticeable in Gran Canaria, dates from the customs of the *Antiguos Canarios*. Azürara says: "They held it an abomination to kill animals, and employed Christian captives as butchers when they could get them." And again, "Instead of killing their captives they thought it sufficient punishment to make them butcher their goats and skin them, and cut them up, an occupation which they looked upon as the most degrading that a man could be put to." Galindo states that it was made unlawful for the butchers even to keep company with any but those of their own profession; they were, in fact, treated just as lepers were by the Jews.

The ancient Canarians "showed remarkable faithfulness and honesty, for if one of them receives anything good to eat, before tasting it he divided it into portions, which he shared with the rest." This is a custom which we noticed in the other islands as well as in the Canaria.

Caves were regularly used by the ancient people, and to this day there are several inhabited troglodyte villages and separate cave dwellings, though now, as formerly, the natives excel in the art of dry-stone building.

The lancia, or leaping pole, was the usual means of rapid locomotion, and it is still used—particularly in Palma—by the natives with great expertness, the rapidity with which a Palmero will bound down a wild mountain side being most surprising. The natives used to catch fish in the night time by making a blaze on the water with torches of pine wood, and I have been out fishing with a man at night who employed identically the same process, doubtless in much the same manner as did his Guanche forefathers.

The modern rough pottery made in the islands closely resembles the old, so far as markings and shapes are concerned, but differs in not being so good in quality.

The general use of "gofio" is a most prevalent and noticeable survival from the days of the ancient inhabitants. Even the name of the food, the method of eating it, and kneading it in a gofio-bag made from a kid-skin drawn off whole, being the same. As in the old days, so now, it is the staple article of food.

A peculiarity in Canaria deserves record, as through the ancient Canarians it may have come down from the ancient Egyptians. I allude to a curious and emphatic way of saying "no" without speaking, by looking at the interrogator and rapidly moving the forefinger in front of and across the face.

A method of laying out the dead by placing one hand across the breast and the other along the side with the fingers turned out, is exactly the same arrangement as is seen in some of the mummies.

A Hint for Future Travellers.

Since we visited these island a tide of visitors has set in that direction, and future travellers may reasonably be asked to pay particular attention to, and to record, any other traits and habits of the peasants which strike them as being inherited from the old race; to explore caves, and to look out for their presence even in what are now inaccessible places, and if any mummies are found, to see that they are not treated as was that which was presented to the College of Surgeons.

Much remains to be done by original research in the islands; and important additions to our knowledge about this extinct people may be expected from the practical observations of travellers.

The Guanches have gone the way of the Dodo and the Mammoth—too gentle, unresisting, and antiquated to combat modern civilisation; and like them are now only visibly represented by specimens in museums. If I have imbued some of these dry remains with the elements of life, my purpose is served—to awaken interest means eventually to advance knowledge. I hope future travellers will be able to tell you much more about the Guanches than it has been possible for me to do.

Note.—The title to fig. 5 (p. 405) should read, "Two Pieces of Guanche Pottery, and Two Gofio-mills."

SOME PHOTO-MICROGRAPHIC APPARATUS.

(Continued from p. 403.)

In fig. 6 is shown a form of photo-micrographic camera, designed by Mr. E. M. Nelson in conjunction with Mr. C. L. Curteis, and made by Mr. C. Baker, of High Holborn.

The camera has been specially designed for use with Professor Abbé's new three-power projection eye-piece, specially corrected for use with Zeiss' apochromatic objectives, and the camera is so arranged that when closed the magnification given by the three-power projection eye-piece is equal to nearly five times the initial magnifying power of the objective used, or an equivalent to the power obtained with an "A" eye-piece, whilst, when fully extended, it gives ten times the initial magnifying power of the object-glass, or the equivalent magnification produced by the use of a "C" eye-piece, a degree of magnification which it is not advisable to exceed.

The accompanying woodcut shows very clearly the whole arrangement. The camera is constructed to take a plate $4\frac{1}{4}$ by $3\frac{1}{4}$, and consists of two cardboard tubes, the one sliding into the other, like the tubes of a telescope, the joint between the tubes being made light-tight by means of a velvet flap, fastened down by an india-rubber band. The light excluding cap is made of cardboard covered with leather, this being found to be quite as efficient as, and not so heavy as, a brass fitting. The outer cardboard tube is fixed to a vertical standard which can be secured to the base-board, at any point within its range, by means of clamp screws working through slots. The focussing screen slides into the back of this standard, which is provided with suitable grooves to receive it.

The focussing arrangements are essentially similar to those previously described.

Archæological Discovery.—An archæological discovery of great interest has been made in the tidal river Hamble, near Botley, Hants. A boathouse is being built at the point of the junction of the Curdridge Creek with the river, some little distance above the spot where there is a still existing wreck of a Danish man-of-war. In removing the mud and alluvial soil to make sufficient waterway, something hard was encountered, which on being carefully uncovered proved to be a portion of a possibly pre-historic canoe—certainly pre-Roman. It is a few feet higher up the river than the old Roman hardway or landing place, and was evidently sunk close to the shore. It is about 12 feet long by $2\frac{1}{2}$ feet wide, beautifully carved, and in a fairly good state of preservation. Some question of ownership is likely to arise, as it was discovered below high-water mark. The adjacent land teems with fragmentary specimens of Roman pottery, bricks, etc., and it is anticipated that the explorations will lead to further discoveries.

General Notes.

Temperature at Cairo. — The average maximum temperature for the week ending July 19th was $106\frac{1}{2}$ degs. F., and the extreme heat $114\frac{1}{2}$ degs. The lowest temperature registered was $72\frac{1}{4}$ degs.

Effects of Unwholesome Water.—According to a medical contemporary, the death-rate at Cairo is now 73 per 1,000. This mortality is ascribed to the polluted water of the Nile being used for drinking.

The Prevention of Sea-Sickness.—According to the *Bulletin Medical*, antipyrine has no effect upon sea-sickness. The *New York Medical Record* proposes oxalate of cerium, given in 15-grain doses every two hours. *Science* recommends that the projecting region behind the ears should be rubbed vigorously with the fingers.

Exploration in Morocco. — We learn that Mr. Joseph Thomson is at Tangier on his way home from Morocco, having been offered an important mission. Mr. Harold Crichton Browne, who is at Rabat, will carry out alone the remainder of the Morocco expedition as originally planned. He proceeds at once to Mequinez and Fez.

Physiological Instruction in the United States.—It appears (*Science*) that in twenty-five out of the thirty-eight States, and further, in all the territories and the district of Columbia, "instruction in physiology and hygiene, with special reference to the effects of stimulants and narcotics, is made compulsory by statute on all pupils in some part of their school life."

Colour-Hearing.—Mr. J. A. Maloney, after describing in the *New York Medical Journal* and in *Science* some interesting experiments on the conduction of sound-vibrations by the bones of the skull, asks:—"May not colour-hearing, in view of the readiness with which the sphenoid bone takes up and delivers vibrations, be due to mechanical stimulation of the optic nerve by the impingement upon it of the sphenoid bone in its passage through the optic foramen?"

A Novel Falsification of Food.—M. van Hamel Roos (*Cosmos*) has recently detected at Amsterdam 30 per cent. of marble dust in ground rice imported from Italy. In Haute Vienne, one of the most extensive millers of the district has been found to have mixed carbonate of lead with his flour. This fraud gives the flour a fine appearance, renders it whiter, and enables the dealer to pass off inferior qualities. The consumer is, of course, liable to the miseries of lead-poisoning.

Dangerous Cookery.—According to the *Medical Press*, a lady at Tournai treated her guests to a very tasty dish of *beignets aux fleurs d'acacias*, the prescription for which she had taken from the family cookery-book. Eleven persons partook of the dish, and soon after all of them showed symptoms of poisoning—vomiting, cerebral excitement, dilatation of the pupils, etc. The supposed "acacia flowers" were flowers of *Cytisus Adami*, a variety of the common laburnum, every part of which is poisonous.

The Green Colour of the Sea.—According to Pouchet (*Comptes Rendus*), the green colour of the sea in many parts is due to the presence of numerous diatoms, radiolaria, etc. The microscopic organisms contain *diatomine*, a yellowish-brown colouring matter, and this yellow, conjointly with the natural blue of the water, constitutes the green colour observed. Pouchet was led to this view by the fact that *Pelagia noctiluca*, which has a yellow colour, appears green when immersed in the sea.

The Cork Industry in Spain.—The British Consul at Barcelona, in a report just published, states that in some places the cork trees have been suffering from the invasion of a pest which threatened to destroy them. A voracious caterpillar appeared by millions in the cork forests, and in a very short time stripped the trees of all the leaves from the tips of the branches to the trunks. These caterpillars are now in their turn attacked and devoured by another insect, a species of beetle of a dark-green colour. Another insect in the form of a crab (*cangrejo*) pursues the caterpillars and destroys them. Moreover, when the caterpillar has passed through its metamorphosis and the butterflies have deposited their eggs, another insect, until now unknown, attacks and pierces the bags containing the eggs and destroys them. It is hoped that by means of these three agencies the complete extinction of the destructive caterpillars may be accomplished.

The Electrical and Allied Trades.—On Monday last a meeting was held at the offices of the London Chamber of Commerce, Eastcheap, for the purpose of completing the organisation of the electrical trade section of the Chamber, with the object of dealing effectively with questions of general interest relating to the trade. Mr. W. Crompton was voted to the chair. The organising committee, appointed at the meeting on the 27th of July last, brought up a report, in which they recommended that a working or executive committee—elected annually by the general body of the trade—should be charged with the ordinary business of the section, and that in the first instance it should consist of thirty-three members, to be increased to forty-eight at the first annual meeting, if the membership then obtained should warrant a larger representation. With a view to an equitable representation on the working committee of the various branches of the electrical trade, the organizing committee recommended the division of the working committee into the following subsections:—Telegraph companies, 5 members; telephone companies, 3 members; electrical supply companies, 6 members; electrical manufacturers and contractors, 13 members; consulting electrical engineers, 4 members; and "general," two members. On the motion of Mr. Reeves, seconded by Mr. Brown Martin, the report was adopted; and on the motion of Mr. Rawson, the working committee were authorised to elect their chairman and vice-chairman, if they wished to do so, from outside their own body. The election by ballot of the working committee was then proceeded with.

The Invention of the Microscope.—This subject has recently been discussed at a meeting of the Paris Academy of Sciences. By general consent the invention of the compound microscope is ascribed to Drebbel, unless he derived his knowledge of the instrument from Jansen. M. Govi considers that the true inventor was Galileo. From 1610, that is eleven years before the invention of Drebbel, the Italian savant is supposed to have used his telescope for viewing very small objects, which he then saw highly magnified. In 1614, Dupont, Lord of Tarbes, relates among the incidents of a journey in Italy, that Galileo had thus given to flies the apparent bulk of lambs, and ascertained the presence of innumerable hairs on their bodies and of pointed claws on their feet. When the Dutch invention penetrated into Italy in 1624, Galileo attempted a reclamation of priority, but soon finding that his attempts were overlooked abroad, he preserved in future silence on this great question, despite the distinctness of the facts established by M. Govi. M. Emile Blanchard persists in thinking that the true inventor of the microscope is not easy to discover.

Restoring the Colour of Faded Flowers.—In spite of all care taken, it often happens that flowers lose their odour during drying. We quote, therefore, the following two processes, given by M. Capus, in *Le Naturaliste*, which it is asserted will revive the colour to a certain extent. Red flowers especially, which have turned blue or violet, may be restored to their primitive colour in the following way:—A slip of white blotting paper is steeped in very dilute nitric acid (1 part acid to 10 or 12 of water). The flower is laid on this slip, and the whole is enclosed between several folds of dry paper and submitted to a moderate pressure for some seconds. At the end of this time the original colour will generally be found to have re-appeared. All flowers do not require the same pressure nor the same strength of acid. If a flower is too pale after the operation, it is because the acid is too weak or the pressure too strong. If the green leaves of the plant come in contact with the acid they lose their colour. Dried plants may also be divided into small lots and placed in a box in which sulphur is burnt. We look upon this latter process with considerable suspicion, on account of the well-known bleaching action of sulphurous acid.

The Public Health.—The Registrar-General's return for the week which ended on Saturday, October 13th, states that the deaths registered in 28 great towns of England and Wales corresponded to an annual rate of 21·0 per 1,000 of their aggregate population. The six healthiest towns were Birmingham, Brighton, Bristol, Derby, London, and Wolverhampton. The highest annual death-rate, measured by last week's mortality, were:—From measles, 1·1 in Huddersfield; from scarlet fever, 3·1 in Blackburn; from whooping-cough, 1·1 in Derby and in Manchester, 2·4 in Cardiff, and 2·9 in Huddersfield; from "fever," 1·2 in Salford; and from diarrhœa, 2·8 in Norwich, 3·2 in Wolverhampton, 3·4 in Portsmouth, and 3·5 in Preston. The 45 deaths from diphtheria in the 28 towns included 26 in London, 5 in Manchester, and 3 in Newcastle-upon-Tyne. The only death from small-pox in the 28 towns occurred in Hull. In London 2,588 births and 1,536 deaths were registered. Allowing for increase of population, the births were 122 below, while the deaths exceeded by 13, the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had been 15·8, 16·0, and 16·5 in the three preceding weeks, further rose last week to 18·7. In Greater London 3,438 births and 1,896 deaths were registered, corresponding to annual rates of 32·4 and 17·9 per 1,000 of the estimated population. In the Outer Ring 14 deaths from diarrhœa, 9 from measles, 8 from diphtheria, and 6 from scarlet fever were registered. Of the fatal cases of diphtheria, 3 occurred in Croydon, and 2 in Walthamstow sub-districts. The 6 deaths from scarlet-fever included 3 in West Ham sub-district.

Globe Lightning.—M. Reimann has recently published some interesting observations on globe lightnings witnessed at Hirschberg, in Silesia, during the storms of the 19th and 29th of April, 1888. *La Nature* gives an abstract of the phenomena from the *Bulletin de la Société Météorologique de France*. Two such globes were seen during the former storm. A woman and her son were at two different windows in the third storey of their house in the Wilhelmstrasse and the Inspectorstrasse. A yellow ball of fire, of the size of a skittle-ball, appeared advancing slowly on the telegraph wires, with a slight noise like that of a flag shaken by the wind. It descended in the middle of a square covered with grass; it then rose up and moved forward, flying higher and more rapidly than before, and passing over the houses of the Inspectorstrasse in a S.S.W. direction. The second ball was seen by another woman, about 4 p.m., from a window looking to the east. The globe of yellow fire advanced very rapidly from the Franzstrasse towards the window, at a distance of 20 to 25 metres, moving from south to north. It passed over the Bahnhofstrasse, and rose upon the roof of a house provided with a lightning conductor, leaving no traces. Its size was about that of a child's head. It was followed by a series of smaller globes like billiard-balls. No sound was heard. The storm of April 29th was extremely violent, and several remarkable flashes were observed. A woman saw a large brilliant ball fall perpendicularly from a cloud over Hirschberg, and break up into several fragments, which disappeared in the air. Another globe-discharge in the storm was very similar to that of the 19th. It was observed by the gardener of the Gymnasium, who was in an arbour of the garden, and by a girl from a window in the Inspectorstrasse, at a distance of 50 to 60 metres from the Gymnasium. The globe traversed a space of about 100 metres. Said the gardener:—"It was a globe of reddish fire, which advanced suddenly from the roof of the Gymnasium with a hissing noise, and burst over the trees of the garden without an explosion. The fragments descended to the left and the right, and disappeared in the air, leaving no traces." The girl saw suddenly, to her right hand, on the house opposite, a ball of fire which advanced rapidly towards the corner of the Gymnasium and rose to the angle of the roof, where it burst without noise. It was about the size of a child's head. The author relates another observation communicated by Herr Rudeck, of Wigandsthal, near Freiburg. On May 14th, during a storm which lasted four hours, about 5 p.m. fifteen persons saw a ball of fire of about the size of a soup-plate, and of a dazzling whiteness, which appeared over Rudeck's house, illuminating the house and the court. It descended perpendicularly, and rested on a tree in the court, at 1½ metres from the house. Several observers saw lightning issuing from the branches and moving towards the lightning conductor. At the same moment two servant girls rushed into Herr Rudeck's sitting-room screaming that there was a ball of fire in the kitchen. It left behind no traces. The phenomenon was accompanied by a peal of thunder.

MARS AND ITS "CANALS."

DURING the last few years the attention of astronomers has been increasingly drawn to certain curious phenomena observed in the planet Mars. These appearances are of the higher scientific value since two only of the heavenly bodies, Mars and Venus, are likely to throw fresh light on the important question in how far any of the other planets may resemble our earth? Mercury is too small, too distant, and too much lost in the sun's rays to afford us any evidence. The exterior planets Jupiter, Saturn, and the rest seem to belong to a totally different class of bodies.

Of the only two planets which remain, Mars offers us the better facilities for observation. Though smaller than Venus, and at a greater distance from the earth, he is at times seen "full," whilst Venus never turns to us more than a portion of her illuminated disc, like the moon about the first quarter. Hence the importance of a thorough scrutiny of Mars. A long time ago it was discovered that around the poles of this planet there exist whitish "caps," which increase or decrease periodically with the season of the year, and which at once remind us of the snowy regions investing our north and south poles.

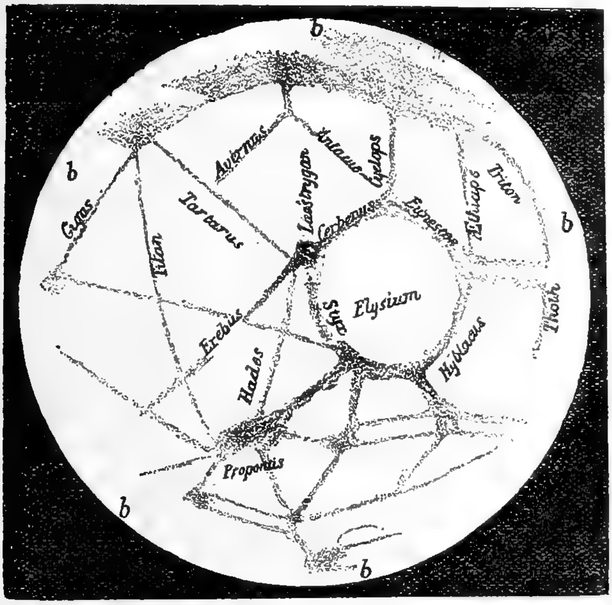

FIG. 1.—MARS AS IT APPEARED ON THE 8TH, 9TH, AND 10TH OF MAY, 1888. (AFTER SCHIAPARELLI.)
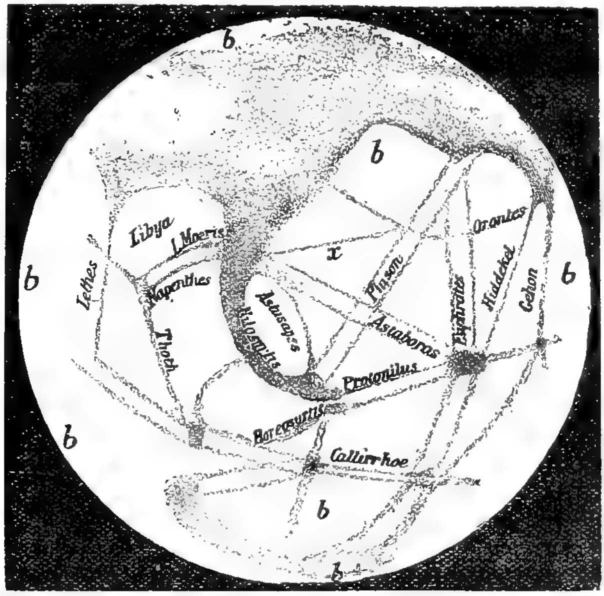
b. White spaces.



MARS AS IT APPEARED ON THE 2ND, 4TH, AND 6TH OF JUNE, 1888. (AFTER SCHIAPARELLI.)
b. White spaces.

Further, there appear on the disc of the planet spots fairly permanent in their outline, and differing in their colour. There are sombre regions which are supposed to be seas, and there are also brighter tracts of a reddish colour which astronomers regard as continents. The land and water, if such they be, as we may provisionally assume, differ both in relative proportion and in configuration from those of our earth. Our ocean occupies at least two-thirds of the earth's surface, and our land is mainly grouped in two large masses, beginning near the North Pole and extending southwards. On Mars the proportions of land and water are nearly equal, and we find, as the late Mr. Proctor puts it, a great number of long and narrow necks of land and of seas, shaped like the neck of a bottle.

We have been thus obliged to premise facts, doubtless well known to the majority of our readers, for the better comprehension of what is to follow.

Such was the state of our knowledge of the surface of Mars when in 1877 Professor Schiaparelli, an Italian astronomer, discovered what are now known as the "canals." The continents of Mars are intersected with lines, most frequently straight, sometimes fine, very dark and distinctly traced, sometimes broader and misty, sometimes black, sometimes grey, blueish, or reddish. These lines seem to place the seas in communication with each other, and they cross and re-cross each other, forming at certain points knots which the telescope has not succeeded in disentangling. In some regions these lines —canals or whatever they may be—display slight windings resembling those of our rivers, though in a much less pronounced degree.

A general notion of the aspect presented by Mars, as seen with a powerful telescope, may be formed by an examination of figure 1, for which we are indebted to our contemporary *Ciel et Terre.*

Strange to say, this discovery of Schiaparelli was received at first with almost as much incredulity as was bestowed upon Galileo's early observations of the phases of Venus, of the moons of Jupiter, or of mountains in the moon. The canals were pronounced by some to be mere illusions due to defects of the telescope or to atmospheric peculiarities. But when other observers confirmed substantially Schiaparelli's results, using other instruments, this sceptical attitude was, of necessity, abandoned.

The next step in the study of a phenomenon, which has been rightly called mysterious, was again taken by Professor Schiaparelli in 1881-82. At that time Mars was in opposition, its entire illuminated disc being turned towards us. Utilising this favourable circumstance, the Italian astronomer observed that nearly all the canals appeared double. This phenomenon, spoken of technically as their *gemination*, requires to be precisely described. Alongside one of the old canals, or at least of one of the canals as they had been previously seen, there appeared a new one (*i.e.*, one not seen before), in most cases strictly parallel to the former, and terminating not at the same points, as if the old canal had been merely resolved into two components by the use of a more powerful instrument, but leading to neighbouring points, as if a new canal had been dug parallel to the former. The totality of these parallel or twin lines, intersecting each other too in all directions, seemed like an inextricable net. A superficial examination might lead to the conclusion that the original state of the surface of Mars had been entirely overturned. Such, however, is not the case; the old lines can be exactly identified, though each is accompanied by a new line. Hence the new map is something like what the old one would look if viewed through the medium of a doubly-refracting crystal, such as Iceland spar.

The discoveries of Schiaparelli had been made with the excellent 8-inch equatorial by Merz, in the possession of the Milan Observatory. But more powerful means were soon placed at his disposal, and in 1886, when Mars was again in opposition, he was able to examine the planet with an 18-inch telescope by the same maker and of the same excellent construction.

In the same season M. Perrotin, of the Nice Observatory, examined Mars with the 38-centimetre ($=7\frac{1}{8}$-in.) equatorial. After several attempts he succeeded in detecting the gemination of many of the mysterious lines, and his observations were checked over by M.M. Thollon, Gautier, and Trépied. Thus was obtained a full confirmation of the beautiful discoveries of Schiaparelli on the singular physical constitution of Mars.

(To be continued)

LUMINOUS OR SILVERY CLOUDS.

According to the opinion of Professor W. Kohlrausch, the luminous phenomena in the sky from November, 1883, to the summer of 1884, during which time splendidly illuminated clouds appeared with great frequency, were produced by volcanic eruptions, although it may also be assumed that the matter of these luminous clouds came from the regions of space. O. Jesse (*Meteorologische Zeitschrift*, v. p. 90) considers the former view the more probable; and, without professing to give a final decision on the whole question, he endeavours to explain the striking fact that between the first appearance of the intense purple light and the first occurrence of the luminous clouds an interval of eighteen months could elapse.

According to Jesse, the luminous clouds consist of a number of minute crystals formed from certain very light gases of unknown nature under the influence of the low temperature of the upper regions of the atmosphere.

As Verbeck assumes, the mass hurled up from Krakatoa, which, on May 20th, 1883, reached a height of more than six miles, attained on August 26th-27th an altitude of from ten to twelve miles, a calculation which agrees fairly with the results of O. Jesse, who determines the height of the luminous stratum of vapour at about eleven miles. Without question the matter ejected from the volcano consisted of solid particles of dust, and also of gases. The latter, with the exception of the condensed watery vapour, were diffused in the air. These gases, in consequence of their rapid ascent, were diffused not in the lower but in the upper regions of the air, and were then lost in space, if we admit that there is no hard and fast boundary between space and our atmosphere. Such a gas, whose point of condensation was not too low, might in consequence of this ascent arrive in regions of such a temperature that it would become liquified. By the rapid evaporation of the liquid thus formed we have a further reduction of temperature and a consequent formation of crystals. In the strata where this crystallisation takes place, the atmospheric air will be freed from the foreign gases, so that further quantities of the same may make their way upwards from the lower strata. It is plain that the gas in question may even be heavier than atmospheric air, but in consequence of the mutual interpenetration of gases it may still arrive at very great altitudes, though more time must elapse before the stage of crystallisation is reached.

After the congelation the crystals fall down into lower and consequently warmer regions of the air until again an evaporation and an ascent takes place. These circumstances may be sufficient to explain the extremely rapid changes of form of the luminous clouds.

More difficult is the explanation in what manner the scattered crystals arrange themselves in large masses so as to form a luminous cloud by the coalescence of minute corpuscles. Here then come into play processes similar to those, in consequence of which thinly-scattered particles of vapour are agglomerated to form sharply defined thunder-clouds. For the coalescence of the widely diffused crystals a considerable time must be required, and we may thus understand the long interval between the eruption of Krakatoa and the first appearance of the luminous clouds.

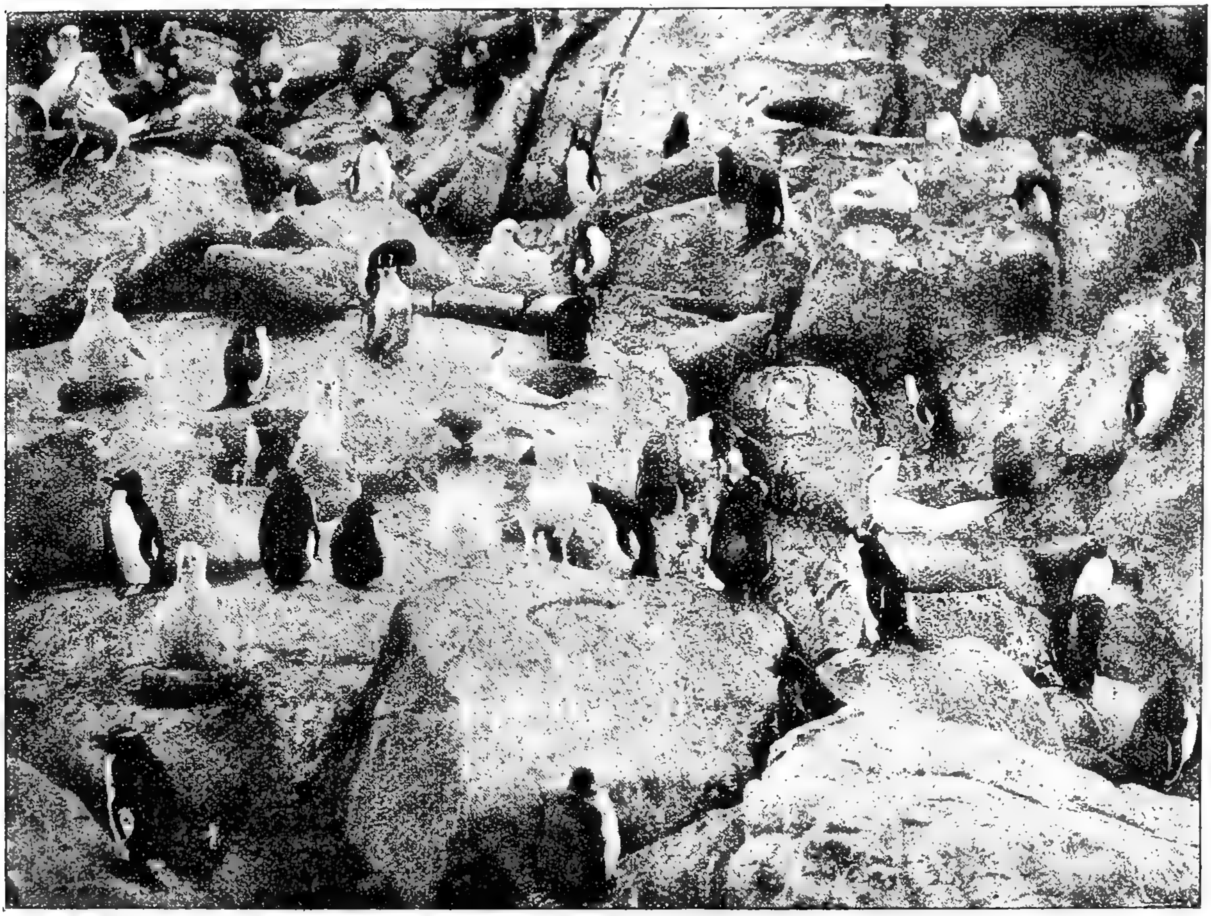
Jesse seeks to explain, further, the periodic appearance by the luminous clouds. Encke had formerly explained the prolonged revolution of the comet bearing his name by the supposition that space contains a resisting medium. William Siemens, in order to account for the constant renewal of solar energy, makes use of the hypothesis that the general space of our solar system is filled with gases which must be regarded as a continuation of the atmosphere of the sun and the planets. At the same time we may assume that the air of the interplanetary space lags behind the planets in their revolutions round the sun. Every planet will then experience a continual, but slow and partial, renewal of its atmosphere. In this manner the hemisphere which is turned towards the direction in which the earth is moving undergoes a constant afflux of matter from the regions of space, whilst from the opposite hemisphere there takes place a constant efflux. In the atmospheric strata, at from six to about sixty miles above the earth's surface, there may be a slight current in the direction opposite to her motion which carries along the minute solid particles suspended in the air. It would, therefore, be probable that the luminous clouds which since 1885 have been regularly seen in the months of June and July will be visible for half a year in the south temperate zone. It deserves notice that at the time of the Krakatoa eruption the north pole was turned towards the direction of motion of the earth, whence, in accordance with the above suppositions, the vapours of the eruption would extend more to the south than the north.

The above hypothesis does not explain the fact that since their first appearance the luminous clouds have considerably decreased. It is possible that the gas has entered into combinations which no longer admit of its ascent, or that the crystals formed in the upper regions of the air have been carried away by the above-mentioned current.

Natural History.

PENGUINS AND MOLLYHAWKS.

The penguins (*Aptenodytes*), a sub-family of the natatorial birds, represent in high southern latitudes the auks and divers of the north. Confined exclusively to cold regions, they abound in the Antarctic seas, and are so numerous that Dr. Bennett estimates the number of these birds on one island alone—Macquarrie's Island, in the South Pacific—to be at least from thirty to forty thousand. Sir James Clark Ross, in his "Voyage of Discovery in South and Antarctic Regions," mentions the immense numbers of penguins which surrounded him on all sides when he took possession, in the name of Her Majesty Queen Victoria, of the then newly discovered land Possession Island (now known as Victoria Land). He does not seem to have been greatly impressed by the appearance of the new annexation; the rocks were bare of vegetation, and there was nothing to be seen in any direction but penguin, penguin, *toujours* penguin. As these feathered inhabitants obviously objected to any sort of interference, manifesting their displeasure by vigorous pecks and blows, and as the odour from the guano, the accumulated deposit of many ages, was anything but agreeable, Sir James and his party were nothing loth to beat a hasty retreat from so inhospitable a shore. Mr. W. Dougall, of Invercargill, New Zealand, seems to have had a somewhat similar experience in his trip with Captain Fairchild in the *Stella* to the Auckland, Bounty, and Campbell Islands, in January of the present year. On every island they touched upon, penguins, mollyhawks, albatrosses, and ice-birds were in proud possession, and on the Bounty Islands, a compact group about 130 miles from the Antipodes Islands, consisting wholly of bare rocks absolutely destitute of vegetation and covered with guano, these birds, especially the two former, teemed in perfect myriads. Mr. Dougall succeeded in taking a series of photographs of these islands, although, owing to the slipperiness of the guano, he found it a matter of no slight difficulty both to get the camera safely to any point of vantage and to keep it steady when there. The fourteen islands which form the groups average about thirteen acres each in extent, and Mr. Dougall asserts that there must have been at least a dozen penguins on every square yard, while the water around was simply alive with them.



Penguins and Mollyhawks on the Bounty Islands.
(From an Instantaneous Photograph taken by Mr. W. Dougall, of Invercargill, N.Z.)

On the shores of South Patagonia these birds abound in such numbers that 300 have been taken within an hour, while in an islet in the Straits of Magellan Captain Drake's crew once killed more than

3,000 in one day, a statement which, in spite of its magnitude, may yet be accepted with a fair amount of credulity, since these navigators were probably the first human beings to set foot on the island, and the birds had been free from molestation for unknown generations.

The penguin rarely quits the vicinity of land, never appearing at great distances out to sea, and are in the habit of forming perfect little colonies in their island homes.

During the Transit of Venus Expedition to Kerguelen Island the Rev. A. E. Eaton, naturalist to the expedition, found that some of the penguin colonies only contained about twelve nests, while others had from 70 to 150, and some of the officers visited a very populous "penguinery," which contained about 2,000.

These large communities were approached from the sea by well-worn paths, almost like sheep-tracks. Dr. Bennett has a theory that the sitting hens, young birds, moulting birds, and clean birds all form distinct classes of the community, and that the line of demarcation between the several classes is strictly defined, no clean bird, for example, being allowed to assort with a moulting bird. The nests are of simple construction, generally a mere hole scraped in the ground, lined with a few dried leaf-stalks and seed-stems of the *Pringlea*. The female seldom lays more than one egg, greyish white in colour, and this egg she never leaves for many moments until it is hatched. She holds it close to her thighs, and if approached during incubation she briskly, if inelegantly, waddles off, carrying her egg with her. During this time the male bird goes to sea for food for the female, who soon grows fat, but as soon as the young bird is hatched both parents go to sea in search of food, and the young bird grows fat in proportion as the old ones get thin. Captain Fitzroy declares that the old birds, when they arrive with the food supplies, solemnly get on a little eminence and make a great noise, between quacking and braying, as if haranguing the penguinery, only interrupting the thread of their discourse to allow the young ones to take their food. Although at first the penguins seemed to have had not the slightest fear of man, they are apparently beginning to associate his appearance with discomfort, if not with death, and the male birds now sometimes take to flight. The females only run a very little distance, often turning round to see how matters are proceeding, and generally returning at once to the nest. The young apparently do not object to strangers, and prefer remaining in the nest, submitting with perfect willingness to be stroked by the intruder, however much the anxious mother may peck at his legs and otherwise betray her disapproval of his presence. A little later in life the youngsters when returning to the nest at night will sometimes linger behind, but are sharply rebuked by the community for such irregular proclivities, all the penguins safely at home giving the truant latecomers severe digs and pecks as they pass them on their homeward way. Mr. Eaton states that the penguins, or "Johnnies," as the whalers call them, are very regular in their habits, repairing every afternoon, when their fishing operations are over, to the shore, where they land in small parties at their accustomed places, and rest quietly on the beach with their heads sunk between their shoulders and their bills up in the air, much after the fashion of very young thrushes. They will commence the ascent to their homes with great energy, but soon begin to slacken their pace, and when once thoroughly tired out no amount of persuasion, even if administered with suasive force by the toe of a boot, will induce a penguin to continue his journey until he chooses. If knocked right over, the "Johnnie" will only pick himself up to peck at the offending boot; and if further measures be resorted to, he simply turns tail, and betakes himself headlong to the sea. A penguin's gait is not as dignified as its erect appearance might lead one to suppose. Its legs are very far back, and its feet broad, almost like the sole of a quadruped's foot, so it stands extremely well, but at each step its body turns from side to side, its feet almost crossing each other, with a decidedly inelegant effect. Its little wings, utterly ineffectual though they be for flight, are not only very powerful swimming agencies, but act as very efficient fore-feet in an emergency on land, and if greatly alarmed a penguin makes off, literally on all fours, with such speed that a careless observer might easily mistake the bird for a low-bodied quadruped. In colouring the penguin is almost a harmony in black and white. The upper part of the head and throat is black; the back dark bluish grey, so dark as to be almost black; the under surface pure silvery white; the bill black; legs and feet black. The one touch of colour is supplied by the broad band of light yellow which runs down the side of the head, narrows towards the middle of the throat, and then merges on either side into the dazzling white of the bird's breast. Its feathers are all set in the peculiar fashion common to the natatores, or swimming birds, and together with the thick under-coating of down, render it impervious to cold and wet. The penguin invariably sits erect in its roosting-place, and unless agitated or hurried, walks upright to the sea, where it throws itself on its breast to encounter the rough seas that break over those shores. The cry of the penguin somewhat resembles the bark of a fox, and the combined noise from an army of penguins is something considerable; indeed, their nocturnal cries have sometimes served as timely warnings to navigators steering in the wrong track. The total length of a penguin averages about three feet, its tail being so rudimentary that it counts but little in the measurement, and the weight averages from thirty to forty pounds. There are several species of penguins, the handsomest being probably the Crested Penguin (*Eudypes chrysocoma*) of Patagonia, a bird with a fine crest of yellow feathers, which it can erect or depress at will, and with a strange habit of throwing its head backwards when on land, and making an extraordinary loud noise, not unlike the braying of an ass, which has gained for it the name of "Jackass Penguin" among sailors.

The Mollyhawk in our illustration is the Antarctic skua (*Stercorarius antarcticus*), a strong, rapacious brown bird, of the family *Laridæ* (gulls), closely akin to the common skua (*S. catarrhactes*) of the Shetland Islands. The Rev. A. E. Eaton states that during the above-mentioned expedition the skuas were at first very plentiful on Kerguelen Island, but were destroyed in great numbers by the sailors, not in mere wantonness, but in self-defence, for the bird had a menacing habit of "swooping with fierce impetuosity directly towards the face of any one approaching their domain, rising only just in time to clear his head, and uttering sharp, despairing cries." As the sailors learnt their method of attack, they simply held a knife, point upwards, above their heads when searching for eggs, and on this knife the skuas would often transfix themselves in their fierce downward swoop. They never, like the skuas in Spitzbergen, feigned to be helpless and crippled to avert danger from their nest, but preferred, at all costs, their intimidation tactics. If they thought they had succeeded in driving away the enemy, they would stand face to face upon the rock, flapping their wings and uttering loud croaks, as if in triumph over their victory. They sometimes croak during flight, their notes much resembling those of the raven or crow; and as their flight also bears some slight resemblance to that of crows, they are sometimes known among sailors as "black crows" and "sea crows." Their more general *sobriquet*, however, is that of "Mollyhawk," from their hawk-like persecution of the petrels, or "Mollies," their staple article of food, though they devour indiscriminately fish, mollusks, birds, or small animals. They chase the petrel by day at sea, killing it while on the wing, and in the evening hunt for them along the shore, flying low and rapidly, ready to pounce like hawks upon any unfortunate petrel emerging from its burrows. This course of conduct they pursue early in the morning as well, and as they are skilful in robbing the petrel's eggs, besides killing the bird itself, it may well be imagined that the skua is an object of great dread to the petrel. Mr. Eaton is of opinion that the skuas are rather perplexed when rabbits occasionally emerge from the burrows instead of the expected petrels, but thinks that even this unusual food would not come amiss to the rapacious robbers, since tame skuas have been known to devour young rabbits. The skua only visits the shore for breeding or pillaging purposes, preferring at other times the open ocean. Its nest is roughly constructed of dried grass, or sometimes, in default of other material, of hard-dried guano; and the two eggs are dark olive-green, blotched with brown. It is most courageous in defence of its young; it allows no other birds anywhere near its nest, and does not hesitate to attack even man if danger threatens the nest. Sailors find the eggs of both penguins and skuas fairly good, but the flesh of both birds is extremely unpalatable, although it is sometimes the only resource for ships' crews in the way of "fresh meat." In order to render it fit for eating at all, the sailors skin the birds and hang them up for some days, leaving them exposed to the evening dew for two or three nights, a process by which some of the disagreeable odour and flavour are said to be removed.

Our illustration is taken from one of Mr. Dougall's photographs of the Bounty Islands, kindly supplied to us by Mr. Joplin, of Stamford, who has a large selection for sale.

Race between Carrier Pigeons and Bees.—A singular wager (*Cosmos*) has been won by a farmer, who is at the same time a pigeon fancier, at Hamme, in Westphalia, against some inhabitants of the town. The bet was that bees, conveyed in fine weather to a distance of a league from Hamme, and let loose at the same time as certain carrier pigeons deposited at the same place, should reach their hive sooner than the pigeons should arrive at their house. On July 25th, at 4 p.m., twelve pigeons and twelve bees belonging to Mr. R. were let loose at Rhysern, a place distant a good league from Hamme. In order to recognise the bees they had been dusted with flour. All the parties stood near the hives of Mr. R., where they could at the same time watch the dove-cot. The first bee, covered with flour, arrived a quarter of a minute before the first pigeon, and the rest of the two troops of aerial travellers arrived at the same second a few instants later.

Evolution in the Song of Birds.—Mr. E. P. Powell, of Clinton, communicating to *Science*, gives some interesting cases of an evolution in the song of the (American) robin, a member of the thrush family. He considers that "with birds evolution must move, as it has moved, in the line of music, plumage, flight, and nest-building." Let us hope that it will not be brought to an untimely end by the extirpation of the little songsters.

Dipterous Larvæ Parasitic in Man.—Portchinski (*Humboldt*) shows that the majority of the cases of disease in human subjects, occasioned by the maggots of flies, are due to *Sarcophagi Wohlfahrti*. He gives this name to the insect in honour of Dr. Wohlfahrt, of Halle, who first described the fly, and proved its parasitic character by rearing it from larvæ *sneezed out* by a man who had been driven almost frantic by headache. *S. Wohlfahrti* seems accordingly to be the European representative of the American fly, *Lucilia hominivora*. According to Meinert, a species of *Lucilia* is parasitic on man also in Europe.

The Heat-Centres in Man.—At the recent meeting of the American Neurological Society, Dr. Ott, of Easton, showed that in the brain of man there are points which preside over the temperature of the body and keep its heat constant. These centres are partly upon the surface and partly at the base of the brain.

Poison Apparatus of the Mosquito.—Mr. G. Macloskie (*Science*) has described and figured the poison apparatus of the mosquito.

Twin Fruits.—Mr. John J. Janney (*Science*) writes that in the year 1851 his garden produced abundant specimens of twin fruits, peaches and plums of various sorts, cherries, apples, and cucumbers. Some of these were but slightly attached together at the foot stalk, whilst others coalesced for their whole length. As similar fruits were common in the markets at the same time, the cause must probably have been seasonal.

Besieged by Bears.—The official journal of the Government of Olonetz reports that the district of Welikogub is regularly blockaded by bears. In five villages the inhabitants do not dare to venture beyond the boundaries. Although not more than 100 miles from St. Petersburg, the district is encompassed by primæval forests, stretching hundreds of versts in every direction. Here bears seemed to have formed a regular settlement. They form groups of seven or eight, and, descending into the cultivated patches, attack the horses and horned cattle, reducing the peasants to despair, making them afraid to till their fields. Their terror is so great that none of them will any longer venture into the forest. The aid of the local authorities has been frequently invoked, in vain; and the peasants were looking forward, as a last hope, to the autumn *battues* of the soldiers of the district, who will, according to usage, organise regular bear-hunts.

THE SENSES OF INSECTS.

II.—Sight.

Although the question would at first seem almost superfluous, it is somewhat difficult to determine whether or not Sight is the most important of the senses which insects possess. On the one hand it is argued, and with great show of reason, that the eyes are generally very numerous, that they command a wide field of view, and that they are mostly present in two, or even in three different forms—strong evidence, one would think, in favour of an affirmative reply to our query. But it is contended, on the other hand, that there are many insects—notably several of the myrmecophilous beetles—which have no eyes at all, while it has also been asserted that, owing to the convexity of the facets which make up the compound eyes, vision, even when present, can only be found of service at close quarters; in other words, that insects are short-sighted.

On this point, therefore, evidence is somewhat conflicting, and it is not very easy to arrive at any definite conclusion. But it is, at all events, well to point out that the arguments of those who deny the importance of the eyes are open to considerable objection. For, in the first place, those insects which are blind are almost invariably dwellers underground, where eyes can be of no possible service. And it would be as reasonable to argue, because they lack those organs, that therefore eyes are not of the highest importance to insects in general, as it would be to urge the eyeless condition of certain cave-dwelling fish as the base for a similar contention with regard to the piscine race.

And with respect to the second assertion, viz., that insects are short-sighted, little or no proof has been brought forward in its support. And we know, without a doubt, that many insects can see for considerable distances. Moths, for instance, are attracted to a gas-lamp hundreds of yards away; and though it may be urged that they receive but a blurred and ill-defined impression of the flame until they approach it closely, the fact remains that their vision is at least in some degree serviceable in perceiving distant objects. And he would be a bold man who should lay down the limit at which that vision ceases to be accurate.

On the other hand, it is impossible to over-estimate the importance of the fact that the facets of the eye-masses are exceedingly numerous, more especially since they are so set as to command a view in almost every direction without any necessity for turning the head. And the number of these facets is at least in some degree proportionate to the speed and activity of the individual species; for the more agile insects would, of course, require the more perfect sight. Thus in the ant, which is comparatively slow in its movements, and in which flight is restricted to the single ascent made by the males and females before pairing, there are no more than fifty distinct facets in the eye. In *Blaps mucronata*, which is one of the most sluggish of our British beetles, there are perhaps two hundred and fifty. In *Meloë*, which, although slow of foot, occasionally exhibits some approach to activity, there are about twice as many. But in certain dragon-flies, which are the analogues among insects of the hawks among birds, there are twelve thousand or more; in some swift-winged butterflies there are seventeen thousand; and in a certain active beetle (*Mordella*) there are more than twenty-five thousand. There are exceptions to the rule, no doubt, but it seems a fairly regular one upon the whole; and its bearing upon the importance of the visual organs cannot be overlooked.

Besides these compound eyes, there are in most insects, though not in all, a very limited number of simple eyes, or *ocelli*, which are generally situated upon the upper part of the head; and these bear a distinct resemblance, as far as the general character of their structure is concerned, to the eyes of the higher animals. In the words of Mr. Rymer Jones, each of these eyes "consists of a minute smooth, convex, transparent cornea, in close contact with which is a small globular lens; behind this lens is placed the representative of the vitreous humour, upon which a nervous filament spreads out, so as to form a retina. The whole is enclosed in a layer of brown, red, or black pigment, which, bending round the anterior surface of the eye, forms a distinct coloured iris and pupillary aperture."

These simple eyes are sometimes present alone, as in the *Thysanura*. Sometimes they are wanting, as in the great majority of the *Coleoptera*. But usually they are present in addition to the compound eyes, and, being directed towards the zenith, command just that quarter which is beyond the ken even of the higher facets of the compound eyes.

These facets, whatever their number, are always hexagonal, and are agglomerated into two great masses, one of which is situated upon either side of the head. In the Whirligig Beetles (*Gyrini*), which skim about on the surface of ponds, etc., each of these eye-masses is divided in two by a corneous ridge, so that, practically speaking, the compound eyes are four in number, the upper pair being available for use in the air, while the lower pair, which alone are immersed, are equally available for use in the water. In almost all cases they project well beyond the level of the cheeks and temples, as perhaps for the sake of analogy we may be permitted to term them, so that the field of view which they command is remarkably extensive, and scarcely any point of the compass is altogether out of sight.

Each of these numerous facets is provided with its own optic nerve; and these nerves, radiating, as it were, from a common centre, transmit the impressions which they receive to a common retina. Behind this is a mass of nervous matter, which leads direct to the brain, or rather to the cephalic ganglion which represents that organ; and this mass communicates with the general retina by what are known as "secondary" nerves, and which are very short and delicate.

Passing to the eyes themselves, each facet is furnished with, or itself consists of, a double convex lens, so formed as to bring to a focus the rays passing through it. Behind every such lens is a six-sided transparent prism, analogous to the vitreous humour in the eyes of higher animals; and to the bases of these prisms are attached the optic nerves.

It has long been a question with anatomists whether insects do, or do not, see with more facets than one at once. That all should be simultaneously employed, or should carry independent impressions to the brain, is manifestly impossible; and two theories have been put forward with the view of clearing up the difficulty. One of these is to the effect that, although all the facets simultaneously see, they convey but one common impression, just as one impression only is borne to the brain by our own two eyes. But as the facets are set in different directions, this explanation is clearly inadmissible. The second theory suggests that one facet

—or at least one small group of facets conveying a common impression—is employed at any given moment, and that the remainder see only in a blurred and confused manner, just as we ourselves dimly see neighbouring objects when gazing into the far distance. This is more probable; but in the present incomplete condition of our knowledge it is quite impossible to pronounce upon the point with any degree of certainty.

Eyes of a third description we find in certain aphides, in the form of supplementary "eye-tubercles," two in number, one of which is situated at the corner of each of the compound eyes. These eye-tubercles are furnished with from five to ten facets apiece, differing little, structurally speaking, from those of the compound eyes, but hemispherical instead of hexagonal. Their particular function is altogether unknown, as is also the reason why aphides, which are for the most part very sluggish creatures, should possess numerous and well-developed eyes, and in three forms instead of in two. But then aphides are in many ways most exceptional beings.

Seeing, then, the highly-developed character of the eyes of insects, their invariable presence in those species to which they could by any possibility be of service, and the utter absence of proof to the effect that their range of vision is so limited as has sometimes been contended, we may surely concede that sight *is* the most important of an insect's senses, and that it is generally present in a very remarkable degree.

Reviews.

On the Distribution of Rain over the British Isles during the Year 1887, *as observed at more than* 2,500 *Stations in Great Britain and Ireland, with Articles upon various Branches of Rainfall Work.* Compiled by G. J. Symons, F.R.S. London: Edward Stanford.

The author remarks in his preface that the year 1887 seems to have had no equal for wide-spread deficiency of rainfall since 1788! He further expresses the opinion that "if the drought from 1738 to 1762, indicated by the observations already collected, is real and recurs, not only will every town in England which receives its water supply from a gathering-ground be put on short supply, but the canals will have to be closed and agricultural operations will have to be modified."

This passage was, of course, written before the present season declared its character. There is now little fear of a short water supply or of the closing of canals, and as to agricultural operations they seem in danger of being suspended altogether. In his first chapter the author endeavours to give a fixed meaning to the terms "absolute droughts" and "partial droughts." By the former he proposes to understand times of more than fourteen days absolutely without rain. The partial drought is to signify times of more than twenty-eight consecutive days, the aggregate rainfall of which does not exceed 0·01 in. daily. A further form of drought receives the rather curious name of "engineers' drought," that is, a drought which an hydraulic engineer must provide against in drawing up a scheme for a water supply, and such drought he defines as a time of "three or more consecutive months, the aggregate rainfall of which does not exceed half the average."

The account of "historic droughts" in the British Islands, from the third century downwards, is especially, in its earlier parts, open to doubt. In our days "burning summers," "scorching heat," etc., are exceedingly rare phenomena.

The observations made last year show a striking deficiency of rainfall, the aggregates ranging up to 17 in. below the averages of former periods. The heaviest fall recorded in any twenty-four hours is that at Queen's College, Galway, on September 1st, amounting to 4·93 in. The accounts of the water famine prevailing during September in various parts, both of England and Ireland, are very striking. In most parts of the British Isles, however, the dry weather was not accompanied by any unusual heat. Chilly polar winds counteracted the effects of bright sunshine by day, and, as we learn from other sources, the temperature, save perhaps in July, was from 2° to 3° Fahr. below the average.

The Scientific Proceedings of the Royal Dublin Society. Vol. V. (N.S.), Parts 7 and 8. July and November, 1887. Vol. VI. (N.S.), Parts 1 and 2. February and May, 1888.

The subjects considered in the parts before us are chiefly either of a geological or a physical character. Mr. A. B. Wynne treats of submerged peat-mosses and trees in certain lakes of Connaught. The author, to account for tree-stumps standing erect under water as if they had grown there, suggests that the stools of the trees in the bogs with horizontal roots retained their position until the boggy ground they grew in had been almost entirely removed. In case of an unusual storm the remaining roots snapped or drew, and each water-logged mass subsided to the bottom, settling upon its broadest surface still in its natural position of growth.

Mr. G. H. Kinahan, M.R.I.A., discusses the deal timber in the lake basins and peat-bogs of north-east Donegal, with especial reference to the fact that the stumps, locally called "corkers," are found *in situ* below the present level of natural drainage. He formerly thought that the flooding of the hollows might be due to beavers. He notes, however, that in Irish, unlike Welsh or Gaelic, there is no name for a beaver, and he has not been able, in Donegal, to recognise any beaver workings, with the features of which he has become acquainted in Canada. He now, with Mr. Plunkett, holds that the trees grew in flats and hollows without drainage outlets in periods when the climate was hotter and drier than at present. When a wetter and colder epoch succeeded the flats and hollows became submerged.

Professor Hall, F.R.S., communicates an important paper on the "Effect of Continental Land in Altering the Level of the Ocean." The author quotes the opinion of Professor Ed. Suess, expressed in "Das Antlitz der Erde," that the surface of the ocean along the margin of a continent may be as much as 3,300 feet higher than the surface along the shores of a mid-oceanic island. The difference of level along the coast of Mexico and at the Sandwich Islands is said to be no less than 4,520 feet.

Professor W. J. Sollas, in a contribution to the "History of Flints," concludes that a bed of average-sized flints may be formed in about fifty years, more or less—a much shorter time than would have been expected.

R. F. Scharff, Curator of the Natural History Department in the Dublin Museum, reviews Dohrn's theories on the origin of the vertebrates. Dohrn draws attention to the fact that his views differ from the current ideas in three main points: the derivation of the vertebrates from worm-like ancestors; that the principle of change of function was the best guide in tracing morphological histories; and that degeneration might proceed to an unlimited extent. In his first paper he holds that the mouth of living vertebrates has originated from a union of two gill-clefts. He regards the hypophysis in Teleosteans as a pair of præoral gill-clefts arrested in their development in such a manner as not to reach the surface of the skin. In Petromyzon he considers that the so-called nasal organ probably still retains to some extent the function of a gill. All previous observers, including Balfour and Gegenbaur, had regarded the visceral arches of the Elasmobranchs as equivalent to the arches in Petromyzon. Dohrn, however, proves that the external cartilages have nothing to do with the arches of Petromyzon. The tunicate eye is regarded by Dohrn as having degenerated from the vertebrate eye to its present condition.

Research. A Monthly Illustrated Journal of Science. Vol. I. No. 4. October 1st, 1888.

The first article in the issue before us, "On Science Teaching in Schools and Colleges," appeals strongly to our sympathies. We most cordially endorse the remark that:—"The examination system of this country requires a most thorough overhauling and remodelling, and in no subjects more so than in science. At present it is to a great extent a curse and hindrance to true scientific progress."

But we feel inclined to go a little further than our contemporary, and to ask if the exceptional stress laid upon examinations in this country is not a main cause of our unsatisfactory position in science?

In the notice of the recent meeting of the British Association, it is very appropriately said that in the address to Section F. the line between science and politics was overstepped more than once.

Mr. T. Mellard Reade, in a paper on "Mountain Formation," seems to accept the theory of Sir W. Thomson, that the earth from the centre to the circumference is "as solid as steel."

There is a bright little article on "Llandudno and its Flora," which will doubtless prove a boon to phytologists visiting that popular watering-place.

The Sixty-fifth Report of the Sheffield Literary and Philosophical Society, for the Year Ending December 1887. Delivered at the Annual Meeting, January 3rd, 1888. Sheffield: Leader and Sons.

The Sheffield Literary and Philosophical Society is a favourable specimen of a number of societies instituted in the first quarter of the present century, for the joint cultivation of literature and science. Exception may, perhaps, be taken alike to the name and to the scope of these bodies. The term "philosophical," save in the phrase "philosophical instruments," is no longer used as a synonym for "scientific." As to the scope of the Society, we often find that literature serves for a disguise under which almost anything may be introduced. As, further, the relations between science and literature are, to say the least, somewhat strained, such bodies would probably be the gainers in efficiency by submitting themselves to a process of dissociation.

Among the papers, etc., printed in this report, literature seems to predominate, if we may judge from the space allotted to "Samuel Bailey, the Bentham of Hallamshire," to "Half-hours with Charles Dickens," and to the "History of a Fascination."

In the first of these memoirs politics crop up to an extent very undesirable.

Of the scientific papers the most important are "The Discovery of the Planet Neptune," by Mr. B. D. Wrangham; "The Principal British Poisonous Plants, and How to Distinguish Them," by the President, Mr. E. Birks; "The Perception of Odours, and the Mistakes of the Colour Blind," by Mr. Simeon Snell; and "Studies in the Border Land of Geology and History," by Dr. H. C. Sorby, F.R.S. We doubt, however, if any of these papers, save the last, makes additions to our former knowledge. In other words, the Society is not engaged to any appreciable extent in the work of original observation and research. May we not here hope for a reform?

Third Annual Report of the City of London College Science Society, 1887-8. London: Howes.

This report shows a very satisfactory activity.

We notice, firstly, a very able paper by Professor G. S. Boulger, F.L.S., on the "Use of Experiment in Biology." We are disposed to agree with him in rejecting as vicious the commonly made distinction between the experimental and the observational sciences, and in regarding experiment as absolutely essential to the advancement of biology.

Mr. G. E. Mainland gave a paper on "Spiders," contrasting the classes *Arachnida* and *Insecta*.

"The New Darwinism; or, the Segregation of the Fit," was discussed by Mr. J. W. Gregory, who curiously still admits the doctrine of the sterility of hybrids. He grants the existence of a fertile hybrid between the hare and the rabbit; he will not be able to deny the similar case of the American bison and the domestic cow, or of the carrion crow and the hoodie, not to speak of the multitudes of fertile hybrids in the vegetable kingdom. Therefore, as a law of nature can admit of no exceptions, the dogma of the infertility of hybrids falls to the ground, and to admit it is to give to the Old School an advantage to which they are not entitled.

THE FOUNDATION-STONES OF THE EARTH'S CRUST.

An Evening Discourse delivered by T. G. Bonney, D.Sc., LL.D., F.R.S., F.G.S., etc., before the British Association, on September 10th, 1888.

Do we know anything about the earth in the beginning of its history—anything of those rock masses on which, as on foundation-stones, the great superstructure of the fossiliferous strata must rest? Palæontologists, by their patient industry, have deciphered many of the inscriptions, blurred and battered though they be, in which the story of life is engraved on the great stone book of Nature. Of its beginnings, indeed, we cannot yet speak. The first lines of the record are at present wanting—perhaps never will be recovered. But apart from this: before the grass and herb and tree, before the "moving creature in the water," before the "beast of the earth after his kind," there was a land and there was a sea. Do we know anything of that globe, as yet void of life? Will the rocks themselves give us any aid in interpreting the cryptogram which shrouds its history, or must we reply that there is neither voice nor language, and thus accept with blind submission, or spurn with no less blind incredulity, the conclusions of the physicist and the chemist?

The secret of the earth's hot youth has doubtless been well kept. So well that we have often been tempted to guess idly rather to labour patiently. Nevertheless we are beginning, as I believe, to feel firm ground after long walking through a region of quicksands; we are laying hold of principles of interpretation, the relative value of which we cannot in all cases as yet fully apprehend—principles which occasionally even appear to be in conflict, but which will some day lead us to the truth.

I shall not attempt to give you an historical summary, but only to lay before you certain facts for which I can answer, and to indicate the inductions which these, as it seems to me, warrant. If I say little of the work of others, it is not from a desire of taking credit to myself, but because it is immaterial for my present purpose, who first made a particular observation and how far his inductions therefrom were correct. The acknowledgment of good work would involve repudiation of bad, and for that, so far as persons are concerned, it seems hardly fair to use the present occasion. So, in the outset of this lecture, I will once for all make a statement which I have sometimes thought of invariably using, like a prefatory invocation, "You are free to suppose that everything herein has been said by somebody, somewhere," but I will add that, as far as possible, every assertion has been personally verified.

The name Cambrian has been given to the oldest in which fossils have been found. This group forms the first chapter in the first volume, called Palæozoic, of the history of living creatures. Any older rocks are provisionally termed Archæan. These—I speak at present of those indubitably underlying the Cambrian—exhibit marked differences one from another. Some are certainly the detritus of other, and often of older, materials—slates and grits, volcanic dust and ashes, even lava-flows. Such rocks differ but little from the basement beds of the Cambrian; probably they are not much older, comparatively speaking. But in some places we find, in a like position, rocks, as to the origin of which it is more difficult to decide. Often in their general aspect they resemble sedimentary deposits, but they seldom retain any distinct indications of their original fragmental constituents. They have been metamorphosed, the old structures have been obliterated, new minerals have been developed, and these exhibit that peculiar orientation, that rudely parallel arrangement, which is called foliation. Except for this some masses are fairly homogeneous, while some exhibit a distinct mineral banding which is usually parallel with the other structure. These rocks are the gneisses and schists—the latter term, often vaguely used, I always restrict to rocks which exhibit a true foliation. In some schists the mineral constituents are comparatively minute, in others they are of considerable size. In the former case we may often venture to affirm that the rock is a metamorphosed sediment; in the latter its original condition is a matter of conjecture. Rocks of the former class often appear, to use no stronger word, to lie above, and so to be less ancient than those of the latter, and beneath that comes a coarser and more massive series, in which granitoid rocks are common. In these last foliation is often inconspicuous, and the rocks in consequence are not markedly fissile.

That these rocks are older than the Cambrian can often be demonstrated. Sometimes it can even be proved that their present distinctive character had been assumed before the overlying Cambrian rocks were deposited. Such rocks, then, we may confidently bring forward as types of the earth's foundation-stones. As the inscriptions buried in the Euphrates valley tell us, the tongue of Accad in the days prior to the coming of the Semite, so these declare what then constituted the earth's crust. If in such rocks we find any peculiarities of mineral composition or structure, these may legitimately be regarded as distinctive. We have only to beware of mistaking for original those which are secondary and subsequently impressed.

In other parts of the world we find rocks of like characters with those above named, the age of which cannot be so precisely fixed, though we can prove them to be totally disconnected from and much older than the earliest overlying stratum. To assert that these rocks are contemporary with the others is obviously an hypothesis which rests on the assumption that community of structure has some relation to similarity of origin. I am well aware that attempts have been made to discredit this. But if we eliminate difficulties which are merely sophistical—those, I mean, created by the use of ambiguous or misleading terms—if we acknowledge those due to our limited means of investigation, such as that of distinguishing a rock crushed *in situ* from one composed of transported fragments—in other words, of separating in every case a superinduced from a primary structure—and if we allow for others due to the limitation of our instrumental and visual powers, I do not hesitate, as the result of long and, I hope, careful work, to assert that certain structures are very closely related to the past history of a rock, and that in very many instances our diagnosis of the cause from its effect is not less worthy of confidence than that of an expert in pathology or physiology. Resemblances of structures, different in origin, do, no doubt, sometimes occur—resemblances not seldom due to partial correspondence in the environments; but in regard to these it is our duty to labour patiently till we succeed in distinguishing them. The difficulty of the task does not justify us, either in abandoning it in despair, or in sitting down, after a few hasty observations, to fashion hypotheses which have no better foundation than our own incompetence or idleness.

As it is impossible in the time at my disposal to demonstrate the proposition, I must assume what I believe few, if any, competent workers will deny, that certain structures are distinctive of rocks which have solidified from a state of fusion under this or that environment; others are distinctive of sedimentary rocks; others again, whatever may be their significance, belong to rocks of the so-called metamorphic group. I shall restrict myself to indicating, by comparison with rock structures of which the history is known, what inferences may be drawn as to the history of the last-named rocks, which, as I have already stated, are in some cases examples of the earth's foundation-stones, while in others, if they are not these, they are at any rate excellent imitations.

Let us proceed tentatively. I will put the problem before you, and we will try to feel our way towards a solution. Our initial difficulty is to find examples of the oldest rocks in which the original structures are still unmodified. Commonly they are like palimpsests, where the primitive character can only be discerned, at best faintly, under the more recent inscription. Here, then, is one of the best which I possess—a Laurentian gneiss from Canada. Its structure is characteristic of the whole group; the crystals of mica or hornblende are well defined, and commonly have a more or less parallel arrangement; here and there are bands in which these minerals are more abundant than elsewhere. The quartz and the felspar are granular in form; the boundaries of these minerals are not rectilinear, but curved, wavy, or lobate; small grains of the one sometimes appear to be enclosed in larger grains of the other. Though the structure of this rock has a superficial resemblance to that of a granite of similar coarseness, it differs from it in this respect, as we can see from the next instance, a true granite, where the rectilinear outline of the felspar is conspicuous. Here, then, is one of our problems. This difference of structure is too general to be without significance. What does it mean?

It is more difficult to obtain examples of schist of like geological age, wholly free from subsequent modification. Apparently the structure and the composition of the rock have rendered it more liable to disturbance. But those exhibited, though by no means perfect examples, may serve to indicate the structure of an Archæan schist, consisting mainly of quartz and mica. We may take them as representative of a considerable series of rocks, which are often associated in such a manner as to suggest that, notwithstanding their present crystalline condition, they had a sedimentary origin. Can this inference be justified?

How shall we attack this problem? Clearly, the most hopeful way is by proceeding from the known to the unknown. Now, among the agents of change familiar to geologists, three are admittedly of great importance; these are water, heat, and pressure. As probably almost all changes in nature, with which we have to deal, have occurred in the presence of water, but those due to it alone are generally superficial, I shall assume its presence, and not attempt to isolate its effects. But we must endeavour to ascertain the results of pressure and heat, when acting singly and in combination, in modifying rocks of a known character; admitting, however, that probably while the one agent has been dominant, the other has not been wholly inoperative.*

The first effect of pressure due to great earth-movements is to flatten somewhat the larger fragments in rocks, and to produce in those of finer grain the structure called cleavage. This, however, is a modification mainly mechanical. It consists in a re-arrangement of the constituent particles, mineral changes, so far as they occur, being quite subordinate. But in certain extreme instances the latter are also conspicuous. From the fine mud, generally the result of the disintegration of felspar, a mica, usually colourless, has been produced, which occurs in tiny flakes, often less than one-hundredth of an inch long. In this process, a certain amount of silica has been liberated, which sometimes augments pre-existing granules of quartz, sometimes consolidates independently as microcrystalline quartz. Carbonaceous and ferruginous constituents are respectively converted into particles of graphite and of iron oxide. Here is an example of a Palæozoic rock, thus modified. It originally consisted of layers of black mud and grey silt. In the former, this filmy mica has been abundantly developed; it is present also, as we might expect, to some extent in the latter. Observe that the original banded structure, notwithstanding the pressure, has not been obliterated. Another point also demands notice. The black lines in the section indicate the direction of the cleavage of the rock, which is, roughly speaking, at right angles to the pressure which has most conspicuously affected the district, while the microfoliation, as we may call it, appears to be parallel to the original bedding, and is thus anterior to the dominant cleavage. The two may form parts of a connected series of movements, but, at any rate, they are so far separated that the pressure which produced the one, acted, roughly speaking, at right angles to that which gave rise to the other, and the folia were developed before they were bent and torn.

Let us now pass on to examine the effects of pressure when it acts upon a rock already crystalline. Here, obviously it is comparatively unimportant whether the original rock was a true granite or a granitoid gneiss; for at present we are only concerned with the effect of pressure on a fairly granular crystalline rock. But in the resultant structures there are, as it seems to me, differences which are dependent upon the mode in which pressure has acted. They are divisible into two groups: one indicating the result of simple direct crushing, the other of crushing accompanied by shearing. In the former case, the rock mass has been so situated that any appreciable lateral movement has been impossible; it has yielded like a block in a crushing-machine. In the latter a differential lateral movement of the particles has been possible, and it has prevailed when (as in the case of an overthrust fault) the whole mass has not only suffered compression, but also has travelled slowly forward. Obviously, the two cases cannot be sharply divided, for the crushing up of a non-homogeneous rock may render some local shearing possible. Still it is important to separate them in our minds, and we shall find that in many cases the structure, as a whole, like the cleavage of a slate, results from a direct crush; while in others the effects of shearing predominate. The latter accordingly exhibit phenomena resembling the effects of a tensile stress. Materials of a like character assume a more or less linear arrangement, the rock becomes slightly banded, and exhibits, as has been said, a kind of fluxion structure. This phrase, if we are careful to guide ourselves against misconception, is far from inappropriate. The mass gradually assumes a fragmental condition under the pressure, and its particles as they shear and slide under the effects of thrust behave to some extent like those of a non-uniform mass of rock in a plastic condition, as, for example, a slaggy glass. But we must be on our guard, lest we press the analogy too far. The interesting experiments which have been made on the flow of solids, and on rolled-out plastic substances, while valuable as illustrations, represent, as it seems to me, a condition of things which must be of rare occurrence in a rock mass, pulverised by mechanical forces only. If I am to reason from them, I must regard the rock not as a fragmental solid—if the phrase be permissible—but as an imperfect fluid; that is to say, I must consider them as illustrative of structures in rocks which have yet to assume—not have already assumed—a crystalline condition.

(To be continued.)

* Heat will, of course, result from the crushing of rock. This some consider an important factor in metamorphism, but I have never been able to find good evidence in favour of it, and believe that as a rule the rocks yield too slowly to produce any great elevation of temperature.

Spurious Cod-Liver Oil.—According to *Cosmos*, a manufacture of cod-liver oil has sprung up in Paris. The raw material is not the fresh liver of the cod, but the stale fish and other refuse of the Halles Centrales, the manufacturers, doubtless, thinking that any oil may serve if it be sufficiently nasty.

Abstracts of Papers, Lectures, etc.

LANCASHIRE AND CHESHIRE ANTIQUARIAN SOCIETY.

On October 6th the members of this Society visited the Geological Museum at Owens College, where they were addressed by Professor Boyd Dawkins, who said he wished to take the opportunity of pointing out the method of arrangement which had been adopted in the section of the museum which represented the history of the Tertiary world and its inhabitants, and which was the only portion of the museum which concerned them as students of the ancient history of man. At the first outlook they might fancy that the subject of archæology had no place whatever in a natural history museum. It seemed to him that the question was one which required some explanation. It was answered, in his own case at all events, by practical experience. He had found, in the course of his inquiry into the history of the earth, in dealing with the Tertiary period, that it is absolutely impossible to keep the history of man out of the later periods of the geological record. He had, therefore, been compelled to organise a portion of the museum in which man found himself recorded in his first coming on the earth, and also in various stages of progress in which he is represented by the implements which are found in various strata. Further than that, when he came to inquire into the history of the rocks themselves, he found that there were strata belonging to the period included in history. For that reason he had been compelled not only to deal with Palæolithic man as a fossil, and as truly a fossil as the Pleistocene mammals by which he was surrounded, but also to place in the museum a small collection of implements, ornaments, and weapons and other articles representing the state of civilisation in the Historic Period. Such then was his justification for putting anything of the nature of archæological specimens into the Tertiary section. He put them there because they form part of the ancient history of the earth. The Tertiary division of the history of the earth begins with the Eocene and ends with the Tertiary period, and the successive stages are marked by the various collections on the east side of the first floor of the museum. Drawing their attention to a few of the most important points which concerned them as students of the ancient condition of man, he referred to a group of animals and shells and a quantity of flint splinters found on the banks of the ancient Thames, at Crayford, in the neighbourhood of London, when the river wended its way on the one hand into Essex and on the other hand into Kent. Those bones and other materials gave them a picture of the life of the times. When they saw the tusks of elephants, the remains of the Irish elk, the bison, the ox, and other animals, all lying side by side, and when they saw along with them splinters of flints which have been struck off in the manufacture of flint instruments, they observed at once the surroundings under which man first of all made his appearance in Britain in the Pleistocene age. They would notice a small group of river shells in this period, among which was one species *(Corbicula fluminalis)* now only to be found in the Nile and other rivers of the South and the East. Next they came to the Palæolithic instruments of the river gravels, representing a primeval condition out of which mankind has been removed for incalculable ages. When he told them those instruments were found over the greater part of this country, the whole of France, over the whole of the borders of the Mediterranean, in Africa and in Europe, and Palestine, and when, further, exactly that type of instrument occurs also in India, he thought they would realise the interest which centres in implements which imply the same rude condition of barbarism over the whole of Europe west of the Rhine, over the whole of the Mediterranean region, as well as in the jungles and forests of India. Then came next the period of the Cave-Men. In the caverns were found the bones of the horse, the rhinoceros, the reindeer, the hippopotamus, all brought in by the hyenas; and in association with them were to be found a whole series of remains proving the existence of man in Yorkshire, Somerset, and Devonshire. Among these remains was the picture of a horse engraved on a polished bit of bone, which might be looked upon as the very earliest specimen of art which they had found in Britain. There were also photographs and sketches and casts of engravings and sculptures from the foreign caves. In the prehistoric period they would see an excellent collection of polished stone axes from Greece, about which he was amused to read a short time ago, that none had ever been found in that part of the world. Those that were in the museum were collected by Mr. Finlay, a well-known resident in Athens. There was also a collection of things from Switzerland, which proved that the arts of spinning and weaving, of husbandry, and of pottery making were introduced into Europe in the Neolithic age. They would also see evidence of the introduction of the domestic animals, the sheep, goats, pigs, oxen, horses and dogs, all coming in with the primeval Neolithic farmer. In another part of the case they would see proof that the Neolithic peoples were acquainted with the art of mining, in a collection which he had obtained from an ancient flint mine in Sussex. Not only that, but they would see a few human skeletons of the people who introduced these arts into Europe, the people who are living to this day in the shape of the small dark Welsh, the Irish, and the small dark Highlander. He might say further that some of those people are to be found now in Yorkshire, in Derbyshire, and he had no doubt that the blood of those people might be found in the veins of some of those around him that afternoon. The remainder of these are found in the alluvia in the deposits of the ancient rivers, and in the peat bogs. as well as in tombs. Going a stage further, they came to the Bronze age, in which were to be found samples of the domestic animals. There was a very curious thing to be noted in the group of human skulls found along with them. Some two years ago Mr. H. D. Pochin, a well-known resident of Salford, asked him (Professor Dawkins) to undertake the exploration of a cavern called Gop, crowning a hill south of the Vale of Clywdd. In a sepulchral cavern close by they found a stone chamber full of human remains. The skulls were of the long type belonging to the small dark Neolithic race he had referred to, but there was one skull which belonged to the conquering race who introduced bronze into this country, and who were distinguishable from the Celt, being altogether a bigger and stouter race than the small dark Welsh. So that they had two distinct types associated together in the sepulchre belonging to the Bronze age. They had also other examples of the Bronze age. He took this opportunity of calling the attention of the Lancashire and Cheshire Antiquarian Society to the extreme poverty of bronze implements in the museum. He should welcome any additions to this part of the collection, and be exceedingly grateful for any help that he could get in filling this blank. Passing from the prehistoric, they now came to the collection which represents the historic period; first and foremost among which they found an interesting number of things from Egypt. They had a most remarkably preserved group of mummies, found recently by Mr. Flinders Petrie, and presented to the Museum by Mr. Jesse Haworth. Two are of a period which ranges from about Anno Domini to 200 years before Christ; while the third is of an early Greek type, which was found in Egypt, and dates from A.D. to 150 A.D. The interest of the last was exceedingly great from an artistic point of view. On the head of the mummy was a most excellently preserved portrait of the occupant. The preservation was simply marvellous; the art singularly excellent; and the discovery altogether an important one. All these three mummies had been found in a deposit of sand near the ancient city of Arsinoe, and they represented burials which took place from time to time of the citizens of that great city. They would also see in the Historic rooms specimens from Babylonia, Rome, Australia, the South Sea Islands, Mexico, and North America. In conclusion, Professor Boyd Dawkins said that of course, naturally after the examination of ancient history of the earth, when they had closed their record at the historic period, they there had full scope for the working out of the history of animals and the plants to which the rest of that part of the museum was devoted. They had, in other words, a philosophical arrangement showing the gradual evolution of things in the Tertiary ages which is still going on, and which finds expression in the history of the present surface of the earth and of the living animals, including man, and of the living plants.

NATURAL HISTORY SOCIETY OF GLASGOW.

THE first meeting of the winter session was held on Tuesday, 25th September, Mr. P. Ewing, Vice-President, in the chair.

Mr. D. Pearson exhibited a living specimen of the Australian piping-crow (*Gymnorhinus tibicen*). The bird belongs to an Australasian group, readily distinguishable from the true *Corvidæ* by the peculiar form of the nostrils, which are long, narrow, sunk in the substance of the bill, and usually quite exposed. The black and white plumage is rather handsome, and bears some resemblance to that of the magpie. The piping notes of the bird are not unmusical, and compare favourably with the song of most others of its tribe. In captivity it displays excellent powers of mimicry.

Mr. J. Steel showed a glass jar with sea water, containing hundreds of the larval form of the common shore crab (*Carcinus mœnas*), and remarked that in their early stage of development these crustacea are pelagic rather than littoral as regards their haunts.

Mr. H. McCulloch exhibited a specimen of *Goliathus cacicus*, a large and beautifully-coloured beetle, from Old Calabar, Western Africa.

Mr. J. J. F. X. King showed a series of specimens of *Œcetis notata*, a neuropteron recently captured by him on the Liffey, near Dublin. He stated that the insect has occurred in various parts of England, but is new to the Irish fauna.

Mr. D. A. Boyd made some remarks on *Smynthurus* and *Papirius*, two genera of Collembola, or "spring-tails," and exhibited a series of specimens of these insects taken near West Hilbride, Ayrshire. He also showed fertile specimens of *Bartramia Halleriana* and *Fontinalis squamosa*, two mosses from the neighbourhood of Largs.

Mr. T. King, Vice-President, showed an extensive collection of fungi from the district around Glasgow, including *Agaricus scobinaceus*, *A. platyphyllus*, and other species of more or less rarity.

Mr. W. Stewart exhibited five species of *Peziza*, including two apparently new to the British flora.

Rev. A. S. Wilson, M.A., B.Sc., read a paper on the "Dispersion of Seeds and Spores," in which he described the various natural appliances for insuring the suitable distribution of these objects, and the means by which the dispersion is aided or effected. The paper was illustrated with diagrams and specimens.

MANCHESTER GEOLOGICAL SOCIETY.

THE annual meeting was held on October 9th, Mr. Joseph Dickinson, the President, in the chair.

Mr. Mark Stirrup, Honorary Secretary, read the annual report of the Council. In it they state that as this was the fiftieth year of the Society's existence it was thought desirable to review its history as recorded in the minutes, books, and publications. The Society was founded by a resolution passed at a meeting of the friends of geological science held on October 15th, 1838, at the York Hotel, King Street, now the site of the Manchester and County Bank. This meeting was presided over by Lord Francis Egerton, afterwards the first Earl of Ellesmere, and the objects of the Society's foundation were then declared to be: "To investigate the mineral and organic remains of the earth, to inquire into statistics, machinery, maps, models, and mining records; to publish the transactions of the Society, with suitable illustrations, and to form a museum to be opened gratuitously to the public." The first annual meeting was held in the rooms of the Royal Institution, Mosley Street, on January 17th, 1839, under the presidency of James Heywood, F.R.S., who, with about four other members, were still living. At the end of this year Mr. Heywood offered the greater part of his house in Mosley Street, at the corner of St. Peter's Square (now the Clarendon Club), and the Society went thereto. The rapidly increasing collection of fossils was also removed there, and a beginning was made in arranging the names and specimens. The British Association visited Manchester for the first time in 1842, and materially assisted the Society by a grant of £100 from its funds towards arranging its collection. Shortly after this an arrangement was entered into between the Society and the Natural History Society for the amalgamation of their geological collections. The amalgamated collection was thenceforward housed at the Museum in Peter Street (where the Society also met), until in the year 1873, by general agreement, the whole collection was transferred to the Owens College, under stipulations as to maintenance and care, the free admission of members and of the public on certain days, and that the College should provide a fitting building for the museum. By providing accommodation for the united collection in the new building in Oxford Road, the Owens College had admirably redeemed its pledge. The collection, rearranged and renamed by Professor Dawkins and his assistants, was now opened in a lofty, spacious, and well-lighted room, ninety feet in length, with the minerals immediately adjoining, accessible in every part. From the year 1873, when the present premises were secured, the Society had made a continuously steady advance in membership and otherwise, and many valuable papers had been read. The revenue of the Society had been carefully looked after, and the reserve fund now stood at over £1,000.

Coming to the ordinary report, the Council had pleasure in stating that the Society showed no signs of decadence or loss of vitality, but rather seemed to have witnessed a renewal of its vigorous youth in the more than average number and quality of the papers that have been brought before the meetings. The papers, twenty-nine in number, had been varied in character, and some of the subjects which had been discussed were especially noteworthy as matters affecting large commercial interests, and in some degree our national prosperity. In accordance with a request in the last annual report, that the Society should take up some definite work in connection with one or other of the committees of the British Association, the Council were pleased to state that a beginning had been made by a few of the members in collecting information as to the distribution of erratic blocks in Lancashire and adjoining counties. A portion of that information had already been embodied in a paper read before the Society. The number of members on the roll, 215 in all, showed a slight diminution. During the year nine new members had been added to the list, nine had resigned, and four had died.

The following officers were elected for the coming year:—President, Mr. John Knowles; Vice-Presidents, Messrs. H. Bramall, J. S. Burrows, G. Peace, and R. Winstanley; Council, Messrs. Barrett, C. Newton, G. H. Peace, J. Ratcliffe, J. Tonge, H. A. Woodman, R. T. Burnett, J. Wilde, C. Pilkington, and H. Saint; Treasurer, Mr. H. M. Ormerod; Hon. Secretaries, Mr. Mark Stirrup, F.G.S., and Mr. G. H. Hollingworth; Auditors, Mr. Clegg Livesey and Mr. A. Pilkington.

MANCHESTER CONCHOLOGICAL SOCIETY.

At the monthly meeting held on October 4th, Mr. Thomas Rogers exhibited specimens of *Limax flavus* and eggs—a slug generally found in cellars, but occurring abundantly in yards near the river Irk, behind the gas works in Rochdale Road. The indifference of this species to the impurities of the atmosphere of a town is one of the few exceptions to the habitats of the Land Mollusca generally. He also showed a fine living specimen of *Helix aspersa*, which had been picked up in Smithfield Market from amongst some artichokes. The specimen when first obtained was quite young, and little larger than a pea, but had since grown into the large size exhibited. Mr. Rogers thought it might have been possibly imported with vegetable produce from Algiers or some Mediterranean port, as the specimen compared favourably with some large shells of the same species which he exhibited from the interior of Morocco.

Mr. R. Standen exhibited a beautiful and well-mounted series of the "darts" of various species of Helix, which he had obtained by dissection of the animals. He drew special attention to the marked distinction, both in size and structure, between the "darts" of *Helix nemoralis* and *Helix hortensis*, as showing beyond doubt that these are really distinct species, a fact now generally accepted by conchologists, although Jeffreys and others considered *hortensis* merely a variety of *nemoralis*. The exquisite appearance of these curious crystalline bodies elicited deserved admiration, showing as they do very varied and elegant forms. The "dart" is a straight or curved, sometimes slightly twisted, tubular shaft of carbonate of lime, tapering to a fine, solid, transparent point above. It is only found in mature shells. After much speculation as to its use, the general opinion now seems to be that it serves an important part in pairing. It has been ascertained that we have in the British Isles, four species of *Helix* which carry two darts, and eleven species which have but one. Two species of Zonites also possess darts.

SOUTH LONDON ENTOMOLOGICAL AND NATURAL HISTORY SOCIETY.

This active and energetic society held its annual Exhibition at the "Bridge House" Hotel, London Bridge, on October 17th and 18th. The specimens brought together illustrated almost every department of natural history, and we feel ourselves well within the mark in saying that a display so beautiful, so varied, and, above all, so instructive, has certainly never been previously brought together on the south bank of the Thames.

The Exhibition occupied three large rooms. In the Nelson Room, on the first floor, we noticed a very extensive assortment of microscopes, microscopic objects, and apparatus. So richly stocked, in fact, was this department that an entire day would have been requisite to inspect everything worth seeing. Next, we noticed a display of birds, reptiles, fishes, and insects; a collection of rocks and fossils, illustrative of the geology of the South-East of England, contributed by Messrs. T. Leighton, F. D. Power, and T. D. Russell. Mr. Livesey contributed some good osteological specimens, whilst Miss M. E. Adkin, Miss F. Billups, and Messrs. Pearce and Step had furnished a good botanical collection. Lastly, that indefatigable naturalist, Mr. J. T. Carrington, and Mr. E. Step had brought together an assortment of fungi —a department too much neglected. In the Wellington Room, on Wednesday, 17th, Mr. R. May delivered two lectures, one on "The Wonders of Minute Vegetable and Animal Life," at 8 p.m., and one on "Curious Houses and Queer Tenants," at 9.30 p.m.

On Thursday evening, at 7 p.m., in the same room, the Sciopticon Company gave a beautiful exhibition of photo-micrographic slides, whilst at 8.15 Mr. G. Day gave a further display of micro-photographic slides illustrative of entomology, geology, etc.

The main display, however, was in the ball-room on the third floor, which was converted into a well-stocked museum. The assortment of birds, birds' eggs, and nests was decidedly good. As regards the display of insects, the Lepidoptera were evidently the favourites. We particularly notice a specimen of *Daphnis nerii* caught at Poplar. Odeoptera played but a subordinate part, though the collection of British beetles furnished by the President, Mr. T. R. Billups, comprised nearly all the species known to occur in Britain. The collections of Mr. J. H. Leech and W. West were also well deserving of admiration.

As for the "neglected orders," a collection of Neuroptera had been furnished by Mr. R. McLachlan, whilst assortments of Hymenoptera, Hemiptera, and Diptera were shown by Messrs. Billups and Verrall. A collection of Mollusca was sent in by Mr. F. G. Fenn, and a nice selection of corals and sponges by Mr. W. Manger.

We can only briefly glance at the specimens illustrative of pathology sent by Mr. W. Roots, and the collection of plants collected by Mr. W. A. Pearce in a journey from San Diego to the Sonora Pass, California.

With the entire display we were not merely satisfied, but delighted; and we hope the immense trouble taken by the committee and their friends will redound to the benefit of the society. It cannot be too widely known that one of its objects is to afford to youths who have a taste for Natural History that practical guidance which books alone fail to impart.

MANCHESTER MICROSCOPICAL SOCIETY.—The members of this Society held a conversazione on October 11th. Amongst the exhibits the micro-photographs taken by Mr. E. Ward attracted much attention. Mr. E. P. Quinn delivered a short and interesting lecture on vegetable traps, and Mr. J. A. Furnivel exhibited with a lantern microscope a number of prepared slides.

EDINBURGH ASSOCIATION OF SCIENCE AND ARTS.—At the meeting held on October 15th, Mr. J. M. Turnbull was elected President, and Messrs. T. R. Proctor and W. Bruce Vice-Presidents for the ensuing session. The retiring President, Mr. J. Melrose, said that the Association numbered 291 members.

RECENT INVENTIONS.

The following list has been compiled especially for the SCIENTIFIC NEWS *by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents, of* 234, *High Holborn, London, W.C.; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester; and* 6, *Lord Street, Liverpool.*

RACKETS.—Mr. W. Hawcridge has patented a press for lawn tennis racket. The object is to prevent rackets from twisting and for keeping them true. Two triangular pieces of wood are used, connected at each angle by screws adapted to allow the racket to pass between them at the base, and to be pressed between them by tightening the screws.

ELECTRICITY.—Mr. S. Joyce, junr., has patented the use of electricity as a source of explosive power. The electric explosive consists of a vessel wholly or partly filled with water, which is heated by the passage of an electric current through a coil of wire inserted in it; steam is thus generated, and the vessel exploded when sufficient pressure has been attained. Other fluids, such as dilute sulphuric acid, may be used instead of water.

CALENDAR.—An improved calendar has been patented by Messrs. B. Weeksler and M. E. Becker, of 128, Queen Victoria Street, and the object thereof is to enable the spectator to trace the day of the week of any date given. It consists of two distinct round pieces, the one rotating within the other. Upon the inner are inscribed the years and dates of the months and on the outer the days of the week and the names of the months. In operation the inner dial is moved so that the year in question is immediately opposite the given month, and the day appearing next the date is that required.

CLUBS.—Mr. W. A. Woof has patented an Indian club. The object is to so construct Indian clubs that their weight may be altered and adjusted to suit the party using them. Externally the shape of the club is as usual, but has its large end bored to receive a screw-bolt and movable metallic weights. The weights are of any suitable thickness, and have a hole in them to allow of the passage of the screw-bolt. When the requisite number of weights have been inserted, the screw is passed through them and screwed into a bush, until the head of the screw is firmly pressed against the outer weight.

CONTROLLING COCKS BY ELECTRICITY.—Mr. H. R. Fisher, of Waterloo Road, has patented an invention for controlling cocks and valves by electricity. A cap is provided which fits on the square shoulder of the plug of the cock, and projecting therefrom is a horizontal lever weighted to balance the resistance of the cock. An electro magnet is placed near the longer end, with its armature supporting the lever. When the circuit is closed, the armature is attracted, and the lever falls; the weight thereon (being loose upon it) slides down so as to increase the leverage, and the cock is opened.

PRESERVING MEAT.—Mr. Benjamin Willcox, of 47, Lincoln's Inn Fields, has been granted a patent for a process for preserving meat and other foods. (A communication from Mr. H. Lalyzer, M.D., of Baltimore, U.S.A.) In this process the pieces of meat are enclosed in an envelope of animal membrane, subjected to the heat of steam (to contract the bulk and destroy the organisms), are coated with plaster of Paris, and then placed in a bath of heated vaseline and paraffin, and finally wrapped with paper tinfoil or other material. By this process the article is made absolutely proof against attacks by germs of any kind.

PRESERVING SEEDS.—Messrs. P. L. Quarante and C. E. Le Revert have patented means for preserving seeds and plants from the action of parasites and hastening the germination and fertilization of seeds. To protect seeds from parasites when sown in the ground, they should be steeped in antiseptic and fertilizing liquids, with which young plants should be watered. The liquid for these purposes is composed as follows:—Acetate of aluminium, 15 parts; acetate of lead, 70 parts; Iceland spar or carbonate of lime, 15 parts. These matters are mixed and dissolved in water, and then used as stated. By this method the germination of the seed is also facilitated.

ELECTRICAL SWITCHES.—Messrs. F. L. Rawson and Mr. White have patented an electrical switch. It consists of a base of suitable material on which are fixed two contact plates. The connection between these arms is made by a switch-arm, consisting of several thin strips of metal placed one upon another and bent over at their ends, so that they press edgeways upon the contact plates. The switch-arm is attached to a handle and centre pin, which forms the centre upon which the switch-arm turns. The lower end of the pin carries a nut, and between this and the underside of the switch base is placed a washer, giving the necessary pressure on the contact plates. To secure a quick break a spring is provided which comes into action and presses on a spring-arm just before the switch-arm leaves the contact plates, and quickly drives the switch-arm rapidly from the same.

ANNOUNCEMENTS.

THE INSTITUTION OF CIVIL ENGINEERS.—The Council invites original communications on the subjects included in the following list, as well as on any other questions of professional interest. This list is to be taken merely as suggestive and not in any sense as exhaustive. For approved papers the Council has the power to award premiums, arising out of special funds bequeathed for the purpose, the particulars of which are as under:—

1. The Telford Fund, left "in trust, the interest to be expended in annual premiums, under the direction of the Council." This bequest (with accumulations of dividends) produces £260 annually.

2. The Manby Donation, of the value of about £10 a year, given "to form a fund for an annual premium or premiums for papers read at the meetings."

3. The Miller Fund, bequeathed by the testator "for the purpose of forming a fund for providing premiums or prizes for the students of the said institution, upon the principle of the 'Telford Fund.'" This fund (with accumulations of dividends) realises £150 per annum. Out of this fund the Council has established a scholarship—called "The Miller Scholarship of the Institution of Civil Engineers"—and is prepared to award one such scholarship, not exceeding £40 in value, each year, and tenable for three years.

4. The Howard Bequest, directed by the testator to be applied "for the purpose of presenting periodically a prize or medal to the author of a treatise on any of the uses or properties of iron or to the inventor of some new and valuable process relating thereto, such author or inventor being a member, graduate, or associate of the said Institution. The annual income amounts to nearly £16. It has been arranged to award this prize every five years, commencing from 1877. The next award will therefore be made in 1892.

The Council will not make any award unless a communication of adequate merit is received, but will give more than one premium if there are several deserving memoirs on the same subject. In the adjudication of the premiums no distinction will be made between essays received from members of the Institution or strangers, whether natives or foreigners, except in the cases of the Miller and the Howard bequests, which are limited by the donors.

LIST.

1. The utilisation of unused sources of power in Nature —such as the tides, the radiant heat of the sun, etc.
2. Standard specifications for the materials used in the construction of engineering works.
3. The influence of sea water upon Portland cement, mortar, and concrete.
4. The construction, ventilation, and working, of railway tunnels of great length.
5. Description of any new or peculiar type of mountain railway for very steep gradients.
6. Recent improvements in cable tramways.
7. The value, with respect to the safety and durability of metallic bridges, of (*a*) increase in the weight of the structure, by the choice of other than the latest design; (*b*) increase in the dead load, by the adoption of a heavy description of flooring, with or without the addition of concrete or ballast
8. The painting and preservation of metals, woods, etc.
9. Recent examples of hydraulic lift graving docks.
10. Forms and construction of masonry dams for reservoirs.
11. The cleaning and deepening of drainage and irrigation canals by mechanical means.
12. On the sale of water by measure.
13. Descriptions of mining machinery of improved design.
14. Gold quartz reduction and amalgamation—description of the various machines, and of their method of working.
15. The physical properties of metals under test.
16. The working strength of iron and steel as affected by (*a*) the amplitude; (*b*) the frequency; and (*c*) the time rate of the stress variations.
17. The present position of the manufacture of steel—its defects, and suggestions for its improvement.
18. The effect upon basic steel of (*a*) chromium; (*b*) aluminium; and (*c*) tungsten.
19. The properties of bronzes and other alloys.
20. Researches on the actual working limits of stress in machinery or structures under known conditions of variation of loading.
21. The corrosion of metal structures, and the best means of preserving them.
22. The effect of wind upon structures, as influenced by (*a*) their superficial area; (*b*) the form or position of the exposed surfaces; (*c*) the shelter of adjacent bodies; and (*d*) the dynamic action of sudden gusts.
23. On forging by hydraulic pressure, and casting under the same.
24. The construction of the working parts of steam engines, in relation to the high pressures and temperatures now becoming general.
25. The practical limit to the working pressure of steam in marine boilers.
26. The various systems of forced draught in boilers, with the economical results obtained.
27. The most recent types of (*a*) mail steamers; (*b*) cargo steamers; and (*c*) war ships.
28. On modern experience in screw propulsion, comprising the comparative efficiency of propellers of large diameter, and of smaller ones deeply immersed, and of the influence of form.
29. On the highest speeds attained and attainable on railways, having reference to gradients, curves, and the locomotives employed.
30. The application of the compound principle to locomotive and to portable engines.
31. Mechanical traction on common roads.
32. The petroleum engine and its applications.
33. The distribution of power by compressed air or by vacuum, and the construction of machines to be worked by compressed air or by vacuum.
34. Hydraulic rotative motors for high pressures.
35. The means of governing and economising high pressure fluid in hydraulic cranes, engines, etc.
36. The construction and working of windmills suitable for raising water for the supply of villages and isolated houses.
37. The best combined system of warming, ventilating and lighting large buildings.
38. The transmission of steam underground in the United States, with the results obtained.
39. The plant used in the execution of important engineering works
40. Tools used in the building of iron and steel ships, and in the construction of boilers.
41. The construction and working of friction-brake dynamometers.
42. Steam cultivation by digging and by ploughing.
43. The generation of alternating currents in dynamo electric machines, and their utilisation for lighting and power purposes.
44. Electric meters for recording the consumption of electrical energy.
45. The construction and maintenance of secondary batteries.
46. Central station electric lighting.
47. The application of electricity to the working of street tramways and of railways.
48. The application of electricity to the working of cranes, pumps, tools, etc.
49. The application of electricity to smelting and metallurgical operations.
50. The application of electricity to the purification of water and of sewage.
51. The purification of copper, and the reduction of copper ores by electrolytic processes.
52. Contributions to the bibliography of special branches of engineering.

For further particulars apply to the Secretary, The Institution of Civil Engineers, 25, Great George Street, Westminster, S.W.

DIARY FOR NEXT WEEK.

Monday, Oct. 29.—Birkenhead Literary and Scientific Society, at 8 p.m.—*Some Psychical Phenomena*, by Rev. A. Sloman.

Thursday, Nov. 1.—Chemical Society, Burlington House, at 8 p.m. Gresham College, Basinghall Street, at 6 p.m. —*Lecture on Law*, by Dr. J. T. Abdy.

Friday, Nov. 2.—Gresham College, Basinghall Street, at 6 p.m. —*Lecture on Law*, by Dr. J. T. Abdy.
Greenock Philosophical Society, Watt Institution, at 8.15 p.m.—*How Jupiter and Venus caused the Great Ice Age*, by Sir R. S. Ball, F.R.S.

SELECTED BOOKS.

On the Senses, Instincts, and Intelligence of Animals. With Special Reference to Insects. By Sir John Lubbock, Bart., M.P. With 100 illustrations. London : Kegan Paul, Trench, and Co. Price 5s.

Elementary Commercial Geography. A Sketch of the Commodities and Countries of the World. By H. R. Mill, F.R.S.E., Lecturer on Commercial Geography in the Heriot Watt College, Edinburgh. London : C. J. Clay and Sons. Price 1s.

Planetary and Stellar Studies, or Short Papers on the Planets, Stars, and Nebulæ. By J. Ellard Gore, F.R.A.S. London : Roper and Drowley.

An Elementary Treatise on Geometrical Optics. By R. S. Heath, M.A., Professor of Mathematics in Mason Science College, Birmingham. London : C. J. Clay and Sons. Price 5s.

A Class-Book of Elementary Chemistry. By W. W. Fisher, M.A., Demonstrator of Chemistry, Oxford. London : Clarendon Press. Price 4s. 6d.

The Metallurgy of Gold. A Practical Treatise on the Metallurgical Treatment of Gold-bearing Ores, including the processes of Concentration and Chlorination, and the Assaying and Refining of Gold. By M. Eissler, formerly Assistant Assayer of the U.S. Mint, San Francisco. With ninety illustrations. London : Crosby Lockwood and Son. Price 7s. 6d.

Kirke's Handbook of Physiology. Twelfth edition. Thoroughly revised and edited by W. Morrant Baker, F.R.C.S., and Vincent Dormer Harris, M.D. London : J. Murray. Price 14s.

The Principles of Agricultural Practice as an Instructional Subject. By J. Wrightson, M.R.A.C., F.C.S., etc., Professor of Agriculture in the Normal School of Science and Royal School of Mines, etc. With Geological Map. London : Chapman and Hall, Limited. Price 5s.

NOTICES.

The Title Page and Index to Vol. I., now ready, price 3d.

Binding Cases for Vol. I., price 2s. each.

Cases and Binding, Vol. I., including Title Page and Index, price 3s.

Vol. I., bound in cloth, with Title Page and Index, 9s. 6d. —by post 10s.

The Back Numbers of SCIENTIFIC NEWS can be obtained from all Booksellers and Newsagents, or direct from the Publisher, 138, Fleet-street, London, E.C. Price 3d. each, or by post 3½d.

METEOROLOGICAL RETURNS

for the ten weeks ending on Monday, Oct. 15th, 1888. Specially prepared for SCIENTIFIC NEWS from official reports.

Scientific News

FOR GENERAL READERS.

Vol. II. NOVEMBER 2, 1888. No. 18.

CONTENTS.

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

The *Saturday Review* commences an article on the subject of "Adulteration" as follows: "Generally speaking, nothing which we eat or drink is what it seems; everything is unreal and what it ought not to be, from marmalade, in the composition of which the common turnip plays no insignificant part," etc., etc.

This statement about turnips in marmalade is so frequently repeated, and is actually believed by so many, that a demonstrative contradiction is demanded. Some years ago I tried the experiment of mixing "no insignificant" proportion of turnip pulp with some home-made marmalade, first using equal weights of turnip and orange, and found the result most nauseous, the rank turnip flavour growing worse and worse the longer it was kept. I then tried two of orange to one of turnip, then three to one, and finally only $\frac{1}{16}$ of turnip—that is, one ounce to the pound—and still the turnip flavour was so evident, both to taste and smell, that such a mixture would be utterly unsaleable. This experiment may be easily repeated by anybody.

A great number of other alleged adulterations, when practically tested, prove to be equally imaginary. That of iron filings in tea was very popular some years ago, definite assertions as to the quantity thus added being made, commonly about 5 per cent. Grocers were convicted and fined for selling tea containing such quantity. I wrote to the *Chemical News* a letter which was published November 21st, 1873, working out the figures as follows. The price of the cheap teas said to be thus adulterated does not exceed 4d. to 6d. per pound in China. If the Chinaman obtains iron filings at 2d. per pound, his gain by such adulteration would amount to about $\frac{1}{10}$ of a penny per pound, or still less when the cost of labour in mixing is deducted. The total deliveries of black tea into the port of London alone amounted at the time to 160 millions of pounds, of which 140 millions came from China. Adding those to tea-drinking Russia, to America, and the British Colonies, the total exports from China amounted to 400 to 500 millions of pounds of tea per annum. If only 100 millions of pounds were thus adulterated (the iron was found in all samples of black tea) five millions of pounds of iron filings would be required annually. How could the Chinaman obtain this quantity of *filings?* It should be noted that only very fine filings would answer the purpose, as coarse filings would shake down to the bottom of the chests.

If the adulteration was perpetrated in England, where is the market? Where are the waggon-loads of iron filings that would be demanded? Who collects them? The quantity produced in each workshop being so small, the collecting of a million of pounds would be a big business. As a matter of fact no market for iron filings exists, except for small quantities used by firework-makers and some other trifling purposes. Nearly all are swept away.

But there is iron in tea; it has been found even in the leaves of plants grown under glass at Kew. "The Yellow River" of China is so called because it is tinted with the ochreous earth which constitutes the soil on which most of the Chinese tea is grown, and tea-leaves gathered in dusty weather are liable to be slightly coated with the ferruginous dust from the soil on which they grow, in addition to containing a little iron, which they naturally absorb from the soil. Upon this basis was erected the whole fabric of supposed adulteration. As I showed in the letter above referred to, the colour of *black* tea is due to the combination of some of the iron it contains with the tanno-gallic acid it also contains. This tanno-gallate of iron is the colouring matter of ordinary black ink. In the dried tea-leaf it exists in an insoluble form.

The idea of substituting sloe leaves in this country, is equally absurd. Where are the sloe plantations? If gathered from the hedgerows, where the wild sloe may be found, who are the gatherers? They should be as numerous and as evident as hop-pickers.

Within my recollection it was confidently asserted that brown sugar was adulterated with sand. Common sense should have refuted this at once, seeing that every cup of tea or coffee sweetened with such sugar would effect a quantitative analysis by displaying a gritty, insoluble residue at the bottom of the cup. Plum puddings or any other solid product of cookery in which sugar was used would be utterly uneatable, on account of the painful effect of attempting to masticate silicious particles.

Doubtless there are some adulterations practised. I have recently detected one in moist sugar, viz., common salt, which is not added for its own sake, but for the water which it causes to adhere to the sugar. It is not added by the usual victim of the Adulteration Act, the retail grocer, but by the manufacturer, and if I am not mistaken, it is done by adding sea-water or brine to the syrup before crystallisation.

Falsification is more prevalent than adulteration, and it is usually perpetrated on the most costly articles, such as high-class wines—so called and paid for—high-priced cigars, etc. Common "Italian red," diluted Catalan, and other very cheap sound ordinary wines are, by skilful manipulation with certain ethers and other flavouring ingredients, endowed with fancy bouquets, and the rest is done by a transmutation of labels according to the varying demands for fancy vintages. The higher the price the greater the temptation. Those who imagine that by paying a high price they are secure from such imposture are the most abundantly fooled. The chateaus that give their names to these choice wines have usually but small vineyards, producing in some cases not more than two or three per cent. of the quantity of wine that is labelled with their names.

There is another kind of adulteration, of which we hear very little, and which is not punishable under the Act of Parliament, viz., the adulteration of silk. About thirty years ago, when at the Midland Institute, I made a series of experiments on aniline dyes for a leading house in the silk-dyeing business. I went through the works at Coventry with the head of the firm, and saw various processes of "weighting" in operation. He expressed his own disgust at the practice, and told me that he commonly received samples of "boiled silk" (that is, the raw silk cleansed from its natural gum by boiling in potash), with orders to return sixty ounces to the pound when dyed. This was especially the case with black silks.

The forty-four ounces consisted of salts of tin, lead, etc., attached to the fibres by mucilaginous compounds. These metallic salts become more or less crystalline when the silk is dry, and cut through the modicum of actual silk wherever folds occur. Ladies know all about the facts of such cutting, though perhaps not of their cause. I have since learned that the progress of applied science has enabled the dyers now to return seventy ounces to the pound.

"China sewings," *i.e.*, the white silk used for sewing the button-holes of white waistcoats, when these were fashionable, were largely loaded with acetate of lead—so much so that it was easily detected by its sweet taste. Sempstresses employed on such button-hole work have suffered from lead colic, due to biting the ends of such silk in threading their needles.

THE RESPIRATION OF BATS DURING THEIR WINTER SLEEP.

If we disregard the earlier investigations of Gesner and Buffon, Saissy was probably the first who examined hybernating animals. He proved that in bats respiration became less frequent, and he even conjectured that in this condition they could support life in an atmosphere devoid of oxygen.

Marshall Hall examined a hybernating bat placed under a glass bell. He could not determine any absorption of gas during an interval of ten hours, whilst the same animal when awake expired in the same time 13 cubic centimetres of carbonic acid. Another bat consumed in sixty hours only 10 cubic centimetres of oxygen, whilst when awake it absorbed the same quantity in one hour. He found the temperature of the animal higher by 2 to 3 degs. Cent. than that of the surrounding atmosphere. According to Regnault and Reiset, the marmot, in its deepest winter sleep, consumes only $\frac{1}{30}$ of the oxygen which it would require in the same time when awake. Valentin, in his numerous experiments on hedgehogs and marmots, found still lower values. Such animals, however, cannot bear the total absence of oxygen, though they can live in an atmosphere containing 10 per cent. of carbonic acid and 5 per cent. of oxygen. The experiments of Horwath on the respiration of the pouched marmot (*Spermophilus citillus*) led to similar results, and Voit found that the marmot stores up oxygen during hybernation.

The more recent researches of Delsaux, communicated in the *Naturforscher* and in the *Archives de Biologie*, were made on the long-eared bat (*Plecotus auritus*) and the common bat (*Vespertilio murinus*). These animals were obtained from the caverns of Maestricht, where they may be found during the winter in thousands, at an average temperature of 6·7 degs. Cent., their bodily warmth being on the mean 7·13 degs. Cent. The animals were kept in the author's laboratory in the dark, and at a temperature of 7 to 8 degs. Cent. Each was kept in a separate cylinder, so that they might not disturb one another.

The respiratory rhythm during the winter sleep is peculiar. In the bats sleeping in the caverns no respiratory movement can be perceived often for a long time. In the laboratory, after long intervals, which may last for fifteen minutes, there occurs a series of very superficial respirations. Noise and light do not affect the breathing, but the slightest touch or agitation occasions at once a series of respiratory movements, followed, however, by long pauses of breathing if the animals are not further disturbed. If the bats are aroused from their sleep their temperature rises suddenly. The position, whether the animal is hanging—its natural attitude when asleep—or lying horizontally, seems to have no effect on the breathing. If the air be exhausted down to a pressure of 50 millimetres of mercury, the bat suffers from asphyxia, but recovers on the re-admission of air.

A Plecotus, which had been kept for half an hour in a cylinder cooled down to 21 degs. Cent., recovered and breathed, although the respiratory movements had previously entirely ceased. Horwath had observed that the hearts of hybernating animals still show regular pulsations, even if their blood has cooled down to + 4 degs. Cent. The animals experimented upon exhaled hourly per kilogramme of their weight 57·3 to 61 milligrammes of carbonic acid at +7·5 degs. to 8 degs. Cent., but only 39·4 to 44·6 kilogrammes at 0 degs. (freezing point). Thus, as in the cold-blooded animals, a reduction of temperature naturally decreases the excretion of carbonic acid.

CREMATION.—We learn from *Cosmos* that cremation has been formally interdicted by the Pope as a "condemnable abuse."

THE SCALY AMPHIBIA OF THE PLAUEN GLEN NEAR DRESDEN.

THE subjoined figures, for which we are indebted to the courtesy of a German contemporary, the *Illustrirte Zeitung*, give a good idea of the structure of a very interesting group of extinct animals.

The teachings of Darwin served as a challenge to geologists to find out the supposed intermediate forms which link together organisms now living and seemingly quite unconnected. What the zoologist had prophetically foreseen, taking his stand upon embryological and morphological researches, the geologist has to seek out in the strata of the earth, furnishing in this manner new and irrefutable evidence of the unity of the organic world, and proving that animals are not the outcome of desultory, special creation, but have advanced in gradual stages to higher and higher differentiation.

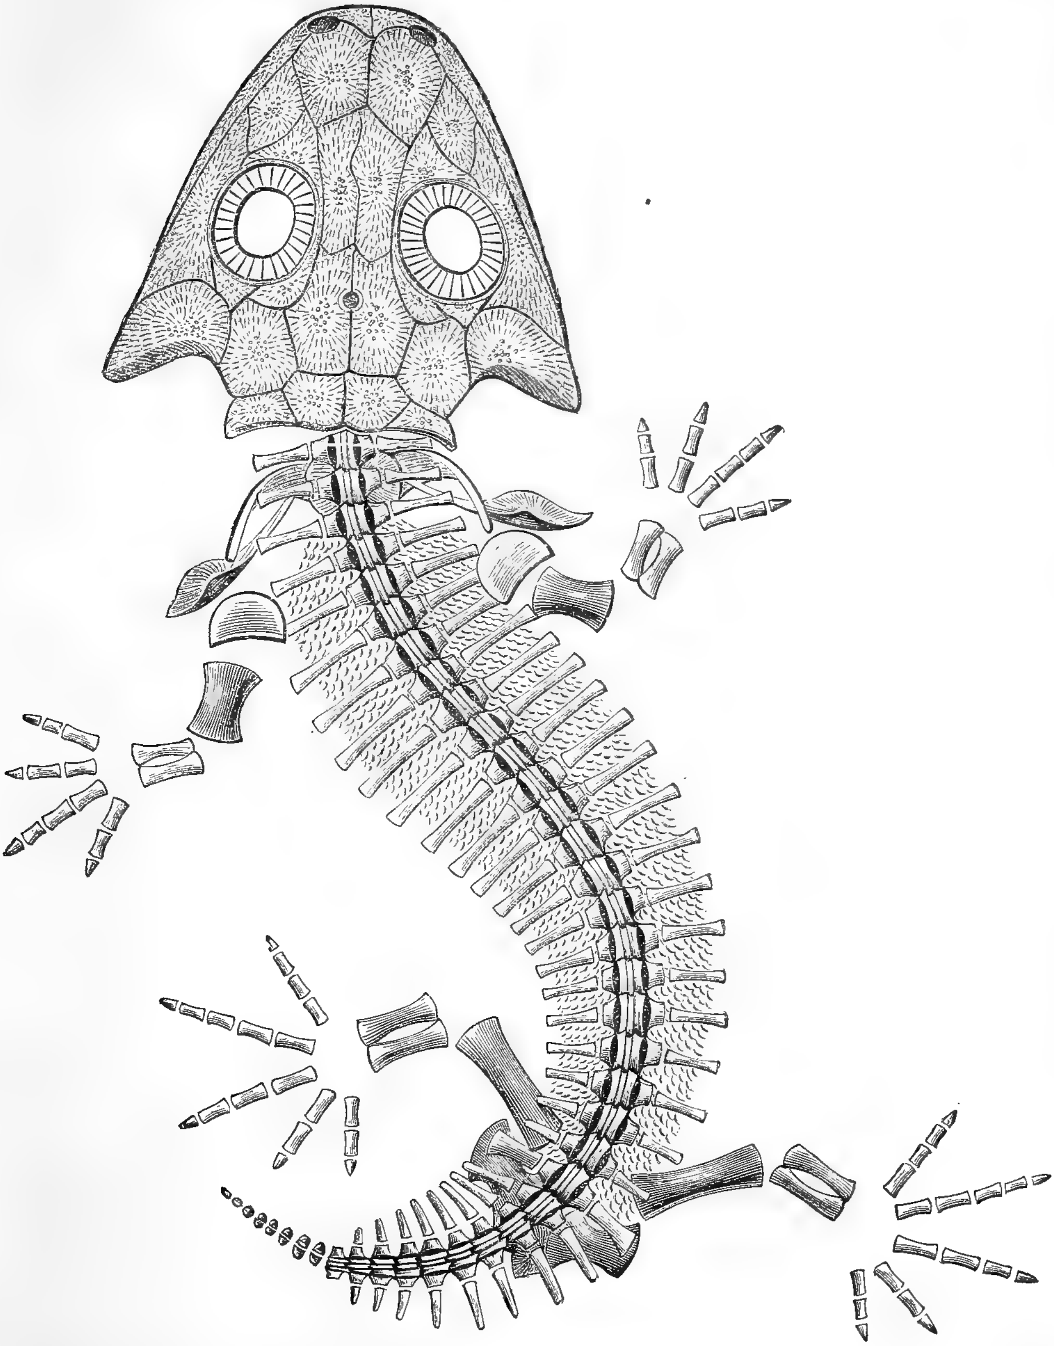

FIG. 1.—PELOSAURUS LATICEPS (FROM ABOVE).

When in the beginning of the present century Lamarck maintained that the horse had been evolved from many-toed ungulate animals by a process of gradual transformation, Cuvier replied that he would not accept this view until Lamarck could show him a three-toed horse. The forerunner of Darwin was brought to silence by this demand. But in our days Cuvier might behold the entire pedigree of the horse from the five-toed Eohippus —an animal no larger than a fox—to the three-toed Hipparion, and so on to the modern one-toed horse, all duly displayed in American museums. The Archæopteryx of Solenhofen (SCIENTIFIC NEWS, vol. ii., p. 309), with its toothed beak and its long lizard-like tail, is a true primæval bird, and fills up an important gap in the most significant manner. Recently more and more intermediate links have been brought to light, and the rocks speak a language convincing to all who will listen.

In the last few years, Professor H. Credner, of Leipsig, has published a series of memoirs on the Stegocephala. In these papers he has made us acquainted with the structure and the development of a group of animals which became extinct millions of years ago, a group whose existence falls in one of the earliest periods of the earth's history, and which comprises the earliest terrestrial, air-breathing vertebrate animals brought forth by our earth.

In the Plauen Glen, near Dresden, a deposit of limestone is being quarried, of small extent and thickness. But it contains fossil newts, varying in length from two to eight inches, and in such numbers that Credner succeeded in obtaining above a thousand specimens. The skeletons of these little creatures lay upon the grey limestone in so faultless a state of preservation that they could be submitted to the most minute examination. Ten distinct forms were discovered by Credner, and the accompanying figure (1) shows in natural size one of the most characteristic species, *Pelosaurus laticeps*. The broad, roof-formed skull, whence the name of Stegocephala, "roof-heads," given to the entire group, is the most striking feature. The body is compact, the tail short, and the limbs well-developed. In the front of the head we see the two nostrils, then the orbits of the eyes, protected by a ring of bony plates, and, finally, a hole in the middle of the skull, between the two parietal bones.

This hole was formerly a puzzle, but its meaning was interpreted last year, since De Graaf and Spencer have shown that in certain lizards there is *an eye* at the same place in the skull. This eye is certainly no longer used for sight, but it possesses the same complicated structure as other eyes among the vertebrates. This so-called parietal eye seems to have been still active in those ancient newts, for Credner succeeded in showing that the fine scales covering otherwise the entire skull were not developed over the parietal aperture, so that the parietal eye lay exposed—an observation of very high theoretical value.

The curious scaly coverings of the abdomen can be seen through the ribs, and are fully shown in figure 2, which represents an allied species (*Branchiosaurus amblystomus*) from below. The short ribs afforded no protection to the abdominal organs. Hence the Stegocephala required a strong scale-armour on their lower surface. Credner has succeeded in showing how this armour was gradually developed during the growth of the animal. It first appears over the region of the heart, then it spreads down over—or rather under—the abdomen, as in figure 1, and lastly, as in figure 2, it covers the lower side of the four extremities and of the tail. As the possession of this scale-armour is characteristic of all the earlier amphibia in contradistinction to those of more recent periods and of the present, the former are known as "scale-amphibia."

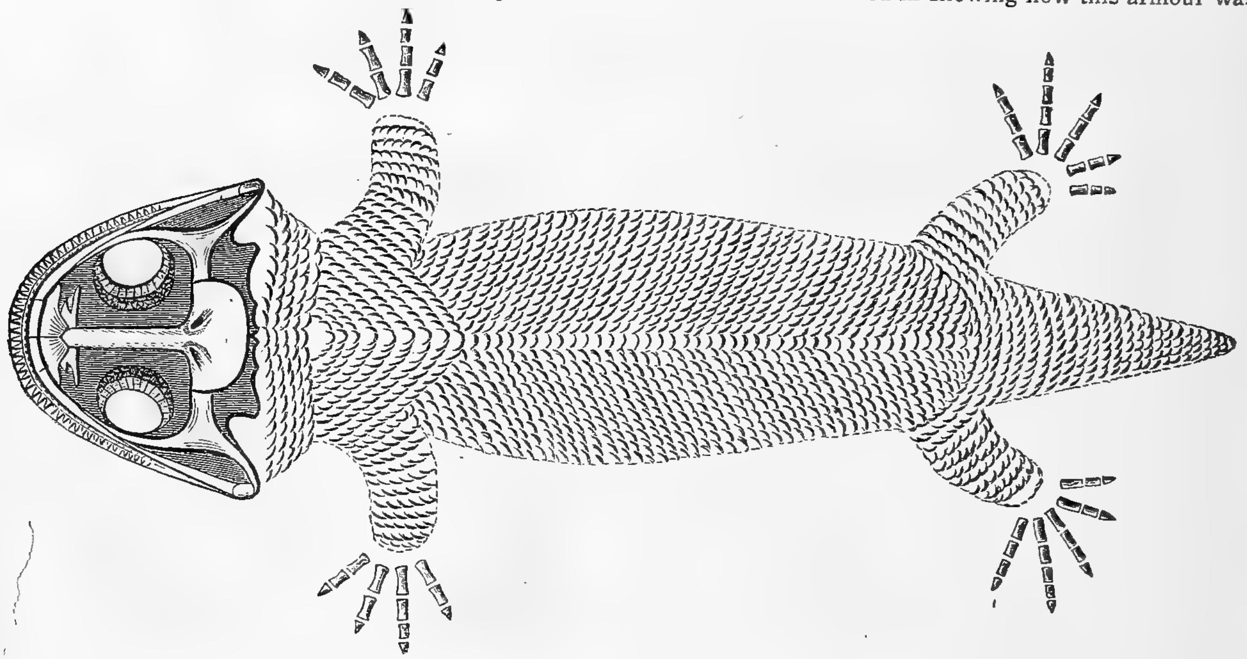

FIG. 2.—BRANCHIOSAURUS AMBLYSTOMUS (FROM BELOW).

A much more important fact was elicited on the study of the younger individuals, *i.e.*, that in youth the stegocephala breathed by gills, but when mature by lungs. Their development, therefore, was exactly similar to that of frogs in the present day. The arches of the gills are not easily recognised, but small, conical teeth were attached to them, exactly as it is observed in modern fishes and amphibia. Such elegant rows of teeth are found in almost all young stegocephala, behind the skull, and both sides of the back-bone. The fossils in question rank among the most highly prized treasures of the Leipzig Geological Museum.

MARS AND ITS "CANALS."

(*Continued from p.* 434.)

WHEN Mars appeared again in opposition this year M. Perrotin had at his disposal a much more powerful instrument than heretofore, an equatorial of 76 centimetres aperture. With this he easily saw the canals, both single and double. He further detected a very curious phenomenon. A small continent to which Schiaparelli had given the name of Libya had disappeared, and was surmised to have been overflowed by the adjacent seas. In this conjecture there was nothing irrational, since a similar occurrence had taken place in 1879. However, the hypothesis of the disappearance of Libya is very doubtful, since M. Perrotin, in a recent communication, announces that this region has reappeared, with the usual light and reddish tint of the supposed continents of Mars. Hence the inundation, if such took place, must have been of a very temporary nature. Schiaparelli also observed (figs. 1 and 2) a canal traversing the northern polar cap. In the dazzling whiteness of the snowy mass there appeared a black line connecting two seas. Nepenthes was excessively black, and presented the same aspect as it did to Holden in 1875. It seemed as if that snowy region which is separated from the polar cap by a black line was less white and brilliant than the polar cap itself.

On May 13th Schiaparelli made the following observations: "Striking novelties have presented themselves in the regions called Phlegra and Propontis; with low magnifying powers we see merely a series of confused shadows, but on employing 500 and 650 they were resolved into a kind of curious triangulation, one side of which is double. This triangulation is continued further to the left. There are at least two more triangles. Their apices form very distinct black spots, somewhat elongated in form, and the ground colour is yellowish."

After the existence of the canals, after their gemination, this triangulation forms the culminating point of the mysteries of Mars. What an analogy between this figure and the trigonometric draughts of our geodetic operations!

Professor Schiaparelli further adds that the lake Triton had changed into a broad gulf of the Cimmerian Sea.

The Milan 18-inch refractor further enabled the observer to distinguish from each other the two margins of certain canals, and to perceive their undulations.

On June 7th Schiaparelli writes, "I have seen the planet fairly well on May 9th, 25th, and 27th, and much better on June 2nd and 4th. I saw the prodigious images which presented themselves in the field, like an exquisite steel engraving, but illuminated with the magic of colours. A power of 650 did not suffice for the complete detection of details, and I regretted having had the disc reduced to 12 inches in diameter. Not only have I confirmed the gemination of Nepenthes and the reappearance of the lake Triton of 1877, but I have also seen the Lacus Mœris reduced to a very small point. Hephæstus has entirely disappeared. Œnotira is no longer visible. Euphrates is double throughout its extent, but it is not as plain as on May 27th and 30th. The two lines are slightly washed out. Callirrhoë and Protonilus are two geminations, very narrow, but geometrically perfect and very black, especially Callirrhoë. These features require a magnifying power of 650 to be distinctly seen. The two lines of Callirrhoë are equal, but in Protonilus the upper line, though much more slender than the lower, is perfectly traced. The Phison is double, almost like the Euphrates. Astaboras is also double, but it is more visible to the left of Phison. Syphonius and Orontes are single, as is also a new line marked X in the drawing (see fig. 3).

"But, perhaps, the most perplexing feature is the frequent and rapid change recognised in Mars. Oxus has grown much fainter, and latterly I can no longer see it, whilst Indus has reappeared. Hiddekel is almost invisible. Gihon is slightly clouded; it goes towards a small lake from which there issue two lines towards the lake Niliacus. The changes which have occurred within a month in Boreosyrtis and the surrounding regions! What a strange complexity! What may all this signify? Evidently the planet has fixed geographical details, similar to those of the earth, with gulfs, straits, etc., irregular in plan. Then comes a certain moment, and all this disappears, giving place to those grotesque polygonations and geminations which evidently seem to form an approximate representation of the previous condition of the planet, but as if masked and almost caricatured.

"How is it, we may here ask, that no decisive observations on the existence of mountains in Mars have been made, or at least published?"

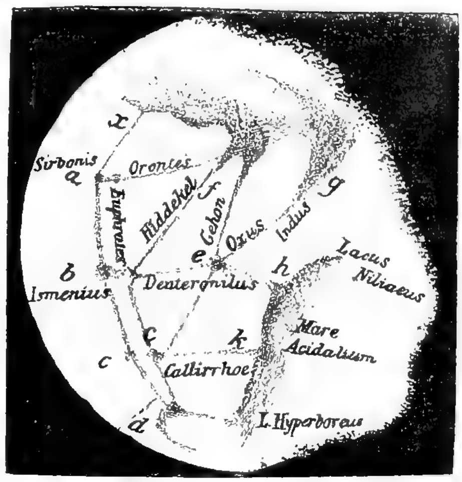

FIG. 3.—SKETCH OF MARS AS IT APPEARED ON MAY 27TH, 1888 (AFTER SCHIAPARELLI).

Before proceeding to the hypotheses which have been propounded in explanation of these strange facts, we may mention the circumstance, noted by M. Schiaparelli, that the phenomenon of gemination is connected with the seasons of the year of Mars, and occurs especially between the spring equinox of the northern hemisphere and its summer solstice. It would be impossible to say if the same state of things occurs at the autumnal equinox.

(*To be continued.*)

THE SERPENT IN THE MYTHOLOGY AND THE WORSHIP OF ANCIENT NATIONS.

DR. MORITZ WINTERNITZ, who is preparing an exhaustive work on serpent-worship in India, has published a preliminary sketch of his views in the

Mittheilungen der Anthropol. Gesellschaft zu Wien and in the *Naturforscher*. He considers that there is scarcely any animal which has played so great and so manifold a part in the religious conceptions of all nations. The mythogenetic or saga-framing imagination has formed the most varied beings out of serpents. At first it is always the serpent as an animal to which fable and worship attach themselves. It is a fact that snake-myths and snake-worship are found wherever snakes exist—that is over the whole earth (?)—but more especially in those lands which are richest in serpents, India and South America. Although the bodily properties of the serpent do not, to the keenly discriminating eye of the naturalist, entitle serpents to take such a position, the lay public, and especially the savage, see differently, and it is their superficial consideration of physical properties which determines the popular conception of serpents. Thus, the uncanny, flashing eye of the serpent, which does not strike the zoologist as remarkable, plays a very prominent part. Hence among the ancient Greeks the serpent was regarded as the most sharp-sighted of all animals. Hence there arose numberless sagas concerning the magical action of the serpent's look—fables which still live in narratives of the fascination exerted by serpents upon birds, and which have made their way even into scientific treatises. We may here, however, interpose a question whether birds and and other small animals by gazing fixedly at the eyes of a serpent may not fall into a trance or hypnotic condition, during which they become a ready prey. This influence, apparently exerted upon their enemies, together with the docility which many serpents evince up to a certain degree, led to the ascription of an exalted intelligence to serpents, and naturally brought them into close connection with magic and soothsaying. Throughout the East the serpent is an object of sorcery. The Delphian oracle—the most famous of all in Greece—was guarded by the dragon python. Many Oriental sagas represent priests and prophets as being indebted to serpents for an understanding of the language of birds. In like manner German fables describe the king as learning the language of animals by eating a white serpent, which reappears in Hindu literature as the all-knowing, deeply learned itself and imparting knowledge. The universality of this article of popular faith appears from the fact that even in South America the serpent appears as oracular.

In consequence of the profound knowledge attributed to serpents, we need not wonder that they were connected with the metallic treasures of the earth. Winternitz suggests that the rich metallic lustre which many snakes display may have contributed to this representation. But we may also consider that the abode of snakes in cavities and chinks of rocks may have led them to be regarded as mine-spirits and guardians of treasures. In the old German mythology the dragons sleep upon gold, and in Greek sagas the "Golden Fleece" and the apples of the Hesperides are committed to the keeping of the serpent. Throughout Asia and America is spread the belief in strange, black, shining stones which serpents bear in their heads. That the mine genii are represented as winged snakes may be due to the speed with which these creatures seem to glide down precipitous rocks.

The moulting of serpents gave rise to fables of another kind. Since the serpent seemed thus to renew its youth, it was regarded as immortal, and was adopted in the mysteries. Here we find the first step taken to the sagas, which describe serpents assuming various forms, and especially as transforming themselves into beautiful youths and maidens.

Above all, the fearful action of its venom has brought the serpent to high popular honours. Says an Indian proverb, "No one is reverenced, however great he may be, until he has wrought evil." Thus the serpent has been deified, worshipped as an evil demon, on account of the terrific death-dealing power of many species. As such it appears in the Hebrew history of the Creation, and in the Zendavesta Ahriman, the evil principle, figures as the great serpent. But on the other hand was the belief that the same being which inflicted sickness and death could heal and quicken. This representation of a conflicting dualism in one and the same being is found distinctly embodied in all antiquity. As examples are the head of the Gorgon, combining beauty and horror, or the lance of Peleus, which alone could heal the wounds it had inflicted. Thus the serpent alone was supposed able to counteract its own deadly bite. Not merely snake-bites, but other diseases, were supposed to be cured by serpents. So closely were they connected with the art of healing that the god of medicine, Asklepios (vulgarly Æsculapius), himself figures as a serpent, and a rod entwined with snakes is still the symbol of his followers. All manner of remedies were prepared from serpents by the physicians of antiquity and of the middle ages, and even in the last centuries the consumption of poisonous serpents by pharmacists was so great that multitudes were imported from Egypt.

But when once serpents had come to be regarded as beneficent beings, healers of disease, only a small step was needed to convert them into good spirits, tutelary genii, the bringers of good fortune. As serpents often were found inhabiting tombs, they were connected with the spirits of the lower world, and regarded as the souls of the departed, the manes, the heroes. Thus snake-worship links itself with the worship of forefathers, as we find alike among the Zulus, the Red Indians, and the Greeks. But the same worship is also closely intertwined with the veneration of the house-gods, the penates. Thus numerous nations viewed serpents as beneficent tutelary spirits, whose destruction would involve the ruin of the family or the tribe. Such was the case among the Teutons, Sclaves, Greeks, Romans, peoples of the East, of Africa and America. In Mexico, Yucatan, and Guatemala even human sacrifices were offered to serpents. The deity Cihuatcohuat, the "woman-serpent," was regarded as the mother of mankind, and the saga of creation among the Quiches of Guatemala tells us that "in the beginning was only God the Creator, the mighty Serpent."

Thus we see the serpent pass through all changes from a rude fetish to mythological beings, evil demons, and good spirits, and ultimately appear as the Supreme Deity.

The deification of the serpent was promoted by the circumstance that various natural phenomena seemed to contain its image. Earthly and heavenly waters, the "serpentine" river, the black storm-cloud, and the descending lightning were all viewed as serpents.

Perhaps the last stage of evolution through which the serpent has passed is when the abstract idea of eternity is shadowed forth as a coiled-up snake. Thus the Orpheic deity, Æon, and Chronos himself are represented as wound round by a serpent.

General Notes.

The Alleged Mongolian Affinities of the American Race.—Dr. D. G. Bienton (*Science*) ably, and as we we think convincingly, combats the theory that the aborigines of the Western Continent are of Mongolian origin.

Boring for Water in Queensland.—We learn that the Government has accepted the tenders of Messrs. Jessop and Haig for boring for water to a depth of 10,000 ft. in the Central district, and 7,500 ft. in the Southern district.

The Decomposability of the Benzol Nucleus in the Animal System.—Dr. N. Juvalta has solved this interesting physiological question in the affirmative. From very careful experiments, he found that the benzol-nucleus, as contained in phthalic acid, is destroyed in the digestive organs of dogs.

Sanitary Neglect.—Dr. Parkinson (*Royal Society of Tasmania*) complains that at Hobart the foul water from a stagnant pool is allowed to pollute the general town supply; that filth is left lying exposed to an almost tropical sun and house slops trickling all day along slimy channels in front of the very doors.

The Origin of Cannibalism.—This custom, widely diffused in ancient times, and still existent, notwithstanding the assertion of Waterton, is ascribed by a writer in *Cosmos* to the "necessity of sacrifice." But as the same custom may be traced in many animals, mammalia, birds, fishes, insects, and spiders, this view cannot be accepted.

East African Exploration.—Count Teleki, with Lieutenant Hohnel, have arrived at Zanzibar, Oct. 28th, and report the discovery of a lake named Basson-Aros due north of L. Baringo. This lake, which is filled by two rivers flowing into its north end from the west and north, extends from 2 degs. to 5 degs. north west of L. Samburu.

Alleged Cure for Yellow Fever.—According to the *Electrical Engineer*, the actinic rays of a powerful arc lamp constitute an effectual remedy for the yellow fever. *Cosmos* admits that solar light is deadly to some bacilli, but questions if such can be the case with the germs of yellow fever, which evidently live and increase in brilliant sunshine.

New Minor Planet. — Dr. Palisa, of Vienna, announces the discovery of the 279th minor planet at 7 p.m. on the 25th ult. The position at the above time was—Right Ascension, 0 h. 53 mins. 36 secs.; North Polar Distance, 87 degs. 5 mins. 2 secs.; moving southwards. The planet is about equal in brightness to a 13th magnitude star.

Yellow Fever.—Surgeon-Major Riordan (*Medical Press*) remarks that yellow fever, though it has repeatedly visited Europe and Africa, has never penetrated into Asia or Australia. It differs from cholera in being confined to warm countries, and in the fact that a person who has survived one attack generally enjoys immunity for the rest of his life.

The Exploration of Greenland.—If Dr. Nansen and his daring companions have effected their purpose they will have left the Bay of Disco on September 16th, in a sailing-vessel, which was to wait for them to that date, and which may be expected in Copenhagen shortly. If they have not reached Disco by that time we shall not learn their fate before next summer.

International Geographical Congress.—The Paris Geographical Society proposes that such a congress should meet in Paris in 1889. Seven sections are proposed: 1. Geodesy, hydrography, topography; 2. Physical geography; 3. Economical and commercial geography; 4. Historical and ethnographic geography; 5. Educational geography; 6. Travels and explorations; 7. Cartography.

Salicylic Acid in Eggs.—According to *Cosmos*, salicylic acid, the use of which in articles of food as an antiseptic is interdicted by law in France, is introduced into eggs. It is dissolved in water, in which the eggs are immersed, and it penetrates by endosmose through the shell and the internal lining of the egg, and diffuses itself into the yolk. It is obvious that a variety of poisons may be introduced into eggs in this manner.

The Earthquakes in New Zealand.—Mr. Gordon, mining inspector, who was despatched by the Government to the Harmer Springs district to report upon the effects of the recent earthquakes, states that he found fissures ranging from one to four inches in swampy ground at the extremity of a line extending 20 miles north-west from the Springs. He found rents in hard ground some 2 ft. wide. He attributes the recent phenomena to chemical rather than volcanic action, owing to the vast quantity of sulphuretted gas liberated in the disturbed locality.

Adulteration of Sherry.—According to Dr. Thudichum, much of the wine shipped as sherry contains sulphuric acid in the proportion of 1 lb. per butt, besides 4 lbs. of sulphates, whilst the alcohol present, which naturally cannot exceed 12 to 14 per cent, is raised fraudulently to 26 per cent. by the addition of "evil spirits." "It is curious," says a medical paper, "that the amount of spirit which would be required to raise the 75,000 butts exported from Xeres in 1886 from 14° to 26° corresponds fairly with the amount of potatoe-spirit imported annually into Cadiz from Germany."

The "Giant Caloric."—Professor S. P. Langley, in his address before the American Association for the Advancement of Science—where, by the way, the opening discourse is delivered, not by the incoming, but by the retiring President—says happily that "the conception of phlogiston before it quitted the world perpetuated in physics the wrong in a multiplied form by generating an offspring specially inimical to true ideas about radiant heat, and which is represented by a yet familiar term. I mean caloric. 'Giant Caloric' is not, perhaps, even yet quite dead, though certainly grown so crazy and stiff in the joints that he can harm the pilgrims of science no more."

Glaciation in the Azores.—Hartung has discovered blocks of gneiss in the midst of a volcanic district, even at some distance from the coast, and has drawn the conclusion that they were erratic blocks, brought by icebergs. In *Humboldt* we find mention of a different view quoted from Simroth in the *Globus*. The inhabitants of Terceira state that these stones have been brought by ships as ballast, and have been used by the country-people for building their houses and garden-walls. This view is supported by the fact that the two spots where these stones have been found are not on the north side of the island, where ice-bergs would be stranded, but on the south and east coasts. The Azores have probably never been glaciated. Simroth was unable to find marks of glaciation even on the Pico, 7,000 feet above the sea-level, where snow falls every winter.

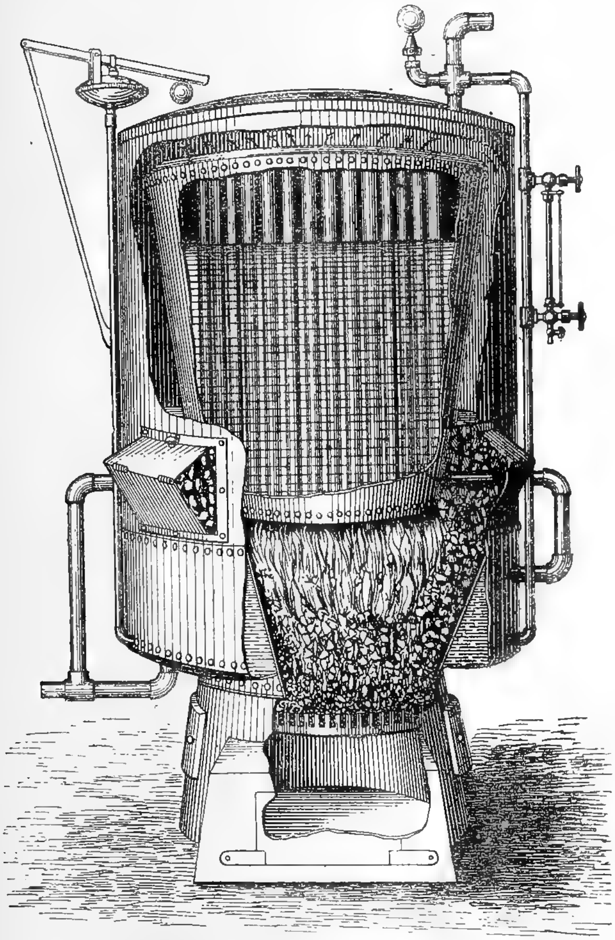
ACTION OF ELECTRIC CURRENTS UPON DELICATE BALANCES.—The *Naturwissenschaftliche Wochenschrift* remarks that as delicate balances are often strongly affected by very slight causes, such as trifling fluctuations of temperature or slight agitations, the question is justified in how far such instruments, as containing iron or steel, are disturbed in their sensitiveness by electric currents. The *Central-Zeitung für Optik und Mechanik* writes that certain manufacturers have refused to introduce the electric light in their establishments lest the current should injure their balances. Hence, G. H. Terry, of New York, has made a formal investigation of the alleged influence. To this end he placed balances of precision near very powerful currents and sought to discover any irregularities. But nothing could be detected. The balances contained very little iron or steel. For greater certainty he therefore placed a piece of iron in one scale and brought very near it a conductor traversed by a powerful current. No action was perceived until the current was brought within 3 millimetres of the iron. From these researches it follows that the currents used in electric lighting can have no effect upon balances of precision.

THE PINE FORESTS OF WESTERN FRANCE.—In a report on the agriculture of the Gironde, the British Consul at Bordeaux refers to the forests which cover about a third of the department, especially the Landes district, where the soil is wholly unfitted for ordinary cultivation. Hence forests of pines (*pin maritime*) have in recent times been planted, and the wood and resin obtained from them have now become an important and, in some instances, the sole source of revenue of the inhabitants of those districts. In the parts distant from towns and other inhabited places, resin is chiefly produced, while in places nearer to Bordeaux or other shipping ports, where means of transportation exist, the production of pit props, railway sleepers, telegraph poles, and wood for fuel forms the chief business. The collection of resin affords a living to a large number of the very poorest persons, and the recent decline in the exportation of this article from Bordeaux has been a great misfortune to the inhabitants of some parts of the Landes district. The decline has been caused by the annually increasing competition of the United States, which has become the chief exporter of resin, to the almost entire exclusion of Bordeaux. A new kind of oil, called pine oil, is now made from the refuse of resin after the latter has been employed in making turpentine. This is used as an illuminant in some private houses in Bordeaux, and burns very brightly; it is cheaper than refined petroleum, and is not explosive. The trees do not appear to suffer by the extraction of the resin, if it be done carefully, and the wood is even better fitted then for certain purposes, such as paper-making and the manufacture of pyroligneous acid, than it was before. The export of pit props made from the Landes pines is an important branch of trade between Bordeaux and English ports adjacent to coal districts. Railway sleepers and telegraph poles are likewise made in large quantities in these pine forests; they are used chiefly in France. Besides, a large quantity of young pine finds its way to England every year to be converted into paper. The Landes is a sandy district in which nothing but pines will grow, and the forests are all of recent origin.

THE PUBLIC HEALTH.—The Registrar-General's return for the week ending Saturday, October 20th, states that the deaths registered in 28 great towns of England and Wales corresponded to an annual rate of 21·0 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The six healthiest towns were Bradford, Brighton, Halifax, Huddersfield, Hull, and Leicester. The highest annual death-rates, measured by last week's mortality, were—from measles, 1·3 in Blackburn and in Wolverhampton, and 1·9 in Leeds; from scarlet fever, 1·6 in Sunderland and in Derby, and 2·6 in Blackburn; from whooping-cough, 1·0 in Cardiff; from "fever," 1·0 in Preston, 1·2 in Salford, 1·4 in Bolton, and 1·6 in Birkenhead; and from diarrhœa, 1·5 in Portsmouth, 2·5 in Preston, and 2·8 in Bolton. The 53 deaths from diphtheria in the 28 towns included 36 in London, and 6 in Manchester. Small-pox did not cause a single death in any of the 28 great towns. In London 2,459 births and 1,641 deaths were registered. Allowing for increase of population, the births were 329 below, while the deaths exceeded by 30 the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had increased in the four preceding weeks from 15·8 to 18·7, further rose last week to 20·0, and exceeded the rate recorded in any week since April last. During the first three weeks of the current quarter the death-rate averaged 18·4, and was 0·3 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,641 deaths included 80 from measles, 33 from scarlet fever, 36 from fever, diphtheria, 12 from whooping-cough, 19 from enteric 1 from an ill-defined form of continued fever, 42 from diarrhœa and dysentery, and not one from small-pox, typhus, or cholera; thus 223 deaths were referred to these diseases, being 19 above the corrected average weekly numbe Different forms of violence caused 51 deaths; 45 wer the result of negligence or accident, among which were 18 from fractures and contusions, 6 from burns and scalds, 4 from drowning, 3 from poison, and 10 of infants under one year of age from suffocation. In Greater London 3,233 births and 2,004 deaths were registered, corresponding to annual rates of 30·5 and 18·9 per 1,000 of the estimated population. In the outer ring 10 deaths from diarrhœa, 8 from diphtheria, 5 from measles, and 5 from whooping-cough were registered. The 8 deaths from diphtheria included 2 in Godstone, 2 in West Ham, and 2 in Walthamstow sub-districts. Both measles and scarlet fever also caused 2 deaths in West Ham sub-district.

THE GORTON BOILER.

IN the construction ot the Gorton heaters, one of which we show in our illustration, the plan of the upright tubular boiler has been wisely retained, and the additional advantages of self-feeding as well as surface burning have been incorporated by an ingenious device, enabling it to work well either way. The coal reservoir is between the lower outside surface of the boiler and the water leg, thus economising a space of from 9 to 12 ins. in diameter in the centre of the boiler for active heating purposes, while the tubes are directly above the fire, the heat passing up through them to the top, and thence down on the outside between the boiler and jacket to the smoke



pipe at the back. The reservoir will hold enough fuel to keep up a steady fire for from twelve to twenty-four hours. The boiler is designed to generate steam in an economical and effective manner, the tubes being placed as thickly as will admit of proper circulation, and its evaporative efficiency is calculated as fully equal to that of the return tubular boiler. The coal pockets in the Gorton are placed sufficiently low down to enable any one, even a child, to put on fuel, and thus there is no reaching up over one's head with a scuttle of coal, as is so very often the case with other styles of boilers, especially centre-feed boilers.

The grate, which is "cupped," or lower in the centre than at the periphery, has its outer or main part resting on ball bearings, so that it can be easily shaken, this allows the coal to feed down as it is needed and distribute itself uniformly; the centre part is independent and arranged to open on one side for removing clinkers. A recent improvement in this grate, and one possessed by no other steam-heating boiler, consists of additional air spaces, which provide for the free circulation of air at all times to the combustion chamber. It is known that the amount of steam produced is in proportion to the regularity and intensity of heat employed to generate it; that hence it is easy to understand, that if the temperature of the fire be lowered through clogging of the grate with ashes, the temperature of the premises is proportionately affected. With the improved grate as now furnished to this boiler, clogging is impossible, as in whatever manner the ashes may fall upon the grate, they cannot interrupt the draught. This ensures perfect combustion and a uniform temperature. These boilers are made of wrought iron, and are simple, of superior construction, and are particularly adapted for warming private dwellings, public buildings, hotels, apartment houses, and office buildings. They can also be used for manufacturing purposes as well as for heating buildings, and are fully guaranteed for a working pressure of one hundred pounds.

STORAGE OF MATERIAL AND FORCE IN PLANTS.

IF we take a pea-seed and place it in moist ground in the spring-time, it will soon begin to grow. First the root protrudes and passes downwards, then a little stem appears and ascends into the air towards the light, and a small group of leaves opens at its extremity. The stem continues to grow, more leaves are put out, they become of a deep-green colour, and if the plant be placed where light, air, and moisture act upon it we soon have a plant some feet in height, with a long stem, many leaves, and at length flowers appear. When the autumn comes the fruits are full of ripe seeds, and at length the leaves wither and dry up, losing their green colour, and the plant dies. Now if we carefully remove the plant entire, with its root, and leaves, and fruit, dry it and weigh it, we shall find that it weighs many hundred times as much as the seed from which it grew. Where has the material which makes up the difference in these weights come from? If the dried plant and all its parts be now completely burnt the weight of the ash or inorganic matter is ascertained. This was derived from the ground. The rest of the weight of the dried plant was manufactured by the leaves of the living plant, from the carbonic acid gas taken in from the atmosphere to the cellular tissue of the leaf, and there, through the agency of the cells of the leaf, under the stimulus of light, the carbonic acid gas absorbed was decomposed, the oxygen being returned to the atmosphere and the carbon united with the elements of water to form a new organic material called starch, which accumulates in the cells which were the agents for its production. This process of manufacturing starch in vegetable cells under the stimulus of light is termed *assimilation.* There is a substance in the cells which perform this work called *chlorophyll*, which is formed previous to the manufacture of starch, and the quantity of starch made by healthy leaves is, within certain limits, proportional to the quantity of light that illuminated the leaves. Now, as to the storage ot this new organic material, starch, when it has been made, this takes place in various parts of the plant. The cell where starch has been produced may itself serve as a reservoir, but usually the newly formed material is transferred to other growing parts, such as the buds and the root. In the case of the pea-plant much material is consumed, first in growth, and later in making the substance of the pea-seeds in the fruit. In many cases the newly formed material is transferred to some thickened part of the plant underground, some part of the stem or root, where it is kept safe till the plant begins to form its seeds. When reserves of material are thus formed underground they are less liable to be attacked by animals. The young pea-plant is destroyed if a pigeon eats off the top of the plant; a potato plant may have its leaves cropped by a cow and yet survive, because it has a reserve of starch in its tubers or thickened underground stems.

Now, as to the storage of force in plants, this is always the result of growth, and examples are mostly seen in the flowers and fruits. The flowers and fruits of plants may be said to be the results of their highest stages of development; a long series of actions takes place in the plant before it produces flowers and fruit. Many acts of growth and much formation of new material occur in the plant before the highly complex flowers appear, and it must be remembered that the formation of new material results from the action of light upon structures in the leaves. If the plant be healthy and has accumulated reserves of starch, flowers and fruit can form in parts excluded from light—light is not necessary to the formation of flowers. Flowers may grow from flower-buds without the stimulus of light; it seems as though some intrinsic forces were accumulated in the plant (probably the results of its inheritance) which will suffice for the growth of the flower from the bud if the plant has accumulated sufficient material.

A good example of storage of force is seen in the Kalmia-blossoms (*Kalmia latifolia*). The corolla closes in both the style and the stamens, which are seen just inside the corolla; the upper enlarged part of the stamen is its anther, or pollen-box, and this is lodged in a small pocket of the corolla. The stalk of the stamen, or filament, becomes bent as the corolla opens. The expansion of the corolla curves the filament outwards; this creates a mechanical tension in the filament. It is said that the "corolla opens;" this is a result of a certain mode of growth in the corolla which it is important to understand. While the corolla is in the bud state the inner surface of the corolla grows less quickly than the outside, and as a result the inner surface of the corolla remains concave, and the corolla closed. When growth is almost completed the inner surface of the corolla grows more quickly, with the result that what was the inner and concave surface now becomes convex and the flower opens, the style is exposed to the air, its stigma becomes the most prominent part of the flower, and the filaments of the stamens are placed under tension, their upper surfaces becoming convex; the anthers are still held mechanically in the pockets of the corolla. It may be seen that the cause of the tension in the filaments results from the movement of the parts of the corolla, and that this results from an alteration in the ratio of growth of the surfaces of the corolla. The tension in the filaments results from the ratios of growth in the surfaces of the corolla, and this is due to the inherited intrinsic forces in the plant. The anther, or pollen-box, discharges pollen through a small orifice at the apex of each cell.

When an insect settles upon the flower it touches first the stigma, which is the highest part of the flower; the shaking which the flower thus receives liberates some of the stamens, and the anthers being liberated fly upwards and discharge their pollen on to the insect, which flies away with some of the pollen of this flower adhering to it. Now consider two such flowers and the bee which passes from one to the other collecting honey. The first open flower that he visits dusts his body with pollen; this he carries to the next flower visited, and there deposits some upon the stigma, at the same time receiving a fresh supply of pollen, which he carries off to the next flower. Thus cross-fertilization of the flower is effected. Whenever we come to observe movements of parts in plants the case is much more complex than with conditions of growth, the results much more striking and wonderful, and such examples are found in the most highly developed parts of the plant. Such examples are not spoken of as due to intelligence in the plant, but are very analogous in their outcome to acts that are termed signs of intelligence in animals. Storage of force is seen in the growth of many fruits, and usually leads to the scattering of the seeds by mechanical means. In a species of wild geranium (*Geranium dissectum*), when the other parts of the flower have fallen, the central axis elongates in its growth; each seed is contained in a case, which is supported by a rod of tissue, which in the early condition of the flower forms part of the central axis, but gradually becomes detached from it. When the seeds are ripe the case containing the seed becomes detached from the base of the supporting column and splits open, the rod is in a state of tension, and eventually becoming detached with a jerk, the seed is thrown some little distance. The cause of the tension in the rod is the unequal growth which occurs in its inner and outer surfaces; the inner surface, or that next to the central support, grows the most; tension or storage of force is thus produced, the mechanical energy is suddenly displayed when any jar is communicated to the plant, and scattering of the seed results. Examples of the storage of mechanical force might be multiplied. The lessons we may learn are that conditions of growth may produce mechanical action, which for a time may be stored up in latent form, and then become suddenly manifested in movement, producing a visible effect, which in its turn leads to important results to the species. Cross-fertilization is very important in producing good seeds. Scattering of the seed is essential to the spread of the species over the surface of the earth.

A Petrified Forest.—M. Philippe Thomas announces to the Paris Academy of Sciences, that he has discovered in Tunisia a gigantic forest, all the trees of which are silicified, and which is thus an exact copy of the celebrated forest of agate at Cairo. M. Flische has recognised the same species as in Egypt, such as *Araucarioxylon egyptiacum*, *Bambusites Thomasi*, and *Cossoni*, a *Ficoxylon*, an *Acacioxylon*, etc. But whilst the palæontologists, Hooker, Fraas, Zittel, and others, disputed on the age of the forest at Cairo, which seemed cretaceous to some and quaternary to others, the age of the Tunisian forest is manifest, and is referred to the pliocene or upper tertiary. M. Bleicher attaches the fact of the silicification of trees to the presence of free gelatinous silica in the enclosing rocks.

Natural History.

COCHINEAL INSECTS.

It is somewhat of a surprise to most of us to learn that Cochineal Insects—which form a tolerably extensive family—are found in many parts of the world, and that their value was at least partially known to the ancients; for one is rather apt to look upon them as quite a modern discovery, and also to consider them as strictly confined to certain specified districts of South America. But although it is true enough that the cochineal of commerce does come principally from these districts, and that *Coccus cacti*, the particular species from which it is procured, is somewhat limited in its distribution, there are many insects belonging to the same genus which yield a dye almost equally valuable, and which, if cultivated in like manner, would probably bring in a very good return for the labour and money expended upon them.

And some of these have been more or less extensively employed for many centuries. Thus the red pigment which can be obtained from *Coccus ilicis*, to be found upon a small species of evergreen oak, and which is plentiful alike in Southern Europe and in Northern Africa and Asia, was largely used by the Phœnicians in dyeing cloth even before the time of Moses, and was known by the title of Thola, or Tola. The Greeks knew it by the name of Kokkos (*Coccus*), and the Persians and Arabians by that of Kermes; from which latter term, by a rather curious series of transitions, our own word "vermilion" is supposed to have sprung. With the dye obtained from this insect were stained the Flemish tapestries, the characteristic red colour being scarcely affected by the action of time; and the Greeks and Romans also appear to have employed it very largely both in their arts and in their manufactures. It has also been suggested, and with great show of probability, that to this same dye was due the "scarlet"—or, as it should be, the crimson—of the curtains of the Mosaic Tabernacle (Exodus xxvi. 1, and xxxvi. 8). And even at the present day it is held in great esteem both in India and in Persia.

Branch of Cactus with Cochineal Insects.

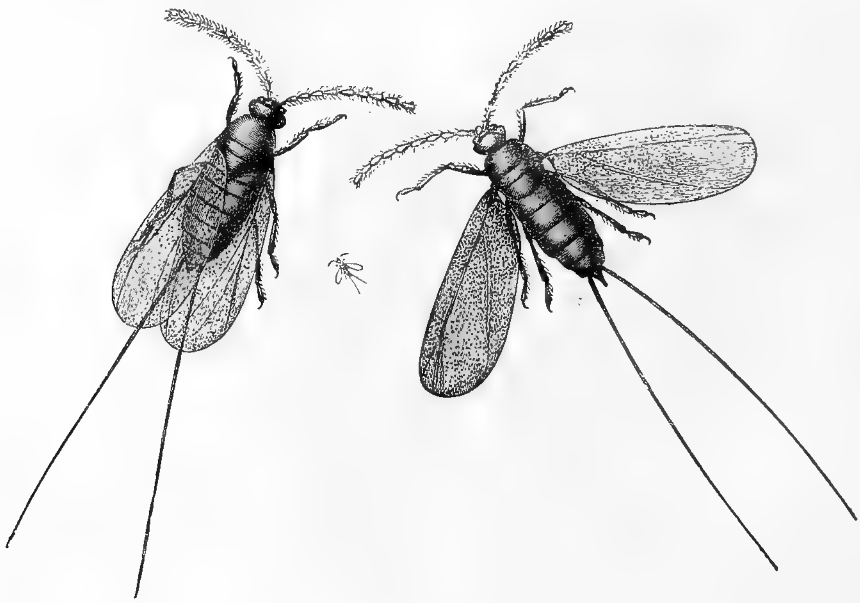
In Poland the place of this insect is taken by *Coccus polonicus*, which is found upon the roots of *Scleranthus perennis*, and which was at one time very greatly in request in the factories of Lithuania. And the Polish peasants use it even now, as do also the Turks and the Armenians, the latter employing it both in dyeing wool and silk, and also in staining the finger nails as an aid to personal beauty. *Coccus uva-ursi*, too, when treated with alum, has been employed for similar purposes, while the Moors, in olden days, availed themselves of yet another species, which lives upon the roots of *Poterium sanguisorba*.

Since the discovery of *C. cacti*, however, the value of all these has greatly diminished, the dye which they yield being very much inferior in brilliancy to that of the South American species. And the cultivation of this, the true cochineal insect, has risen to the rank of a very important industry. It is carried on principally in Mexico, the native country of the insect; but of late years exportations have been made to Algeria and the Canary Islands, and in both colonies the cochineal gardens, which for some little time met with bitter opposition and almost total neglect, are now in a very flourishing condition, and amply repay the expenditure laid out upon them.

Just as is the case with those remarkable creatures the scale insects (Scientific News, vol. i., p. 397), the sexes of the cochineal are very different in appearance, and would scarcely be recognised as belonging to the same class of beings. For the male is a handsome little four-winged fly, with a pair of feathery antennæ and two long hairy filaments springing from the tail, while his mate is an apterous, gall-like creature without the power of locomotion, and with hardly any indication of her insect nature at all. But she it is from whom the dye proceeds. The food plants are two, both being species of prickly pear (*Cactus cochinilifer* and *C. opuntia*); and these are planted out in regular lines, carefully trimmed and tended, so as to allow of free passage between them, and surrounded with a high fence of reeds and stakes to shelter them from the wind. Some of these plantations contain as many as fifty or sixty thousand plants, but the majority do not much exceed an acre in extent, and are for the most part in the hands of native Indians, who are generally distinguished by the title of *Nopalleros*.

For the first two years of their growth the plants are not brought into use; but by the beginning of the third season the more healthy ones have gained sufficient strength to enable them to withstand the incessant drain upon their juices. A quantity of newly-hatched *Cocci* are then procured, generally in April or May, and are kept for three weeks or so entirely indoors, in order that the inclemencies of the weather may not injure them while they are yet young and small. At the end of that time they are transferred to the shelter of somewhat primitive sheds, consisting merely of a rough-roof raised upon poles, so that, while the little insects are protected from rain, the air finds free admission upon all sides. And there they remain, still feeding on the succulent branches upon which they were purchased, until about the end of August, when the fecundated females are placed upon the leaves of the growing *Cacti*, there to complete their development. For some four months they are allowed to feed on without interruption, and then the first gathering is made, which yields under favourable circumstances a return of about twelve hundred per cent. upon the insects purchased. This gathering is followed four months later by a second, and four months later still by a third; and these two latter harvests are generally of a still more profitable character.

The task of taking the insects from the plants is deputed to Indian women, who squat upon the ground in their curious and seemingly uncomfortable manner, and brush them into trays by means of the tail of a stag or a squirrel, or a bamboo twig formed into somewhat the shape of a pen. As soon as a sufficient number have been collected they are killed, either by plunging them into boiling water or by placing them in heated ovens, or merely by exposing them to the rays of the sun. And then, as soon as their bodies have thoroughly dried, they are ready for the manufactory.



Male Cochineal Insects.

The importance of the cochineal gardens may be judged from the fact that, even so long ago as the time of Humboldt, the quantity annually exported from South America exceeded half a million sterling in value; and Dr. Bancroft estimated the yearly consumption in Great Britain alone at 150,000 lbs., worth some £375,000. And this quantity has since been very much increased. It is also worthy of mention that the rent of a fairly productive *Coccus* garden varies from £50 to £60 per acre, while it cannot be purchased outright for much less than £1,000. The dye itself, by the way, when compressed into small cakes, is sometimes used in lieu of money, and travels from hand to hand many times over before it at last reaches the factory.

From a congener of the cochineal insect is obtained lac, which is so largely employed in the manufacture of sealing-wax and of various varnishes; and from it is also procured a crimson dye which possesses some little commercial value. In the years 1807-1809, indeed, the sale of this dye at the India House, in point of actual colouring matter, was estimated as equivalent to half a million pounds of cochineal. The dye, as in the true cochineal, appears to afford nourishment to the young grubs until they leave the protecting shell into which the dead body of their mother collapses.

The economic entomologist can scarcely fail to be struck with the fact that these valuable insects are closely related to some of the most mischievous. Thus, on one side of their family, as it were, they are connected with the scale insects, or mealy bugs, which are so destructive to many of our fruit-trees and cultivated plants, while on the other they are allied to the *aphis*, that greatest of all the insect pests which vex the farmer's heart. Even if it be true that a man may be known by his friends, certainly an insect is not to be known by its relations. And it is quite possible that we may ultimately find of value many insects which are either noxious themselves, or which are at least closely related to others of the most highly mischievous character. A green dye, for instance, has been extracted from the caterpillars of the cabbage butterfly. And as our knowledge of natural history increases we shall doubtless be obliged to alter our present views with regard to many insects, and to detect in the future a friend where now we see but a foe.

A Hybernating Dragon-fly.—It may interest entomological readers to know that a certain European species of dragon-fly is in the habit of hybernating in the *imago* state, which singular discovery has only very recently been made by a well-known German specialist. It is not at all unimprobable that other species may be discovered to hybernate also, since so very little has hitherto been done towards the elucidation of their economy. Most dragon-flies pass the winter in the *larva* state, and seldom allow themselves to become torpid, even in the most severe weather.

The Batrachia of Southern India.—In a work recently published by Mr. Edgar Thurston, of the Government Museum at Madras, fifty-five species of frogs, toads, and cœcilians are enumerated. The newts, or tailed batrachians, are not represented in Southern India. In Ceylon only thirty-three species of batrachians occur, eighteen of which are found also on the mainland. The *Madras Weekly Mail*, noticing the above work, adverts to the gymnastic feats of the "chunam frog." A genial writer, seated one evening in his garden, was finishing an interesting chapter, when an adventurous "chunam frog" lighted like a dab of mud behind his right ear, and there stuck! The batrachians of Southern India, however, are as yet very imperfectly known.

The Size of the Cobra.—In the *Madras Weekly Mail* we find a controversy raging as to whether a serpent shot by a certain "Jungle-wallah" was a cobra (*Naja tripudians*) or a hamadryad (*Ophiophagus elaps*). One writer offers a reward of 25 rupees to any one who can produce a cobra over seven feet in length, whilst the hamadryad reaches double that length. The latter snake, further, inhabits wild forests only, whilst the cobra is equally at home in the city or in the wilderness. The hood of the cobra, with the well-known spectacle markings, is represented in the *Ophiophagus* only by a small dilation of the skin lower down the back, without spectacles. The *Ophiophagus* has, moreover, indistinct yellowish bands across the body. It is clearly established that this snake attacks passers-by without any provocation.

Causes of Variation in Organic Forms.—Professor C. V. Riley (American Association, reported in *Science*) concludes a memoir on this subject by saying, "All that evolution recognises is the transmutability—the generic identity—of the forces of nature, which in their aggregate action may properly be defined as omnipresent energy. We know, as a matter of the simplest observation, that this combined force or energy is essential to the continuance of life, not only upon our planet, but deductively in the universe. We are justified in inferring that it is capable, under fit conditions, of originating life from what we know as non-living matter. Evolution, in fact, inevitably leads to the inference that vital force is transmutable into and derivable from physical and chemical force."

Species of Termites.—Of these insects, twenty-four distinct species are now recognised, nine of which are African, nine American, two Asiatic, and two European.

New Evidence against the Squirrel.—A correspondent of the *Field* records the fact of a squirrel attacking a green woodpecker and disabling it, so that its rescuer had to put the poor bird out of pain. We think that all lovers of birds ought to declare war against this felonious rodent.

Co-operation of Frost and Destructive Insects.—Professor von Ettingshausen observes that trees which have suffered from frost are especially liable to be attacked by the cockchafer (*Melolontha maialis*). Inversely, trees which have been damaged by destructive insects are unusually sensitive to frost.

Reviews.

Report of the Commissioner of Agriculture, 1887. Washington: Government Printing Office.

This report contains a large amount of valuable information on the injuries occasioned by insects, birds, parasitic fungi, etc., and on the means for their repression. Especial attention is due to the experiments on the food of hawks and owls, birds much more useful than is generally supposed. If we leave out of consideration the great horned owl, a bird which no longer occurs in Britain, it will be seen that the food of the remainder consists essentially of mice. For the horned owl little can be said, as his food is almost entirely composed of game and poultry. Even the smaller hawks seem to do more good than harm, since their stomachs were found to contain mice and grasshoppers in profusion.

On the sparrow question we find no new facts, the evidence against this "winged rat" being found so conclusive that no further inquiry is needed. The opinion arrived at is expressed in such phrases as "The best methods of abating the sparrow scourge." The agent recommended is grain or maize meal, fifteen parts of which are mixed with one part of white arsenic. The grain should be moistened with a little gum-water before stirring in the poison. Strychnine or any other poison of rapid action is not recommended, since if one member of a flock falls down dead or is even taken ill, the remainder fly away and never return. The chief objection to this plan is that, especially in severe weather, harmless or even useful birds may be destroyed at the same time. American observers are fully aware of the fact that the "head and front" of the sparrow's offending is that he drives away more useful birds, such as the swallows.

We are glad to see that the badger is recognised as serviceable, as he destroys mice and "gophers."

The Entomologist to the Department has made a number of investigations on destructive insects. Many of his results will be of general value in the British colonies. Mention is made of an epidemic which in 1867 almost extirpated one of the most dreaded enemies of the American farmer, the "chinch-bug" (*Bliosus leucopterus*). It has now, however, reappeared, and is calculated to have last year occasioned a loss to the extent of *sixty million dollars* in nine of the States.

In dealing with aphides, scale insects, a great step in advance has been effected. A so-called "resin compound" is made by dissolving three pounds of common soda-crystals and four pounds of resin in three pints of water over a fire. When properly dissolved, water is slowly added, still boiling, to make up thirty-six pints of liquid. This is then, whilst luke-warm, emulsified with an equal measure of kerosene oil. Arsenic is then added in the proportion of one pound to fifty-five of the compound. This mixture, more or less diluted with water, is driven over the trees infested, and destroys even the "woolly blight" (*Schizoneura lanigera*) of the apple-tree, known in this country as the "American blight." It is said neither to injure the beneficial *syrphus* larvæ, nor the internal parasites of the plant-lice.

Damage has been done both to potatoes and to human beings by swarms of blistering-beetles (*Lytta cinerea* and *Epicauta vittata*). These visitors injured the stems and leaves of the potato-plant in the day, and flying into the houses at night, blistered the faces and hands of the inmates.

Concerning the Colorado beetle, we find that its eggs and larvæ are eagerly devoured by a small carnivorous beetle, *Calcathus gregarius*.

The subject of vegetable pathology and of the fungi which attack crops has received great attention. It can scarcely be denied that the highly specialised plants and trees which we cultivate are more liable to the attacks both of animal and vegetable parasites than was the case centuries back. The vine is, perhaps, more exposed to such enemies than any other crop. The downy mildew, black rot, anthracnose, and root-rot are described as being destructive, and two more diseases—bitter-rot and white-rot—have lately been identified. Very few other fruit-trees entirely escape damage from analogous enemies. Among the remedies which have been used with success are the Bordeaux mixtures (sulphate of copper and lime, dissolved separately) and "Sulphatine." The latter is produced by mixing two and a half pounds of anhydrous sulphate of copper with fifteen pounds of ground sulphur and ten pounds of air-slaked lime.

But were we to call attention to half the important matter contained in this bulky volume we should quite exceed permissible limits.

THE FOUNDATION-STONES OF THE EARTH'S CRUST.

An Evening Discourse delivered by T. G. Bonney, D.Sc., LL.D., F.R.S., F.G.S., etc., before the British Association, on September 10th, 1888.

(Continued from p. 442.)

ILLUSTRATIONS of the effects of direct crushing in a granitoid rock are common in the Alps. Those of a shearing crush are magnificently developed near the great overthrust faults in the north-west Highlands of Scotland.

In the former case, where a granitoid rock has been affected only to a moderate extent, and the resulting rock in a hand specimen would be called a gneiss without any very definite mineral banding, we find that under the microscope it exhibits a fragmental structure, the felspars are often somewhat rounded in outline, are frequently rather decomposed and speckled with minute flakes of white mica of secondary origin, and commonly seem to "tail off" into a sort of stream of microlithic mica, which has doubtless resulted from the destruction of felspar the residual silica making its appearance as minutely crystalline quartz. The original quartz grains have been broken up, and are now represented by smaller grains, often in rudely lenticular aggregates, like little "inliers" of quartzite. The original flakes of black mica have been tattered and torn, and now appear as streaky clusters of flakelets, often less than one-sixth the original length. In extreme cases of crushing, the felspar has almost disappeared; the constituents are all reduced in size, and the rock at first sight would no longer be called a gneiss, but a fine-grained mica-schist. It has become extremely fissile, and the flat faces of the fragments exhibit a peculiar sheen, as if it had received a varnish of microlithic mica. In short, from a granitoid rock a microcrystalline mica-schist has been produced, which, however, differs markedly from the rock to which that name is ordinarily applied.

Let us now turn to a rock of similar nature, in which the effect of shearing is more conspicuous. I have selected a specimen, in which, as in the first example above, some of the felspar still remains in recognisable fragments. These, however, are commonly destitute of the "tail" of mica-microliths, and bear, at first sight, some resemblance to the broken porphyritic felspars which occur in a rhyolite. The mica, whether primary, but fragmental, or secondary, tends to get associated in undulating layers; the quartz also has a more uniform aspect and a more linear arrangement. In the most extreme cases the felspar all but disappears (though I fancy that it has here a better chance of surviving), the quartz and the mica are more and more aggregated in definite but thin bands, and the former, when viewed with crossing nicols, exhibits streaks, which, for a considerable distance, are almost uniform in tint, as if its molecules under a stress definite in direction had acquired a polarity, so that groups of these act upon light almost like a single crystal.

The effects of mechanical deformation, followed by mineral change, are also remarkably conspicuous in the case of pyroxenic rocks. Augite, it is well known, is by no means a stable mineral, and under certain circumstances is readily transformed into hornblende. This occurs in more than one way without mechanical action, but of these I do not now speak. Only of late years, however, has it been known that pressure can convert a dolerite into a hornblende-schist. Of this, through the kindness of Mr. Teall, who first proved the occurrence of this alteration in Great Britain, I can show you an example. The rock has lost the structures of a dolerite, and has assumed those characteristics of many hornblende-schists. I say of many, because though the rock is distinctly foliated it does not exhibit a conspicuous mineral banding. My own observations confirm those of Mr. Teall, though I have never been so fortunate as to obtain, as he did, a complete demonstration of the passage from the one rock to the other.

It seems, then, to be demonstrated, that by mechanical deformation, accompanied or followed by molecular rearrangement, foliated rocks, such as certain gneisses and certain schists, can be produced from rocks originally crystalline. But obviously there are limits to the amount of change. The old proverb, "You cannot make a silk purse of a sow's ear," holds good in this case also. To get certain results you must have begun with rocks of a certain character. So that it is often possible, as I believe, to infer not only the nature of the change, but also that of the original rock. Hitherto we have been dealing with rocks which were approximately uniform in character, though composed of diverse materials—that is, with rocks more or less granular in aspect. Suppose, now, the original rock to have already acquired a definite structure—suppose it had assumed, never mind how, a distinct mineral banding, the layers varying in thickness from a small fraction of an inch upwards. Would this structure survive the mechanical deformation? I can give an answer which will at any rate carry us a certain way. I can prove that subsequent pressure has frequently failed to obliterate an earlier banded structure. In such a district as the Alps we commonly find banded gneisses and banded schists, which have been exposed to great pressure. Exactly as in the former case the new divisional planes are indicated by a coating of films of mica, by which the fissility of the rock in this direction is increased. The mass has assumed a cleavage-foliation. I give it this name because it is due to the same cause as ordinary cleavage, but is accompanied by mineral change along the planes of division, while I term the older structure stratification-foliation, because so frequently, if it has not been determined by a stratification of the original constituents, it is at any rate a most extraordinary imitation of such an arrangement. In many cases the new structure is parallel with the old, but in others, as in the "strain-slip" cleavage of a phyllite, the newer can be seen distinctly cutting across the older mineral banding. As an example, take a rock mainly consisting of quartz and mica. Sometimes there has been a certain amount of crushing of the constituents, followed by a recrystallisation of the quartz and the formation of a pale-coloured mica. Sometimes when the direction of the disturbance has been at right angles to the stratification-foliation the latter is made wavy, and the mica-flakes are twisted round at right angles to their original position. Sometimes there has been a dragging or shearing of the mass, so that a considerable amount of mica has recrystallised along the new planes of division. To put it briefly, I assert, as the result of examining numbers of specimens, that though in certain cases the new structure is dominant, a practised eye seldom fails to detect traces of the older foliation, while in a large number of instances it is still as definite as the stripe in a slate.

We have got, then, thus far, that pressure acting on rocks previously crystallised can produce a foliation; but when it has acted in Palæozoic or later times, the resulting structures can be identified, and these as a rule are distinguishable from those of the most ancient foliated rocks, while at present we have found no proof that pressure alone can produce any conspicuous mineral banding. I am aware that this statement will be disputed, but I venture to plead, as one excuse for my temerity, that probably few persons in Great Britain have seen more crystalline rocks, both in the field and with the microscope, than myself. So while I do not deny the possibility of well-banded rock being due to pressure alone, I unhesitatingly affirm that this at present is a mere hypothesis, a hypothesis moreover which is attended by some serious difficulties. For if we concede that, in the case of many rocks originally granular, dynamic metamorphism has produced a mineral banding, this is only on a very small scale; the layers are but a small fraction of an inch thick. No one could for a moment confuse a sheared granite from the Highlands with a Laurentian gneiss from Canada or with an uninjured Hebridean gneiss. For the former to attain to the condition of the latter, the mass must have been brought to a condition which admitted of great freedom of motion amongst the particles, almost as much, in short, as among those of a molten rock. Clearly the dynamic metamorphism of Palæozoic or later ages appear to require some supplementary agency. Can we obtain any clue to it?

An explanation of broadly banded structures was long since suggested, and has recently been urged with additional force, which avoids some of our difficulties. We know that the process of consolidation in a coarsely crystalline rock has often been a slow one; the constituent minerals separate gradually from the magma, of which sometimes so little may remain that a rock with a true glassy base has been mistaken for one holocrystalline. The residual and still unsolidified magma would admit of a slow flowing of the mass, but there would be so little of it that the crystals already individualised, though altered in position by differential movements, would be affected by strains, and liable to fracture. Such a rock, when finally consolidated, would exhibit many phenomena in common with a rock modified by dynamic metamorphism, but would differ in the greater coarseness of its structure. This may prove to be the correct explanation of the curious foliated and banded gabbros in the Lizard district. That some crystalline rocks must have passsed through this stage I am now in a position to affirm, from evidence not yet published.

Let us, however, see whether another line of investigation may not throw some light on our difficulty. I have already mentioned the effect produced by the intrusion of large masses of igneous rocks upon other rocks. These may be either igneous rocks already solidified, or sedimentary rocks. The former may be passed over, as they will not materially help us. In regard to the latter, the results of contact-metamorphism, as it is called, are, as we might expect, very various. Speaking only of the more extreme, we find that sandstones are converted into quartzites; limestones become coarsely crystalline, all traces of organisms disappearing, and crystalline silicates being formed. In clayey rocks all signs of the original sediments disappear, crystalline silicates are formed, such as mica (especially brown), garnet, andalusite, and sometimes tourmaline; felspar, however, is very rare. Fair-sized grains of quartz appear, either by enlargement of original granules or by independent crystallisation of residual silica. It is further important to notice that, as we approach the surface of the intrusive mass—that is, as we enter upon the region where the highest temperature has been longest maintained—the secondary minerals attain a larger size and are more free from adventitious substances—that is, they have not been obliged as they formed to incorporate pre-existing constituents. The rock, indeed, has not been melted down, but it has attained a condition where a rather free molecular movement became possible, and a new mineral in crystallising could, as it were, elbow out of the way the more refractory particles. I can, perhaps, best bring home the result of contact-metamorphism by showing what its effects are on a rock similar to that which I exhibited in illustration of the effect of pressure-metamorphism on a distinctly stratified rock. These are, in brief, to consolidate the rock, and while causing some constituents to vanish, to increase greatly the size of all the others. It follows then that mineral segregation is promoted by the maintenance for some time of a high temperature, which is almost a truism. I may add to this that, though rocks modified by contact-metamorphism differ from the Archæan schists, we find in them the best imitations of stratification-foliation, and of other structures characteristic of the latter.

One other group of facts requires notice before we proceed to draw our inferences from the preceding. Very commonly, when a stratified mass rests upon considerably older rocks, the lower part of the former is full of fragments of the latter. Let us restrict ourselves to basement beds of the Cambrian and Ordovician—the first two chapters in the stone-book of life. What can we learn from the material of their pages? They tell us that granitoid rocks, crystalline schists of various kinds, as well as quartzites and phyllites, then abounded in the world. The Torridon sandstone of Scotland proves that much of the subjacent Hebridean had even then acquired its present characteristics. The Cambrian rocks of North and South Wales repeat the story, notably near Llynfaelog in Anglesey, where the adjacent gneissoid rocks from which the pebbles were derived, even if once true granites, had assumed their differences before the end of the Cambrian period. By the same time similar changes had affected the crystalline rocks of the Malverns and parts of Shropshire. It would be easy to quote other instances, but these may suffice. I will only add that the frequent abundance of slightly altered rocks in these conglomerates and grits appears significant. Such rocks seem to have been more widely distributed—less local—than they have been in later periods. Another curious piece of evidence points the same way. In North America, as is well known, there is an ancient group of rocks to which Sir W. Logan gave the name Huronian, because it was most typically developed in the vicinity of Lake Huron. Gradually great confusion arose as to what this term really designated. But now, thanks to our fellow-workers on the other side of the Atlantic, the fogs, gendered in the laboratory, are being dispelled by the light of microscopic research and the fresh air of the field. We now know that the Huronian group in no case consists of very highly altered rocks, though some of its members are rather more changed than is usual with the British Cambrians, than which they are supposed to be slightly older. Conglomerates are not rare in the Huronian. Some of these consist of granitoid fragments in a quartzose matrix. We cannot doubt that the rock was once a pebbly sandstone. Still, the matrix, when examined with the microscope, differs from any Palæozoic sandstone or quartzite that I have yet seen. Among grains of quartz and felspar are scattered numerous flakes of mica, brown or white. The form of these is so regular that I conclude they have been developed, or at least completed, *in situ*. Moreover, the quartz and the felspar no longer retain the distinctly fragmental character usual in a Palæozoic grit, but appear to have received secondary enlargement. A rock of fragmental origin to some extent has simulated or reverted to a truly crystalline structure. In regard to the larger fragments, we can affirm that they were once granitoid rock, but in them also we note incipient changes such as the development of quartz and mica from felspar (without any indication of pressure), and there is reason to think that these changes were anterior to the formation of the pebbles.

To sum up the evidence. In the oldest gneissoid rocks we find structures different from those of granite, but bearing some resemblance to, though on a larger scale than, the structures of vein-granites or the surfaces of larger masses when intrusive in sedimentary deposits. We find that pressure alone does not produce structures like these in crystalline rocks, and that when it gives rise to mineral banding this is only on a comparatively minute scale. We find that pressures acting upon ordinary sediments in Palæozoic or later times do not produce more than colourable imitations of crystalline schists. We find that when they act upon the latter the result differs, and is generally distinguishable from stratification-foliation. We see that elevation of temperature obviously facilitates changes, and promotes coarseness of structure. We see also that the rocks in a crystalline series which appear to occupy the highest position seem to be the least metamorphosed, and present the strongest resemblance to stratified rocks. Lastly, we see that mineral change appears to have taken place more readily in the later Archæan times than it ever did afterwards. It seems, then, a legitimate induction that in Archæan times conditions favourable to mineral change and molecular movement—in short, to metamorphism—were general, which in later ages have become rare and local, so that, as a rule, these gneisses and schists represent the foundation-stones of the earth's crust.

(To be continued.)

Abstracts of Papers, Lectures, etc.

JUNIOR ENGINEERING SOCIETY.

At the opening meeting of the eighth session, which took place on October 12th, the presidential address was delivered by Professor W. Cawthorne Unwin, F.R.S., M.Inst. C.E., on "Illustrations of the Use of Theory in the Work of the Engineer." After some introductory remarks from the chairman, Professor Unwin said that the name of the society suggested to him that he might venture to speak to them as an older to younger engineers. He began work as an engineer more than thirty years ago, and they could hardly imagine with what scanty means of attacking the problems before them they were provided with at that period in the days before Rankine.

Nevertheless, it was pleasant to look back and to remember that one saw the birth and development of so many of the processes, the improvement of so many of the machines, the invention of so many of the structures, the use and construction of which was now the ordinary business of the engineer. Nothing was so striking in looking back on the history of engineering during the last thirty or forty years as the growth in connection with the practice and business of engineering of a body of scientific principles forming a science of engineering. The engineer had in part acquired and in part discovered the scientific principles applicable to his daily work. Purely scientific men, whose experience was confined to the laboratory, were apt to forget that a large part of the work of an engineer was nothing else than experimenting on a very large scale, and, to tell the truth, with very heavy penalties in most cases for failure. Not seldom the engineer's researches extended far beyond immediate practical interests, and were carried out in a spirit as truth-loving as any laboratory experiments. They still heard of an opposition of science and practice. If, however, they would concede the dependence of practical engineering on a body of scientific principles forming a theory of engineering, he would ask their attention first to the subject of technical education. The derivation of the word engineer showed that an engineer was recognised as a man who worked with his brain, not with his hands. Of course, in the business of engineering there were engaged a large body of artisans whose value depended on their skill of hand, and he had the greatest respect for the work they did. Most of them had, no doubt, noticed two remarkable articles on technical education, by Lord Armstrong and Sir Lyon Playfair. Lord Armstrong wrote on the vague cry for technical education, and showed an obvious distrust of some things which were advocated in that name. Sir Lyon Playfair replied that he failed to see to what exactly Lord Armstrong objected, and that he was throwing cold water on efforts beginning to bear useful fruit, and promising to have an influence of the widest kind on the national welfare. It was clear that in Lord Armstrong's article he was thinking almost exclusively of the education of the artisan class, and concerning that class it was further clear that Lord Armstrong was in no way opposed to their general education; but where Lord Armstrong stopped, and became doubtful or hostile, was at attempts to give in school the specific training in a handicraft or trade which hitherto had been gained directly in the shop. He thought Lord Armstrong wished well to any increase of intelligence in workmen, but doubted—and he (Professor Unwin) was disposed to agree with him—that scientific training would make men better workmen. They who were engineers could understand very well how impossible it was to train the vast number of fitters or boiler-makers or other artisans connected with engineering anywhere else than where large and heavy actual work was going on. Sir Lyon Playfair, he thought, did not fairly meet Lord Armstrong on this point, and did not very distinctly keep clear general education and special technical education, nor sufficiently mark the difference between the means necessary for acquiring the skill of hand of the craftsman, and those suitable for educating the brain-workers who did the thinking and designing in all constructive industry. For the young engineer Professor Unwin thought that regular and systematic technical instruction in the strictest sense was needed, and it was through these that advanced scientific teaching might come to have a real and powerful influence on the maintenance of our mechanical superiority—and so on the welfare of the country and of every classs in it. However good a school for the workman, the shop was a most imperfect school for the engineer. The value of acquiring handicraft skill in the case of the engineer was easily overrated, and the long time spent in the workshop involved in one direction a good deal of loss. During years at the bench much of school knowledge of science and mathematics disappeared. He thought that Lord Armstrong a little underrated the need of college training for engineers. There were two ways in which a technical college and the engineers in practice might work together with mutual advantage. One was that they might, without interfering with the apprenticeship system, give facilities to apprentices to make use of the college, so that the workshop training might be supplemented by scientific training. The other was that they might give some small advantages to young men who had had a technical training at that difficult point in their career at which they first entered on practical life. If in any way they could attain a system by which the theoretical education went on *pari passu* with the practical education, and that without sensible interference with the ordinary apprenticeship, it would be a good thing. It appeared to him that engineers might, without sensible harm to the rules of the workshop, spare apprentices for one day a week to attend a course of instruction in college. Evening instruction after shop hours was too scrappy and disjointed to do much good. But instruction carried on systematically through one clear day a week would be much more valuable. Professor Unwin then referred to a remarkable paper by Mr. Thomson, one of the most distinguished of American bridge builders, which seemed to throw doubt on any reliance on theory in practical engineering, and who, in support of his contention, stated that during the past ten years 250 American iron bridges had completely broken down. They must not take too literally Mr. Thomson's view—meant, probably, half humorously—that American bridges failed because they were built too scientifically. As an example of what he thought were right and wrong ways of theorising, he referred to the question of the collapse of boiler-flues, and with the aid of diagrams made some valuable and interesting remarks from a technical point of view on that subject.

Liverpool Science Students' Association.—At the opening meeting, held on October 16th, Miss E. N. Wood gave a *résumé* of the botanical work of the summer session. The President (Mr. Osmund W. Jeffs) then delivered the annual address, which dealt mainly with the geology of the Cheshire hills.

St. John's Natural Science Society, Upper Holloway.—On Tuesday, October 16th, a very interesting lecture on "Leaves" was delivered to the members of this society by Mr. J. McKerchar. The subject was illustrated by means of diagrams, dried specimens, growing plants, and by a series of excellent microscopic preparations.

The Microscopical Society of Glasgow.—At the usual monthly meeting of this society, held on October 16th, Mr. C. Fred Pollock, M.D., gave a concise and comprehensive description of the human skin, with its various layers, glands, muscles, and appendages, such as hairs and nails.

THE BEATING OF THE HEART.

FEW of the marvellous phenomena of our own physical life excite our curiosity so early or so keenly as the throbbing of the heart in the breast. The child speculates as to the cause and object of this rapid and incessant pulsation, and only gives up his inquiry because the problem is too hard. The expert physiologist spends a working life in getting to understand fully and experimentally little bits of the driving engine of the blood-circulation. Toil as he may, the explanation never grows perfectly simple. Special facts, gradually seen to be important, but at first sight irrelevant or superfluous, break up that easy and luminous theory which is still hoped for, never found. Perhaps it is not untrue to say that the more the heart is studied, the harder it is to understand.

We shall only succeed in giving the reader a clear view of the cardinal facts by leaving out altogether a host of recorded details which the working physiologist is bound to keep steadily in view. Let us attempt to answer but two questions—

1. How is it that the heart never becomes fatigued?
2. How is its rhythmical beat kept up?

The simplest answer to question 1 is that the heart *does* become fatigued. Indeed, it becomes fatigued very quickly, but recovers itself after a very short rest. We have heard of men who undertake for a wager to walk 1,000 miles in 1,000 hours. The heart undertakes to contract, say, 5,000 times in an hour. It becomes fatigued, and rests after each contraction, and this interval of fatigue is in itself enough to occasion a certain kind of rhythmical action, of which examples could be quoted. The motive power is put forth in response to stimulus, and is exhausted in a moment. A short spell of rest enables the stimulus to provoke a fresh contraction. This leads us to ask where the motive power is stored up. The answer is furnished by experiment upon a fresh-killed frog. Cut out the heart; it still continues to beat. Cut it across just below the line which marks the junction of the ventricle with the two auricles; the upper half continues to beat, but the lower half is paralysed. Divide the upper half into two; each quarter continues to beat. There must therefore be motive centres within the heart sufficient to keep up pulsation. Indeed, by a somewhat difficult and minute dissection these centres can be found. They are minute ganglia, or groups of nerve-cells.

Given ganglia in communication with the muscular fibres of the heart, a rhythmical contraction at once becomes possible. Some stimulus, *e.g.*, the pressure of blood in the auricles, excites the ganglia. These stimulate the muscles, contraction follows, and the impulse is spent. The nervous force has been discharged, and requires time for recovery. The muscular force has also been discharged, and requires time for recovery. It is probably in this very simple way that detached organs which contain ganglia are occasionally seen to beat. A frog's tongue, the foot of a fresh-water mussel, or a small strip of the bell of a jelly fish may pulsate after removal from the body, provided that it contains a ganglion in communication with muscular fibres. It is possible, though not proved, that the muscular fibres of the intestine, and the muscular fibres of the heart in various animals of low grade, may keep up their peristaltic action in the same way.

But in all hearts which have been carefully and experimentally studied a more complicated piece of machinery is added. This takes the form of an inhibiting nerve, which checks the ganglion before its force is wholly spent. Inhibition is just as effective as fatigue in keeping up a rhythmical movement. The sequence now becomes—(1) stimulation of the cardiac ganglia; (2) the overpowering by accumulated stimulus of the inhibiting force; (3) discharge; (4) renewed inhibition.

In higher animals the inhibiting nerve is a long nerve, called the pneumogastric, which traverses the neck and originates in the medulla oblongata, at the back of the brain. Irritation of the pneumogastric by an interrupted electric current, pressure, or chemical stimulation may be made to produce a long-continued stoppage of the heart. Čzermak was able to stop his heart at pleasure by pressing this nerve against a small bony tumour in his neck. The regulation of the rate and force of the heart's beat is by means of the pneumogastric transferred to the brain, and brought into relation with what is going on in distant parts of the body. If the body of a frog is laid open, and a light but smart blow is given to the intestine, the heart will stand still. But if the medulla or both the pneumogastric nerves have been previously destroyed, no such effect follows. It was the impulse transmitted to the medulla from the intestine which stimulated the inhibitory nerve, but when the nervous path is broken the heart is altogether out of relation with the intestine.

Czermak (*Physiologische Vorträge*, I.) has devised a model which enables the student to gain a clear idea of the combined effect of stimulus and inhibition in producing rhythmical motion. A stream of water, regulated by a tap, descends upon what he calls a boat. This boat is poised upon an axis. It has a flat base, and a partition across its middle, at right angles to the two triangular sides. At starting the boat is tilted up, one of its two compartments being turned upwards, while the other rests upon an adjustable support. The stream flows into the upper compartment, and fills it to the point at which it counterbalances the other. Then the boat capsizes, and empties itself. The other compartment now begins to fill, and so on. It is a pretty enough sight to see the boat oscillating by the action of a constant stream of water.

In this model we have a cause of movement—viz., the stream of water, and a cause of stoppage—viz., the support beneath, which checks the fall of the boat. The joint effect of the motive and restraining forces is a rhythmical action. If the fall is increased by lowering the support beneath the boat, the oscillation becomes slower and more forcible. If the support is raised the oscillation becomes quicker and weaker. Increase or diminution of the stream affects the rate, but not the force, which is entirely determined by the amount of fall. The model gives us, therefore, four possible combinations of rate and force. The oscillations may be (1) *strong—quick*, (2) *strong—slow*, (3) *weak—quick*, (4) *weak—slow*, and the very same combinations are met with in the pulse. It is not too much to say that Czermak's model is a trustworthy guide to the cause of each variation.

Into other details of the movements of the heart we shall not enter at present. The student or teacher who will make Czermak's boat, and master its analogy with the pulsating heart, has won a solid foundation for further observation and reflection.

THE AUSTRALIAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

The President's Address.

THE inaugural meeting of the Australian Association for the Advancement of Science was held in the Great Hall of the Sydney University on Aug. 28th.

After a few opening remarks from Lord Carrington, who presided, Mr. H. C. Russell delivered the presidential address. After referring at some length to the history of the British Association, he said: At the very time that Sir David Brewster was using his pen and his influence to stir up the scientific men of England to greater effort in the cause of science, and to the formation of the British Association for the Advancement of Science, the British Government were sending to Sydney one of the most energetic scientific men that ever set foot upon Australian soil, with a view of keeping alive the dying embers of the first attempt to plant science in this part of the world. And I think it most fitting that, at this first meeting of the Australasian Association for the Advancement of Science, we should remember that first effort to promote science in a country so remote from the homes of science. It is difficult now to form any idea of the condition of society in Australia when Sir Thomas Brisbane landed, and nothing but the habit of disregarding difficulties, which a long military experience had taught him, would have made it possible in his mind to form a scientific society under such circumstances. But he had been so accustomed to go into strange places and make his own surroundings that it appeared to him possible to do the same here. He landed in the end of November, entered upon his official duties on December 1st, 1821, and by January 2nd following he had found out the only scientific men in the colony, formed them into the Philosophical Society of Australia, and had the first paper read. He never seems to have anticipated any difficulty in managing this handful of civilians, who, however, soon got beyond his control. His own enthusiasm for science was very remarkable. In the midst of the harassing marches and all the perils of the great Continental war in which he bore a part, even when he had to sleep six nights in the snow with nothing but his overcoat to cover him, and found himself frozen to the ground each morning, and once with 900 men frozen to death around him, he always had his astronomical instruments in his baggage, and brought them into use whenever there was half a chance. It was this intense love for science, coupled with his military ideas, which made him so anxious to get all the scientific men around him in a duly organised society, each to do his duty rigidly or suffer the consequences. But with all his enthusiasm he soon found that a small army of scientific workers was not so manageable as the armies he had been accustomed to. The members of this first Australian society, according to Judge Field, were Alexander Berry, Henry Grattan Douglas, M.D., Baron Field (Judge), Major Goulburn (Colonial Secretary), Captain Irwin (Bengal N. I.), Captain P. P. King, John Oxley (Surveyor-General), Charles Stargard Rumker (astronomer), Edward Wolstencroft, his Excellency Sir Thomas Brisbane, K.C.B., F.R.S. (President). I find no record of the rules of this society, excepting one, and that was if a member failed to read a paper when his turn came he forfeited £10. They met at each other's houses in turn, and the only refreshment allowed was a cup of coffee and a biscuit. It seems that the society was more of a mutual friendly association or scientific club than a formal society. At that time there was no public library, and but one bookseller for the whole of Australia, so the members catalogued their books and lent them to members. With such a strong incentive to write papers, there can be no doubt that meetings seldom lapsed for want of a paper, but they were not published in proceedings, and the only existing record is given by Judge Field, who published four of them in his "Geographical Memoirs"—(1) "On the Aborigines of New Holland and Van Diemen's Land," read January 2nd, 1882. (2) "On the Geology of Part of the Coast of New South Wales, from Hunter River to the Clyde," read in the same year by Alexander Berry. (3) "On the Astronomy of the Southern Hemisphere," by Dr. Rumker, read March 13th, 1822. (4) "On the Maritime Geography of Australia," by Captain P. P. King, R.N., read October 2nd, 1822. Mr. Oxley also read a paper, and Major Goulburn some notes on meteorological observations; and lastly, Sir Thomas Brisbane communicated meteorological observations. We have evidence, therefore, that seven at least of the twelve were workers. Allan Cunningham (botanist) also contributed papers to Judge Field's memoirs—one describing his travels from Bathurst to Liverpool Plains in 1823, and the second on the botany of the Blue Mountains, as observed in November and December, 1822. Judge Field does not say that these papers were read to the society, so that he may not have been a member, but without doubt all the members did good service in the colony. The society which was thus commenced with such flattering promise of usefulness was destined to but a brief period of existence. A question arose between the Government and some of the members as to the value of the dollar—the coin then current—which led to estrangement aud the breaking up of the little band of workers who cultivated science. It appears that this was caused by the decree that the dollar, after the centre had been punched out to make a small coin equal in value to sixpence and known as a "bit," should still pass for its original value, the effect of which was severely felt by business people, because it raised the value of the pound sterling 25 per cent. But the great work which Sir Thomas did in Australia, and what I am disposed to think induced him to accept the position of Governor in the distant colony, was his astronomical work. He had applied before taking the appointment for the consent of the Government to start an observatory when he got to Sydney, but that being refused, on the ground that they were then making arrangements to establish an observatory at the Cape, and did not think it necessary to have two southern observatories, he at once determined to take the whole cost and responsibility upon himself, purchased a complement of instruments, and selected two assistants—Dr. Rumker, as a first-class astronomer and mathematician, and Mr. Dunlop, for his great natural ability and enthusiasm in the pursuit of astronomy. He brought the whole with him, astronomers and instruments landing in Sydney in November. The observatory was at once marked out, within 100 yards of Government House, Paramatta, so that he could at any convenient time take a share in the work; but he could not wait for the building. I find, from the observations, that he observed the sun's solstice in December, and he so hurried on the building that it was completed and ready for use by the end of April. He, with both assistants, worked at high-pressure observing until June 16th, 1823, when Mr. Rumker, owing to some difference in opinion between himself and Sir Thomas, left the observatory. Dunlop at this time was not a trained astronomer, but he was a ready learner, and a little training from Sir Thomas made him master of the instruments, and then he began that well-known feat of observing which probably has never been equalled. By the end of February, 1826, or in two years and eight months, he made 40,000 observations, and so catalogued 7,385 stars. He then left the observatory, and in sixteen months at his own house in Paramatta he catalogued 621 nebulæ and clusters of stars, made drawings of the Milky Way, Nebeculæ, major and minor, and many nebulæ, catalogued and measured 253 double stars. For this he got the gold medal of the Royal Astronomical Society, and afterwards gold medals from the Royal Institute of France and from the King of the Belgians. Meantime Rumker had returned to the observatory, and agreed to carry out a work that was recommended by Sir Humphry Davy as President of the Royal Society, viz., the measurement of an arc of the meridian in New South Wales (that arc is not measured yet). Sir Humphry Davy urged that "the measurement of an arc of the meridian in New South Wales would not only be of importance to astronomy in affording data for determining correctly the figure of the earth, a matter of great interest to navigation, but would likewise be useful in laying the foundation for a correct survey of our colonies in that great and unexplored country" (dated 20th October, 1823). Five years later, in 1828, things had made some progress; Mr. Rumker had agreed to measure the arc, and he ordered the apparatus; but in January of the following year, 1829, he again left the observatory, and that for the time was an end of the arc of the meridian proposal. Dunlop was reappointed in 1831, and the observatory lingered on without publishing until 1840, when it was dismantled. One cannot look back at the history of that observatory without pain, owing to the misfortunes which seemed to upset every effort to make it useful. Sir Thomas was evidently a first-class observer with the sextant, but knew nothing of fixed instruments; hence he bought a lot of instruments second-hand, and wholly unfit for the work they were intended to do. Sir Thomas Brisbane had the command of men and means in abundance, the will and the ability to direct, and so all but the two little ifs was ready for the measurement of an arc of the meridian—a work too long left undone, and one which I hope this association will take up, not with its funds, but with its influence, and urge on to completion. It is a work of the greatest scientific and practical importance. The four great colonies interested in this question have each done a part of the work which will be allotted to them when the arc, which must extend from the south to the north of the continent, is finally measured; and if this association rightly uses its influence the work will be done. At present our surveys are quietly going on upon the assumption that the earth is a regular spheroid, when it is more than probable, from the arrangement of land and water, that it is nothing of the sort at this particular part of its surface. Sir Thomas Brisbane evidently contemplated this when he left England, for he took with him the pendulum apparatus to determine the figure of the earth, and left his friends in England to bring the necessary pressure to bear upon the Government to get the arc measured under his administration. I have introduced the subject here as one in every way suitable to occupy the attention of the association, or at least one section of it, and I thought the early history of the conception would be new to most of us. And its author is in every respect well worthy of remembrance at our first meeting. He was the first man who can fairly be called a patron of science in Australia, having spent, in furnishing the observatory alone, without salaries, more than £1,600. He was the first to form an association of scientific men in Australia, with a view of advancing science, and Sir John Herschel justly said of him, when presenting the gold medal of the Royal Astronomical Society for the Paramatta catalogue, "It will be to you a source of honest pride as long as you live to reflect that the most brilliant trait of Australian history marks the era of your government, and that your name will be identified with the future glories of that great colony in ages yet to come, as the founder of her science. It is a distinction worthy of a British governor. Our first triumphs in those fair climes have been the peaceful ones of science, and the treasures they have transmitted to us are imperishable records of useful knowledge, speedily to be returned with interest to the improvement of their condition, and their elevation in the scale of nations." Amongst the eleven men who formed the first scientific society of Australia there was far more than an average amount of ability. The great weakness of the society, and that which made it impossible for it to exist except under the fostering care of the Governor, was its want of numbers; and unfortunately, in many branches of science the same difficulty exists to-day, and makes it always difficult, and in some sciences impossible, to keep alive societies for their promotion only. Even in those societies which include a number of subjects, and thereby add to their numbers the workers in each, it is often difficult to find enough original work, and perhaps I ought to say enthusiasm, to keep a healthy amount of vitality at its meetings. I am sure there are many here present who have to do the work of scientific societies who must have felt this, and who have often wished, as I have, for something to put a little additional vitality into the members, and for something, also, which would bring together a greater number of workers in each branch of science, so that ideas might be interchanged, and a little healthy emulation aroused. Not something to withdraw members from their own societies and steady work, but something to make us feel that it will not do to go to sleep, because our fellow-workers in the other colonies are very wide awake. The Australian Association for the Advancement of Science seems to me to meet our case exactly. Its meetings only last for one week in each year, and therefore cannot take members from their local societies, and by assembling the workers in each branch of science from all the colonies, by asking them to form committees and work side by side for a time, it promotes the exchange of ideas upon the same subject, and the pleasure which that affords. There can be no more fitting time to explain the steps which have led up to our Association for the Advancement of Science than this, our first meeting, when I hope all the members are present. I have no doubt that to very many the information will be new, and under any circumstances we must leave for those who come after us an account of the origin of an effort in the cause of science which I am sure will have an important and lasting influence on the scientific progress of Australia. The first step was taken by Professor Liversidge, who is himself an institution for the advancement of science, and knows no fatigue in that service. Round him everything has revolved in perfect order to the complete preparation for this meeting. On September 16th, 1884, in a letter to the *Herald*, which was afterwards reproduced by most of the colonial and some of the home papers, he pointed out that the interest created in Australia by the announcement at the British Association meeting in Montreal of Mr. Caldwell's discovery of the oviparous nature of the platypus and porcupine had led to the suggestion that they should meet some day in Australia, but that he thought this was improbable at present, owing to the time it would take and the cost, and he suggested that we should make preparations for the realisation of the proposal by bringing about a federation or union of the members of the scientific societies of Australia, Tasmania, and New Zealand into an association on the lines of the British Association, and that the first meeting should be in 1888, as one of the features of the Centennial year. He had previously, viz., in 1879, mentioned the proposal to a few, but thinking matters were hardly ripe to press it, he had not gone further. Nearly two years then elapsed, and no one took up the suggestion, so in his address as President of the Royal Society in May, 1886, he said, "I am still of opinion that arrangements should be made for holding a meeting of those who wish to form an Australasian Association in 1888, and I shall be glad if those who are in favour of it will kindly send me their names." "If the proposed Australasian Association for the Advancement of Science should really become an accomplished fact, as I hope it will, the first meeting should, I think, be held in 1888," and he then sketched an outline of the rules for it, based on those of the British Association. On June 30th, 1886, came the first support to his proposal; the Council of the Royal Society of New South Wales resolved to take a part in furthering these views, then promises of support came in from the other colonies. Thereupon in July, 1886, he sent a circular to the presidents of the various Australasian societies, telling them that his proposal had been favourably received, and requesting them to appoint members of their council or delegates to represent them at a meeting of such delegates from various societies as soon as possible. The number of representatives or delegates from each society was to be one for each 100 members. On July 28th, 1886, the Royal Society of New South Wales appointed five delegates; thirty-four other societies agreed to join, and twenty-eight appointed delegates for the meeting, which was called for 10th November, 1886. At the meeting sixteen delegates were present—seven from New South Wales, two from New Zealand, two from Queensland, five from Victoria. They framed and adopted the provisional rules which we now have, and which are the British Association rules altered to suit our circumstances. It was resolved that the president, hon. secretaries, and hon. treasurer should be elected by ballot from the representatives of the colony in which the meeting is to be held, and the presidents of sections from members in the other colonies, and that the first election shall be held in Sydney in March, 1888; and further, that the first meeting should be held in the beginning of September, 1888, in Sydney. Special appeal was then made in the daily press to all who intended to join the society to send in their names, so that they might be eligible for election to the official positions, officers for which had to be elected by ballot, and the elections were delayed as long as possible to give every one time to join. The delegates were called together, and met on March 7th, 1888, and they elected—H. C. Russell, F.R.S., President; Prof. Liversidge, M.A., F.R.S., and Dr. George Bennett, F.L.S., Hon. Secretaries; and Sir Edward Strickland, K.C.B., Hon. Treasurer. Since then the council, composed of the delegates from the various societies taking part in the work, have held 13 meetings, and have found plenty to do in arranging the details for the meeting, electing vice-presidents, presidents, and secretaries of sections, collecting papers to be read, etc., for this meeting, and have caused to be sent out 6,000 circulars to members of scientific societies in Australia; they have, in fact, been sent to every member whose address was known to them; and thinking it possible that there were many others who would join an association with such a wide basis, they have appealed to the public through the daily papers of all the colonies very frequently, by advertisement and paragraph, and the result is that to-day our numbers are 750, which, I think, is very satisfactory and encouraging. I may mention that in Australasia there are only 38 scientific societies known to the officers of this movement. All these were appealed to by letter; 34 expressed their ntention of taking part in it, and of these 28 sent representatives to the meetings—this out of a population which may be roughly stated at 4½ millions. In 1831, when the parent society was formed, the population of the United Kingdom was 23 millions, and there were in existence 39 scientific societies (I am unable to say what was the number of members). I have endeavoured thus briefly to sketch the history of the movement which has resulted in the present association. Like the British Association, our basis is broad enough to take in "whatever desire there may be in the country to promote science," and those who have joined hope that no man will stand aloof who has any desire to help in the advancement of science. After the experience gathered by a similar institution in the old country, I have no fear for the future of this movement. I do not expect the association to emerge from the shell of its first meeting perfect; that would be unreasonable; but I believe that we have accepted a constitution and acquired an impulse which in the course of time will lead us on to the realisation of our purpose. The scientific man works very much alone, isolated from those around him by his peculiar manner of life, and from his fellow-workers by distance, because so far the world expects each scientific man to be a world in himself, to be able to do all it wants of that science, and is not disposed to keep several where one can be made to do. The call of the British Association, therefore, to meet once a year those who are like-minded, appeals to his social instincts in a very effective way. Hence the opportunity of going to the meeting to see and talk with his fellow-workers is not to be lost. It is a real pleasure to have a talk with kindred spirits, and a very effective motive for application all through the year, for no man would choose under such circumstances to neglect his self-culture, and feel at the meeting that he was far behind his fellows. Then these meetings naturally lead to the formation of committees, who must work up all those subjects which the individual cannot manage. One of our first duties will be to work up all the facts known in every branch of Australasian science, if you will allow me to use the term. I mean all those branches of science which are more immediately connected with the material advancement of the colonies. This I hope will not take long, and then we shall be in a position to advance in these subjects. Every worker knows how necessary it is to have all facts in clear and orderly arrangement, as a preliminary and necessary step to any safe advance. It may seem to some that I am asking too much—that we are all hard-worked men, and but few in numbers, and have no time for such work; but exactly the same may be and has been said of the men who are the workers in the British Association, yet they are not the men of leisure, but the busy men of science, who do the work, and it is very instructive to watch how they respond to the call of the association; it comes like a call to arms that must be responded to, and is responded to often at great personal sacrifice, and with no other motive than loyalty to the cause they serve. But the parent association has just the same power over hard-worked professional and business men; in thousands of cases it has taken from such a man a week of ill-spared time during which he attended the meetings, and by so doing has succeeded in setting him to work for a year, thinking how he can advance the cause of science. As like produces like, so these meetings of workers make many new workers; and as we read down the list of names of those who have been drawn into the great army of workers we find the name of every distinguished man in the United Kingdom—men with a practice or business in which they had no spare moments; Stephenson, Scott Russell, Brunel, Bessemer, Nasmyth, Armstrong, Warren de la Rue, Spottiswoode, Whiteworth, Siemens, and so on, through all that grand muster roll of which any nation would be proud. Now, I do not for one moment suppose that we with four millions can make the same display of talented workers that the United Kingdom can from thirty-seven millions; but we can find some, and I am quite sure that our association will be the means of bringing to the front many men amongst us, now scattered through the country, who have ability and genius, and who are willing to take up some of the subjects which require investigation and work them out; men whose daily work is of another kind, but who have nevertheless a keen love for science and investigation and the spare time to take up a limited subject and fill up the whole detail. I am convinced that there are many such who require no other stimulus than that of being invited to render services of the highest order. They want to work, but do not know where to begin; while, on the other hand, a crowd of suggestions meets the busy scientific worker at every turn. Ideas that want realising are continually floating in his thoughts. Now it is some promising line of investigation, some experiments that only want making to put the finishing-touch to a long line of reasoning, and establish some new scientific fact or some new law of nature. Now it is a new view of an old and well-fought difficulty, some new vantage-ground that promises success; but he cannot leave the pressing duties of the present hour to work out the promising future. And for him to meet those who have time and ability to work is like hope in the wilderness, and if our association can bring them together it will have done much to promote science. It has been said that amateurs at science do little in the more difficult subjects of investigation; but those who say so overlook the fact that when a man does do difficult work they cease to call him an amateur, and class him with professional men. It is a well-known fact that some of the greatest honours in scientific work were won, and are being won, by men who would be properly classed as amateurs—men who have stolen from leisure and from sleep the hours necessary for their favourite study. It is a mistake to class all amateurs as alike. As well say that all business men are alike. Science seems ever to point forward. The question answered to-day suggests two for to-morrow. There may be no halting-place, and none is desired. Obedience to the law of service develops into a service of love, and the search for truth is the pleasure of existence. And if we are true to our colours we we will see that truth is not stored away in dusty papers, but published to the world, so that every one may see what and how it is. The British Association has put the best men to do this, and to publish the known facts in every science to the world, and has found this the best method of helping that great majority who are ready and willing to help if taken up to the front and shown clearly the boundary between what is known and what is unknown. It is this noble example that we wish to follow. The Australian Association is for the advancement of science, and if it fails in that it will fall to pieces. But it is not the hobby of a few individuals or of one colony; it takes in all who wish to advance science in all the colonies it meets here this year—in Melbourne, probably, next year, going to another colony every year, gathering up the enthusiasm of each colony in turn, and will come back to us when we are very glad to receive it. By its charter the association is bound to promote the intercourse of scientific men and lovers of science; to give a stronger impulse and a more systematic direction to scientific inquiry; to obtain a public recognition for the claims of science, and to endeavour by every means in its power to promote scientific inquiry; to grapple with the scientific questions that affect the material advancement of this portion of the British dominions—questions in chemistry, physics, and geology; in mining, mineralogy, and engineering; in meteorology, water conservation, and irrigation; and every other subject that may promote our national advancement. I hope you will not think my subject is running away with me, for the experience of the British Association fully justifies us in believing that we may expect all this and much more from our association. We are often told of the influence of science upon material advancement; but there is another thing that I should like to dwell upon, but that I fear to keep you too long. We hear too little about the influence that scientific work has upon a man's character. There is a science culture as well as a classical culture, and it would be worth while tracing its influence upon those who get it, and through them upon society. And we hear far too little about the influence which science is having upon the young, by exercising their powers of observation and reason on the phenomena of nature around them. Scientific education is spreading through all classes of the community, and slowly, but surely, like the advance of every great truth, the world has learned to recognise the fact that science is the great lever in the material advancement of the people; nay, more, that we cannot have material advancement without a previous advance in science. If we are to have new processes in the arts, new applications of the laws of nature for the wellbeing of mankind, we must first have the study of nature and the laws which govern its operations before we can hope to employ them for our advantage. In a new country like this, with all its local variations in the laws of nature, its uncultivated forest fruits and flowers, its unknown vegetable and mineral wealth, the fact is forced upon us in a thousand ways that we must know or we must suffer. And we use the word science in its comprehensive sense. There have been those who said that the proper study of mankind is man, and who, while strenuously denying to this study the dignity of a science, have thought no other science worthy of culture. And there have been others who have asserted that man's only study was nature in the things around him, neglecting altogether the science of man. But man and nature are correlative, and therefore true science must embrace both studies. And even in the things around us we must not take the vulgar view, which only sees the necessity for cultivating those branches of science that are direct producers of gold and minerals. As a well-known politician in another colony once said to me when I asked him to spend a few pounds on pure science, "Will it affect the price of beef and mutton? If not I won't spend a shilling on it." Unfortunately he is not alone in his opinion; there are many whose only measure for scientific value is a coin of the realm. If there is to be a true advance of science it will not come from one-sided efforts. Each branch must be pushed forward in its own special direction, and in—what is just as important—its relation to all other branches of science. Science stands or falls as a whole; if we limit it to certain purposes or persons it ceases to be science, and becomes mere empiricism. This association stands as a protest against the short-sighted and utilitarian policy of those who would cultivate only what they characteristically call the bread-and-butter sciences. Our purpose is the advancement of all the sciences, believing, as we do, that the true advance of one is inseparably connected with that of all the others, and by the advance we do not simply mean the increase in knowledge of its laws, but also in the application of it to the wants of mankind. Too often in the past the advance of science has been checked for generations by those who said they knew that the earth stood still, and who did their best to make it do so, and our protest is against the views of men of the same stamp in the present day, who think they know everything and select what is useful. Is that dreamy astronomer to be banished because he sits in some darkened dome peering through his telescope at some distant star, and wanting to know where it is. What has that got to do with the material advancement of the people? says the Utilitarian. Nay, that very quest, turned into a demand for better mechanical contrivances, better glass, and better workmen, led Fraunhofer to strain every nerve to meet it. He examined light in its passage through lenses most minutely, and thus learnt how to correct the previous errors in his telescopes, and while he did that he found those definite lines in the spectrum that will for ever be known by his name. He recognised their exact coincidence with those given by well-known terrestrial substances, and so gave the world the spectroscope, that most wonderful instrument working out through the most abstract science, the quickest, most perfect—ay, even the cheapest way of answering a thousand pressing questions in the money-making arts. Has chemistry served its purpose when it analyses our soils and our minerals, when it makes a mixture to take gold from quartz and money out of every slag? Is it not to go into our schools, and colleges, and universities, and teach those who will never use its solvents those wonderful affinities in nature, those laws of combination and dissolution, of solution and crystallisation, the laws which formed the water, built up the solid rock, the earth, the flowers? Is the study of pure mathematics to be banished because it cannot find an equation for the locality of a big nugget, when it has found and is finding thousands of equations which are mines of untold wealth in the material advancement of humanity? No, certainly not; for it is fitting that man, dwelling in that infinitely complicated organism his body, which responds on its ten thousand strings to every breath of nature, should study not one or two, but all the laws which govern it for weal or woe, and learn to place himself in harmony with all.

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents, nor can he take notice of anonymous communications. All letters must be accompanied by the name and address of the writer, not necessarily for publication, but as a guarantee of good faith.

TOTEM CLANS AND STAR WORSHIP.

I read with much interest the paper of Mr. George St. Clair on the origin of Totemism, which you published in Nos. 15 and 16. It contains many views new and ingenious, and is full of interesting facts. I think, however, that the author has been led to exaggerate the part astronomy can have played in the formation of Totem clans. This desire to explain everything by astronomy is natural to the school of which Dupuis was the most brilliant representative, and was excusable when a high astronomical knowledge was attributed to the ancients. As I have already noticed somewhere else, the study of the Babylonian documents shows that real astronomy was unknown before the Greeks. The Babylonians did not know even astrology, a science which was devised by the Greeks of Alexandria, and which required a certain knowledge of the course of the planets. The Babylonians only took omens, and in these the sun played but a little part. The group of stars which presided over one month was not that in which the sun was rising, but that which occupied the most prominent place in the sky during the month. Another error was to believe that the year was always divided into twelve months; the Egyptians and the Semites divided primitively the year into ten parts. A remembrance of this division was retained by the Romans.

Another point. Knowledge of the stars, even empirical like that of the Babylonians, requires a long period of observation. If such knowledge be possessed by any organised society, it must have been constituted for a long time. I conclude, therefore, that totemism is anterior to star worship, and certainly anterior to a knowledge of the star groups. I go further; stars have received names of animals, like bull, goat, etc., because of their being assimilated to a great flock. They were named from those animals men saw round themselves; and if they had, as is pretty certain, special reverence for certain animals, they naturally gave to the stars these names in preference.

As to animal worship (which might in certain cases have been the origin of the totem clan system), its origin has been very well demonstrated by Dr. Oberziner ("Il Culto del Sole") and Professor Sayce ("Introduction to the Study of Language"). It proceeded on one way from a kind of universal sentiment of sympathy for all that lives, and on the other it was accelerated by the phonetic resemblance of names and also by symbolism. Astronomy certainly played no part in it. I, however, entirely agree with the lecturer as to the fact that every worshipper of an animal-god considered this animal as his ancestor. This never had been stated so clearly before.

There are many other points I should like to touch, as, for instance, the origin of exogamy, but I must put an end to this letter.

G. Bertin.

RECENT INVENTIONS.

The following list has been compiled especially for the Scientific News *by Messrs.* W. P. Thompson *and* Boult, *Patent Agents, of 234, High Holborn, London, W.C.; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester; and 6, Lord Street, Liverpool.*

Paper.—Mr. J. Jameson has patented a safety paper to afford means of protection against erasure. It is coated with a very fine spray of a dense solution of a highly-soluble colour, and is thus rendered very sensitive, and will readily show whether it has been tampered with by erasure or any other alteration.

Explosive.—Messrs. E. Kubin and A. Siersch, both of Vienna, Austria, have invented a new explosive which on ignition prevents danger of explosion of fire damp or other gases in mines. The mixture used for this purpose is sulphate or chloride of ammonia intimately mixed (in the proportion of from 20° to 50° of the entire compound) with dynamite blasting gelatine or other explosives. On the explosion of this compound it will be decomposed into gases which are non-inflammable.

Electric Motors.—Mr. W. H. Mordley has patented an electric motor. This invention has reference to improvements in the construction of alternate current electric motors and to their application in connection with secondary batteries or accumulators for charging the same. The main object is to so construct alternate current motors that they shall possess the power of starting from a state of rest the speed regulating properties attaching to synchronous action and a high efficiency; this has hitherto been very difficult to do.

Electric Measuring Instrument.—Messrs. R. E. B. Crompton and J. Swinburne, of Chelmsford, have invented an improved apparatus for measuring the electric current. A needle is magnetised, and is suspended within a coil as in an ordinary vertical detector, but the needle is balanced so as not to stand at right angles to the axis of the coil; so that in deflecting the current has to overcome the gravity of the needle (or a spring may be used for a like purpose), and the angle of deflection is recorded on the scale in the usual manner.

Impure Liquids.—Messrs. E. Hermite, E. J. Paterson, and C. F. Cooper have patented means for disinfecting impure liquids, such as sewage, by mixing with the liquid to be disinfected certain chlorides, and then passing the mixture in thin sheets between electrodes connected to the terminals of a dynamo electric machine, and thus causing an electrical current to traverse the liquid as it passes the electrodes. The effect of this is a partial decomposition of the chloride, which causes an oxidation of the impurities rendering them innocuous.

Syphon Bottle.—Mr. H. Goffe, of the firm of Goffe and Sons, Birmingham, Warwickshire, is the inventor of improvements in syphon-ærated water bottles for fire extinguishing. The inventor takes an ordinary syphon bottle, and near the lower end of the spout he drills a hole, so that when it is desired to use the bottle as a fire extinguisher, all that it is necessary to do is to place the finger over the open end of the spout, when the liquid, being under considerable pressure, issues from the hole in a jet according to the size of the same.

DEPTH OF LIQUIDS.—Mr. F. C. Clare has patented means for ascertaining the depth of liquid in vessels. This invention is specially suitable for lamp reservoirs to indicate whether it is partially filled or nearly empty. A float is provided having a hole through it for the passage of a spiral rod, which is pivotted at the top and bottom in discs so that it can rotate freely. The hole in the float is shaped so that the rod freely moves and revolves as the float rises or falls, and on the upper disc is a pointer attached to the rod, which, as the spindle revolves, indicates the height of the liquid.

INK.—Mr. W. Hackney has patented a writing ink. The object is to prevent the inconvenience caused in many climates by the ink drying in the bottle, on the pen, or otherwise. This is prevented in the case of inks in which water is the chief constituent by adding chloride of calcium in the solid state to the ink, and by employing paper impregnated with sulphate of sodium, which will form, by double decomposition with the chloride of calcium, a salt which is not objectionable. The employment of this paper for writing upon prevents the objectionable qualities engendered by the employment of the chloride in the ink.

FLEXIBLE FILMS.—Mr. J. E. Thornton has patented a photographic flexible film. It is prepared in the following manner:—A suitable material, such as glass, is procured upon which to prepare the film, and a transparent material known as "algin" is employed for the preparation. This substance is soluble in water, and possesses the peculiar property of becoming insoluble in water after treatment with dilute mineral acid. To prepare a film it is only necessary to dissolve sufficient in water to make a thick glutinous solution, which is then flowed out on a level surface and allowed to dry. The resulting film is afterwards rendered insoluble, and is then stripped off the glass for use.

FIRING NAVAL ORDNANCE.—Mr. P. J. Crampton has patented means for firing naval ordnance. The object is to provide means whereby the guns can be fired automatically when the vessel is on an even keel. A plate is employed which has its plane constantly parallel with the horizon. On this plate are electrical contacts connected in pairs, and above them hang arms with corresponding contacts. The electrical circuit is connected with electric wires for firing the guns. The points on the arms are kept in a plane parallel with the horizon when the ship is on an even keel, by means of stops, and it is only when the electrical circuit is complete that the guns can be fired.

BALLOONS.—Mr. H. Lane has patented a method of constructing spherical balloons and other forms of gas or air bags of shapes known as solids of revolution. A spindle is constructed with tapering extremities bearing at each point of its length a geometrical proportion to a corresponding point of the balloon to be constructed. The spindle is supported on anti-friction wheels. The substances of which the balloon is constructed are spread over the surface of the spindle, the latter being rotated as the material is added. The fabric is then detached from the spindle and held in reserve until it has made sufficient revolutions to complete the amount of fabric required; the two extremities of the fabric are then joined together.

ANNOUNCEMENTS.

CAMBRIDGE.—At Emmanuel College the next examination for open scholarships will commence on Tuesday, December 11th, 1888. There will be offered for competition five scholarships, one of £80, two of £60, and two of £50. The scholarships are tenable, in the first instance for two years, but the tenure may be prolonged and the value increased if the scholar makes satisfactory progress and distinguishes himself at the annual college examination. The scholarships will be awarded for proficiency in classics, or mathematics, or natural science, or any two of these branches of study. Candidates in natural science are required to show a competent knowledge of chemistry. Every candidate must be under nineteen years of age at the commencement of the examination. The successful candidates must enter Emmanuel College and commence residence at the latest in October, 1889. Every candidate is required to send his name, with a copy of register of birth and a certificate of good moral conduct from some M.A. of Oxford or Cambridge, to Mr. W. Chawner, M.A., Tutor of Emmanuel, before Friday, December 7th, to whom all inquiries for further details concerning the examination should be addressed.

At King's College the next examination for scholarships will commence on Tuesday, December 11th. Four Eton entrance scholarships, two open entrance scholarships of £80, two exhibitions of £50, and at least three exhibitions varying from £70 to £40 will be offered. The scholarships and exhibitions, except one exhibition for natural science, will be offered for proficiency in classics, mathematics, or history. The open scholarships and exhibitions are open to all persons under nineteen years of age, who have not yet commenced residence. Candidates must send their names to Mr. G. W. Prothero, M.A., Senior Tutor of the College, not later than December 3rd, of whom further details of the examination may be obtained on application.

The Special Board for Geology and Biology recommend that the sum of £80, from the Worts' Travelling Scholars' Fund, be granted to Mr. M. C. Potter, M.A., of Peterhouse, to enable him to make botanical researches and to collect specimens in Ceylon during the winter months of 1888-9, on the understanding that he report the result of his investigations on his return.

LONDON MATHEMATICAL SOCIETY.—The following gentlemen will be recommended, at the Society's annual meeting, Nov. 8th, for election on the Council for the ensuing session:—J. J. Walker, F.R.S., President; Sir J. Cockle, F.R.S., E. B. Elliott, M.A., and Professor Greenhill, F.R.S., Vice-Presidents; A. B. Kempe, F.R.S., Treasurer; Messrs. M. Jenkins, M.A., and R. Tucker, M.A., Hon. Secretaries; A. B. Basset, M.A., Dr. Glaisher, F.R.S., J. Hammond, M.A., Prof. H. Hart, M.A., Dr. F. Larmor, C. Lendesdorf, M.A., Captain P. A. Macmahon, R. A., S. Roberts, F.R.S., and Dr. Routh, F.R.S.

GREENOCK PHILOSOPHICAL SOCIETY.—From the programme of arrangements for the coming session, sent us by the Honorary Secretary, Mr. J. Slater, we find that the following lectures will be given:—"The Great Ice Age," by Sir R. S. Ball; "Buried Cities of Ancient Egypt," by Miss Amelia B. Edwards; "Earthquakes, Volcanoes, and Geysers," by Commander C. Reade, R.N.; "A Dredging Cruise in the Atlantic," by the Rev. W. S. Green; "Ceylon as seen by Myself," by Prof. R. Wallace; besides a number of lectures on literary subjects.

NEW PUBLICATIONS.—Messrs. Iliffe and Son are about to publish a work which should prove of considerable value. It will be entitled "The Indispensable Handbook to the Optical Lantern," being a complete encyclopædia on the subject of optical lanterns, slides, and accessory apparatus. A specially useful feature will be a *catalogue raisonné*, descriptive of all the different sets of slides now on sale. This will undoubtedly fill a considerably felt want, as intending purchasers have had hitherto no information beyond the mere titles of the sets by which to make their selections, and these in many cases inadequately describe the features of the slides.

NOTICES.

The Title Page and Index to Vol. I., now ready, price 3d.

Binding Cases for Vol. I., price 2s. each.

Cases and Binding, Vol. I., including Title Page and Index, price 3s.

Vol. I., bound in cloth, with Title Page and Index, 9s. 6d. —by post 10s.

The Back Numbers of SCIENTIFIC NEWS can be obtained from all Booksellers and Newsagents, or direct from the Publisher, 138, Fleet-street, London, E.C. Price 3d. each, or by post 3½d.

SELECTED BOOKS.

Force and Energy, a Theory of Dynamics. By Grant Allen. London: Longmans, Green, and Co. Price 7s. 6d.

Steam and the Steam Engine (an Elementary Manual of). By Professor Jamieson, M.Inst. C.E., Glasgow Technical College. With numerous illustrations, and examination questions at the end of each Lecture. London: C. Griffin and Co. Price 3s. 6d.

DIARY FOR NEXT WEEK.

Monday, Nov. 5—Gresham College, Basinghall Street, at 6 p.m.—*Lecture on Geometry*, by the Dean of Exeter.
Society of Engineers, 9, Victoria Chambers, Westminster, at 7.30 p.m.—*The Practice of Foundry Work*, by Mr. H. Ross Hooper.

Tuesday, Nov. 6.—Society of Biblical Archæology, 9, Conduit Street, Hanover Square, at 8 p.m.—*Is* אַבְרֵךְ (*Abrĕk*) (*Genesis* xli. 43) *Egyptian? The Thematic Vowel in Egyptian*, by Prof. P. le Page Renouf. *On Cuneiform Despatches from Tûshratta, King of Mitanni, Burraburiyash the Son of Kuri-Galzu, and the King of Alashiya, to Amenophis III., King of Egypt, and on the Cuneiform Tablets from Tell-el-Amarna*, by Mr. E. A. Wallis Budge.
Gresham College, Basinghall Street, at 6 p.m.—*Lecture on Geometry*, by the Dean of Exeter.

Wednesday, Nov 7.—Gresham College, Basinghall Street, at 6 p.m.—*Lecture on Geometry*, by the Dean of Exeter.
Dundee Naturalists' Society.—*The Flora of New Zealand*, by Mr. Alexander Hutton.
Entomological Society, 11, Chandos Street, Cavendish Square, at 7 p.m.

Thursday, Nov. 8.—Gresham College, Basinghall Street, at 6 p.m.—*Lecture on Geometry*, by the Dean of Exeter.
Society of Telegraph Engineers and Electricians, 25, Great George Street, Westminster, at 8 p.m.—*On Ocean Temperatures in Relation to Submarine Cables*, by W. Lant Carpenter, B.A., B.Sc.
London Mathematical Society, at 8 p.m.—*On the Confluences and Bifurcations of certain Theories*, by the President. *On Cyclotomic Functions*, by Prof. Lloyd Tanner. *A Theory of Rational Symmetric Functions*, by Capt. P. A. Macmahon, R.A. *Raabe's Bernoullians*, by Mr. J. D. H. Dickson. *Certain Algebraic Results deduced from the Geometry of the Quadrangle and Tetrahedron*, by Dr. Wolstenholme. *The Factors and Summation of* $1^n + 2^n + \dots + n^n$, by Rev. J. J. Milne.

Friday, Nov. 9.—Greenock Philosophical Society—*The Buried Cities of Ancient Egypt*, by Miss Amelia B. Edwards.

METEOROLOGICAL RETURNS

for the ten weeks ending on Monday, Oct. 22nd, 1888. Specially prepared for SCIENTIFIC NEWS from official reports.

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

We have all read of the mysterious proceedings of the working bees when the queen of the hive is removed; how they break up three of the cells of neuter babies, make a pendulous royal cell of cylindrical form and greater dimensions, then by supplying the infant neuter maggots with royal food, convert them into female or queen bees, one of which ultimately receives the homage of the whole swarm. In the ordinary course, where no outside interference has occurred, the female is similarly evolved by modification of board and lodging.

With all our science we can do nothing like this. We can only study and admire, without any hope of imitating.

Many have thus studied the mysterious proceeding, and lately a Swiss gentleman, A. von Planta (an old fellow-student in Dr. Anderson's laboratory at Edinburgh), has worked out the chemistry of the different varieties of the pap which is respectively supplied to the cells of baby maggots which are ultimately to develop into male drones, neuter workers, or royal females.

This juice or pap is in all three cases a whitish, sticky substance, which more than thirty years ago was described by Leuckart (*Deutsche Bienenzeilung*, 1854, 1855) as a product of the true stomach of the workers, which they vomit into the cells in the same way that honey is vomited from the honey stomach. Others regarded it as a product of the salivary glands of the bees. Schönfeld, in numerous recent papers, has shown that Leuckart's view is the correct one. Schönfeld obtained saliva from the salivary glands of the head and thorax, and found it to be very different from the pap deposited in the cells; also that this is similar, both chemically and microscopically, to the contents of the bee's true stomach. He described also the anatomical structure by which the ejection from the stomach is effected.

Von Planta's investigations of the chemical composition of the contents of the bee's stomach and of the juice supplied to the three classes of cells entirely confirm the conclusions of Leuckart and Schönfeld. Preliminary microscopical investigations afforded the following results, which were quite in accord with the results of subsequent chemical analyses :—

1. The food of the queen-bee larvæ is the same during the whole of the larval period; it is free from pollen grains, their substance having been reduced to a thickish but homogeneous juice by the digestive action of the worker-bee's stomach.

2. The food of the larval drones is also, for the first four days of the larval period, free from pollen. It appears to have been digested in like manner, but after four days it is rich in pollen grains, which have, however, undergone a certain amount of digestion.

The following table of average percentages of several of Von Planta's analyses is given in the *Journal of the Chemical Society*:—

	Food Stuff of		
	Queen Bees.	Drones.	Working Bees.
Water	69·38	72·75	71·63
Total solids	30·62	27·25	28·37
In the Solids—			
Nitrogenous material	45·14	43·79	51·21
Fat	13·55	8·32	6·84
Glucose	20·39	24·03	27·65
Ash	4·06	2·02	—

"All were of greyish colour; that of the queen bee was the stickiest, that of the workers the most fluid. Peptone appeared to be absent; the greater part of the nitrogenous material present was proteid. The ethereal extract was in all cases acid, but formic acid was absent." The sugar contained in pollen grains is invariably cane sugar, but in this food supplied to the larvæ it was found to be, in all cases, invert sugar, or glucose, the form of sugar which is formed in the bodies of animals—ourselves included—by the action of the salivary diastase upon the starch and cellulose of vegetable food.

Not only is there a difference in the composition of the food, but the quantity supplied varies very greatly.

The juice from 100 queen-bee cells yelded 3·6028 grammes of dry substance, that from 100 drones' cells 0·2612 gramme, from 100 workers' cells 0·0474 gramme.

Reviewing these results, some approach to a theory may be framed. We may, I think, venture to conclude that the fundamental character of the royal food which effects the development of the queen is that it is supplied in a partially digested condition, thus permitting the infant maggot to devote more of its vital energies to the business of assimilation and growth. The other maggots are supplied with food in this condition at first, but afterwards they have the pollen in semi-digested condition, and finally when fully grown they get it directly in its crude state from the plant.

This nearly corresponds to the proceedings of the mammalian vegetarians. The cow supplies the young calf with digested grass in the form of milk during the period of most rapid growth, and those who are behind the scenes at cart-horse shows know that the prize specimens are fed upon milk; they commonly have a couple of cows in attendance upon each. Bulk is thus attained, if nothing else.

The above table shows that the greatest difference between the food supplied to the queen and the other young bees is in the fat, the quantity of which is about twice as great as that provided for the ordinary worker maggots that are not to be developed into queens. This is curiously analogous to the difference between the milk of the herbivora and graminivora and the grass or grains of the food of the adult. Even in the carnivora, which obtain more fat in their ordinary food, there is still an excess in the milk. Thus, according to Dr. Miller's analyses, cow's milk contains an average of 4 per cent., goat's 4½, sheep's 4½, while the milk of the bitch contains 14·8, about 3½ times as much. The milk of the porpoise contains 45·8 per cent. of fat.

Analogy justifies us in supposing that the fatty matter supplied to the cells is obtained by the adult bees from starch, glucose, or other vegetable sugar; and here it is that the greatest change occurs in the course of digestion of vegetable food; the conversion of carbo-hydrates into hydro-carbons, the splitting or dissociation of the water of the carbo-hydrate, the disposal of the oxygen, and leaving the carbon with the hydrogen only. Much work is demanded for effecting this change, and a corresponding exhaustion of energy is saved for the work of larval growth.

These microscopic and chemical investigations, however interesting in themselves, contribute nothing towards a solution of the mystery of the balancing of the sexes which occurs spontaneously in most species, notably so in man. If variations of food had any influence here, it would surely show itself now that we have so many sectarians in the matter of food; some that abjure alcohol, others abstaining from flesh food; some denouncing tea, coffee, tobacco, etc., and even cases of total abstinence from all liquids; men and women who use neither cups nor glasses, nor even the oyster-shell of Diogenes, but depend upon fruit and green food for all the liquid they require. Then we have whole tribes, like the coast Lapps, that feed only on fish; others, like the Fjeld Lapp, who depend almost exclusively on the reindeer, gathering only a few pot-herbs in the summer; others feeding on raw flesh, on roots, etc., etc.

In none of these have we any special preponderance of either male or female infants when any considerable number of families is counted. Neither climate nor seasons, nor sedentary or active habits, have any visible effect.

It is true that certain families consist mostly of boys, others of girls; but, somehow, they balance each other in the mass, just as the proportion of mere accidents remains the same when we take large averages; like the constant percentage of undirected letters containing valuables that are annually deposited in the boxes of the Post Office, or the number of people annually killed in the streets of London.

We have no record of any race, of any place or period, that has been specially distinguished by its preponderating production of either male or female infants.

THE LATE ERUPTION OF VULCANO.

THIS formed the subject of a paper in the Geological Section of the British Association, at the late meeting at Bath, by Dr. Johnston-Lavis and Dr. Tempest Anderson. It was illustrated by photographs thrown on the screen by a lantern, some of which we now reproduce. They were taken by Dr. Anderson in May of this year, and consequently represent the island as it was before the eruption.

Identified in the older mythologies with the forge of Vulcan and the workshop of the Cyclops, where, according to Virgil, the armour of Æneas was forged, this island has always been an object of awe and superstitious dread to the dwellers in the two Sicilies.

In later times, when fear and fancy had begun to give way to curiosity, the historians, geographers, and philosophers of Rome gave more sober and accurate accounts of its phenomena; and its later name of Vulcano, or Volcano, has gradually come to be applied to all mountains of similar character. Numerous eruptions are recorded from it, by Thucydides, Aristotle, and in the second century before Christ by Diodorus. It is probable that the small island of Vulcanello, now connected with Vulcano by later eruptions, was formed at this period.

In the middle ages it was regarded as the place of torture of Theodoric, an Arian emperor.

From the end of the fifteenth century a long series of eruptions are recorded, which have frequently driven away the inhabitants and devastated the island.

Vulcano is an island about five or six miles in greatest length, and is situated to the south-west of Lipari, from which it is separated by a narrow strait. The southern part of the island consists of several semi-circular crater rings, which have been formed at successive periods, as the point of eruption has shifted along the line of the great fissure which, no doubt, underlies the island. Towards the north-west end is the large active cone and crater, surrounded by a deep valley (Atrio) which separates it from the old crater rings.

Its summit is truncated, and shows vestiges of several craters, which have been successively formed and destroyed. One of these, the Forgio Vecchio, is well-shown in the centre of fig. 2. Above the Forgio Vecchio is the great fumarole referred to in Mr. Narlian's letter. In the irregular summit of the mountain are many fumaroles, and towards the south part is the large crater the bottom of which is shown in fig. 3. Its floor contains many large and active fumaroles, from which vapours constantly escape, with often much noise. These vapours consist of steam containing boric acid, arsenic, and other substances. Some years ago chambers for condensing these vapours were erected on the floor of the crater at a cost of several thousand pounds, and a road, shown in fig. 4, was constructed, leading down to them, but a slight eruption of the mountain destroyed them utterly in one day. In May, 1888, no attempt was being made to utilise these vapours, but sulphur was still extracted from above the Forgio Vecchio. The workmen live in caves excavated in the Faraglione,

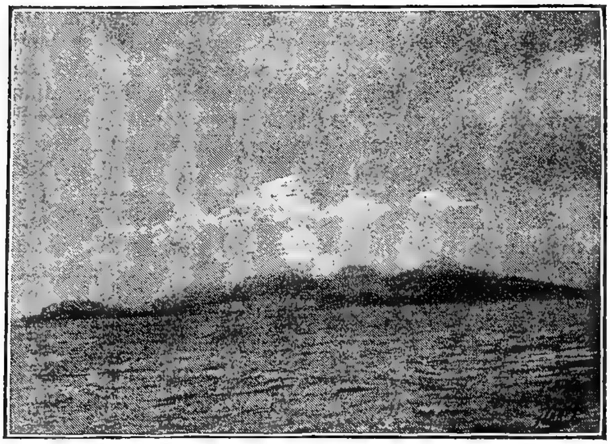

FIG. 1.—VULCANO FROM THE NORTH-WEST.

the detached mass of rock shown in fig. 2, just behind the white villa of Mr. Narlian. Some of these caves are of great antiquity, and were the source from which the ancient Romans obtained much of their alum. Though affording, according to our notions, only very limited accommodation, they are preferred by the natives to houses, as being warmer in winter and cooler in summer,

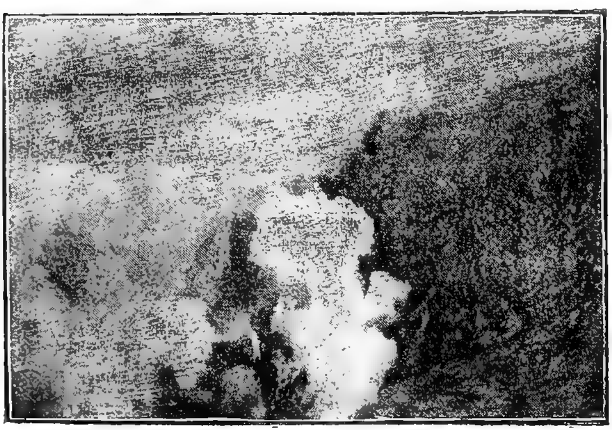

FIG. 3.—VULCANO. THE CRATER.

and also, it appears, as being safer abodes than those of their more pretentious neighbours'. The dark lava-stream shown in fig. 2, to the right of the picture, consists of obsidian, and was probably erupted in 1775. It is remarkable for its steep slope, and the manner in which the materials forming its lower part have been piled up on reaching more level ground, thus showing the extremely imperfect state of fluidity in which it was poured forth.

The following letter of Mr. Narlian, whose villa is shown in fig. 2, gives a most graphic account of the recent eruption :—

"Lipari, Aug. 30th, 1888.

"My dear Dr. Johnston-Lavis,—I have your kind note of the 22nd inst., and will give you a short account of the strange doings of our old friend the crater of Vulcanus.

"On the 3rd inst. we had an outburst in the crater, with stones, flames, thunder (regular lightnings). It was strong enough to throw stones of considerable size to the sides of

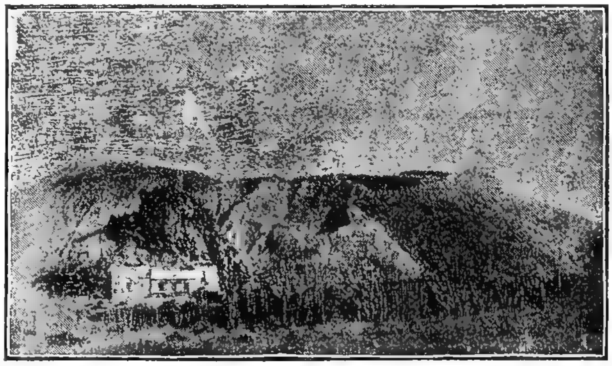

FIG. 2.—VULCANO. MR. NARLIAN'S HOUSE IN THE FOREGROUND; THE FARAGLIONE BEHIND IT; THE FORGIO VECCHIO AND OBSIDIAN LAVA CURRENT ON THE SLOPES.

the mountain. This lasted perhaps 10-15 minutes, and then ended. After some time we began to have, at the interval of every 20-30 minutes, a great rush of thick smoke, lasting some 10-12 minutes at a time. We had often seen such eruptions during 12-13 years I have been on the island, and I hoped it would end like former eruptions. Towards evening, however, these rushes of smoke, steam, and ashes (which

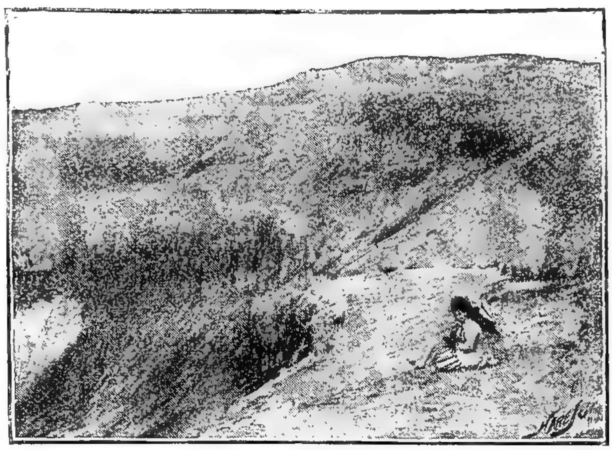

FIG. 4.—VULCANO. THE ROAD INTO THE CRATER.

used to be projected into the air to about twice the height of the mountain) had completely ceased. As the night approached, the leading fumarole (which was very active, giving off an offensive smell for months before the event) had begun to show a clear high flame, much paler than the flames produced by the burning of wood, and somewhat greenish or bluish. This phenomenon, together with the sudden stopping of the smoke, was not evidently a good omen. Consequently, I spent all the night dressed on a sofa in the drawing-room. Towards morning I was overpowered by sleep, and went to the little bed-room which looks towards the mountain, rested on the bed, and soon was evidently sound asleep. Soon afterwards I was awakened by a tremendous din, which can hardly be described. As I jumped up from my bed I felt stones falling on the roof as hail—such cannonading going on. I understood what was the matter, ran to the opposite room, where I had made my children sleep that night. They were also up, in consequence of indescribable noise of thunder, rush of gases, flames, falling of huge boulders, rocks, etc. I took them to the drawing-room, but as soon as the door was opened a big stone, red hot (all these stones were quite red with heat) fell through the roof, ceiling, and floor a few yards from us, smashing all, setting fire to everything. Now I took my children back to the bed-room, which looks on to the verandah, and tried to gain the terrace by that side. The house doors were shivering and shaking, so that it was a difficult matter to open the doors. At last I succeeded, but before we were out in the verandah another stone fell at our feet, was smashed to fragments, and burned the feet and legs of my boys. Now we passed through the verandah, regained the house at the top of the stairs; here another stone fell very near us (none of these stones were less than 2 ft. in diameter). This last stone (which is the fourth that struck the house, including the one that fell on the ceiling of my bed-room while in bed) had nearly blocked our way out in the rubbish that it brought from the roof. We passed through over the heap of rubbish, and were now out in the open to the north of the house. By this time (not many minutes after all) the whole place was lighted up, woods, grass, buildings, hedges—all was on fire; the huge boulders and stones were literally raining everywhere about us—what confusion! Natali, the faithful boy, had by this time come to the help of my little boys. We all began to run to Vulcanello and away from the dreadful thundering mountain. All the means of communication we possessed at Vulcano consisted in an old half-broken 20-ft. boat and a lighter, both of which the men in their panic and mad despair had taken away with them, leaving us on the sands of Vulcanello. Towards noon, however, boats of rescue reached us from Lipari, and we thus ended one of the most eventful days of our life.

"On revisiting the spot I saw the whole plains below the mountain, to the distance of one and a-half miles, especially the neighbourhood of the house and the men's habitations, literally covered with boulders and rocks of all sizes, which have embedded themselves in the ground to various depths. The most huge of them is near the well of the house, and is not less than 10 yds. in diameter, or better in length, and is some 10-11 ft. deep in the ground. This is about three-quarters of a mile from the crater. Another, of nearly equal dimensions is on the shore near the Quarantana at the end of the bay of the Levante. Rocks of one yard in diameter are as plentiful as can be as far as the middle of Vulcanello, near the Punta Samossa. We have to thank God for going unhurt through this 'hail-storm.'

"After this awful calamity, which has caused me so much loss, the crater has recommenced the rushes of steam, ashes, etc. This was a time of comparative diminution of activity, which has lasted for some days. Soon, however, it began the old game of throwing stones, boulders, ashes, etc., every two or three minutes in all directions. No doubt many of these boulders are 10-15 yds. across, and are projected as far as the sea, but often fall back in the crater itself. This state is continuing incessantly and uninterruptedly, causing further damage and frightening everybody.

"During the last three or four days the noise of the thunder and eruption is so loud that from Lipari (at the distance of six miles) it would be impossible to distinguish it from a prolonged thunderstorm.—Yours truly,

"A. E. Narlian."

Intercolonial Meteorological Conference.—An Intercolonial Meteorological Conference met in September at Melbourne. Mr. Ellery was elected Chairman. The other members present were Sir James Hector, Mr. C. Todd, Mr. H. C. Russell, Mr. C. L. Wragge, and Commander Shortt.

THE WHOMBEYAN CAVES.

Mr. W. S. Leigh, of the Geological Survey Branch of the Australian Department of Mines, has given the following account of the new cave recently discovered by Mr. M. Chalker at the Whombeyan Caves, near Goulburn, New South Wales.

"The entrance, a round opening about 2 ft. in diameter (which it is proposed to enlarge) is situated on the face of a rather steep hill, and is about 200 yards north-west of the mouth of the old cave, and 500 yards from proposed site of the cave-house. After passing through the entrance into the new cave a perpendicular descent of 25 ft. is made, and then a further descent for a like distance on an incline, the passage progressively increasing in size the lower you descend, until the bottom is reached, where it opens out into a large chamber about 50 ft. by 30 ft., and averaging 10 ft. in height. This chamber contains a fine collection of stalactites and columns, etc., and may be termed the 'Hall,' as the main caves radiate from it in three different directions.

"The first branch to the right of the entrance runs about due north about 100 yards in a zigzag line on a comparatively level floor, and averages about 10 ft. in width and 12 ft. in height. The floor for 20 or 30 ft. from the entrance is remarkably pretty in its formation, resembling a stream of crystals overflowing from a large basin, the stream below the main basin being composed of innumerable miniature basins in terraces, each basin being filled with a pure white coral-like formation. Other parts of the floor are covered with spherical stalagmites resembling snowballs. The stalactites in this, as also in the other branches, are grouped more regularly than is usually the case, as they run in almost parallel lines across the limestone roof. These, as well as the other formations, are remarkable for their snowy whiteness and transparency, the only exception being an occasional nest of stalactites resembling terra-cotta in appearance, and so lending a pleasing variety of colour. A very singular feature here is a large column of stalactites having small stalactites varying in size from the thickness of a needle to half-an-inch in diameter projecting at all angles round its base, the whole resembling very much the trunk of a tree with the young shoots sprouting up all round.

"The middle branch cave, by far the largest, consists of a chain of chambers ranging from the size of a small cabin to that of a lofty cathedral. These are formed by the immense rocks falling and wedging themselves together in all shapes, which necessitates the making of a number of steep ascents and descents. The chambers are well filled with all the prettiest formations met with in other caves. An instance is also observable of a large column formed of a number of stalactites, having been naturally broken across at a point about half way between the floor and the roof, the broken surfaces being separated from one another by a space of about 2 ins., so that the upper part of the column remains suspended from the roof.

"A further extension of this cave was discovered during my inspection, and I may safely say it is the crowning discovery as yet in the whole cave, being a roomy chamber at the extreme end (as far as yet known) of this branch, the floor of which might appropriately be named the 'crystal lakes,' the so-called lakes being a large number of pure white and transparent basins formed into a succession of terraces, each basin being partly filled with minute crystals having the exact appearance of water, the illusion only being discovered by touch. To see this formation alone would well repay the visitor for the trouble experienced in reaching it.

"The third branch, to the left of the last described, is comparatively small, and consists of a narrow winding passage, at the end of which is an almost circular chamber, being the main part of the branch. It contains a good collection of stalactites and stalagmites, and also some fine coral-like beds, the floor being of a crystallised dripstone. Fossilised bone deposits are found in some parts of the cave, a few specimens of which I brought down for examination. The roots of the Kurrajong tree, growing 50 ft. overhead, appear through the roof of the cave, and seem to take root again below the floor, some of them having a thick coating of lime. This cave in some respects resembles very much the Imperial and Lucas caves of Jenolan—the former in the fineness, transparency, and delicacy of its stalactitic structures; and the latter in some of its spacious and lofty chambers; and I may safely add that some of its formations, a proper description of which it would be difficult to give, if seen by the aid of the magnesium wire or other such light, would be proved to be quite equal to some of the best found at the far-famed Jenolan Caves. I may add that this discovery cannot be over-estimated, and it adds immensely to the interest of the Whombeyan Caves for those desirous of studying the wonderful and beautiful phenomena of the ancient subterraneous river channels hollowed out of the massive marble and limestone.

"In conclusion, I may state that as time and circumstances permit, further explorations will be carried out, it being my firm belief that other large chambers exist connected with this cave."

ROMAN REMAINS AT LLANTWIT-MAJOR.

LLANTWIT-MAJOR, or more correctly, from a Welsh point of view, Caerworgan or Caerwrgan, is a quaint little agricultural town in Glamorganshire. It consists almost entirely of queer-looking cottages, arranged in a most curious and irregular manner in the crooked streets, with nice little gardens back and front. Llantwit contains many ancient fragments pleasing to the antiquary. It is accessible from the Cowbridge station on the Great Western Railway, and is also an agreeable drive of about eighteen miles from Cardiff.

Situated a mile to the northward of Llantwit is a field, which, on entering, does not strike the visitor by exhibiting anything extraordinary or different from any ordinary pasture or meadow; but on rounding a haystack, peculiar inequalities of the surface attract attention, and a line of large pieces of rock, resembling stones for building, indicate that something is going on, and on wending our way in that direction, we observed a trench extending some distance, large heaps of earth, stones, and sundries showing us at once that some extensive excavating operations were going on, and from a tent in the field were evidently still in progress. Looking around, we could not help thinking, whatever could have induced any one to come to this out-of-the-way spot, and when there, what was it made them think of digging for Roman remains; and as our readers will most likely be as inquisitive as we were on this point, the history and *modus operandi* of these excavations will, doubtless, be as acceptable to them as they were to us.

Mr. Storrie, the astute and able curator of the Cardiff Museum, is an ardent naturalist, and makes frequent rambles in remote parts in search of things and specimens of scientific or general interest. One of these excursions, in quest of botanical specimens, led him to the field in question. He was attracted by the peculiar hillocks and irregular ridges, and expressed an opinion, that archæological remains of considerable importance were hidden under the surface; and as his opinion, in such matters, is regarded as second to none in the district, at his request the Cardiff Naturalists' Society took the matter in hand, and having procured the necessary funds, decided to make excavations in the field.

A preliminary probing of the field seemed to indicate that walls existed under some of the ridges, and when sufficient evidence was obtained by this means steps were taken to commence operations in a systematic manner. As a first step it was decided that a trench should be cut straight across the ridges, in a direction which appeared to intersect the greatest number of buried walls or ridges, or whatever they were.

The work of digging a trench about 5 feet wide and 2 feet deep was started in August of this year, from the

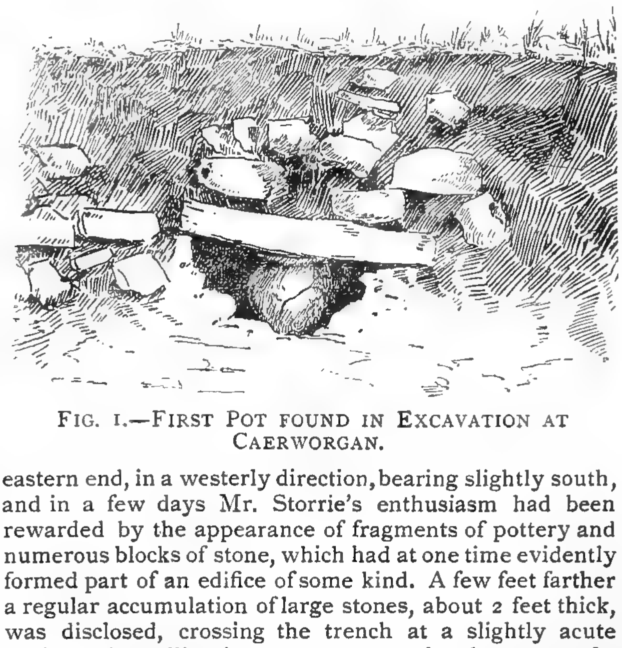

FIG. 1.—FIRST POT FOUND IN EXCAVATION AT CAERWORGAN.

eastern end, in a westerly direction, bearing slightly south, and in a few days Mr. Storrie's enthusiasm had been rewarded by the appearance of fragments of pottery and numerous blocks of stone, which had at one time evidently formed part of an edifice of some kind. A few feet farther a regular accumulation of large stones, about 2 feet thick, was disclosed, crossing the trench at a slightly acute angle, and recalling in many respects the characters of a dry stone wall. Within about 30 feet from this, a perfectly well-defined dry stone wall was encountered more than 3 feet thick, and running parallel to the other wall. About 20 feet from this wall an interment was observed under a large flat stone. On removal, it was found to consist of an urn of black pottery (now in the Cardiff Museum), containing charred remains, along with extraneous matter from the surrounding soil, such as earth, worm casts etc. From our illustration (fig. 1.) it will be noticed that the urn was evidently interred with much care. It would seem, therefore, to have contained remains of some importance, and Mr. Storrie expresses an opinion that a tumulus formerly stood where the urn was found. In close proximity to this, another wall was soon exposed to view, running parallel with the others, but of much greater solidity, being nearly 4 feet thick, and built of stones and mortar. Fragments of pottery, including some Samian (?) ware, were frequently dug up, and among the *débris* a piece of a bronze fibula. Another 70 feet brought the trench to another wall of stone and mortar, only 2 feet thick, and not running right across the trench; further investigation brought an angle of this wall to light, and it was almost certain that some enclosed space had now been entered. The excavations from this point teemed with interest. The trench passed over the wall forming the angle, as noted above (being evidently the wall of an enclosed space), exposing 27 feet of it, when another wall at right angles to it was met with, and thus introduced a second enclosed space. In the first enclosed space part of a quern, or hand-mill, was dug up, whilst the small corner of the second enclosed space, included in the area cut by the trench, proved to have plastered and decorated walls as well as a tesselated floor; moreover, human remains were exhumed here.

(To be continued.)

SUBMARINE EARTHQUAKES AND ERUPTIONS.

FREQUENTLY and closely, as it is remarked in the *Naturforscher*, as the quakings of the dry land have been investigated concerning the manner of their occurrence, their extension, and their causes, exceedingly little is known concerning the quakes of the sub-oceanic portion of the earth's crust. Nothing has been ascertained and recorded beyond the bare fact of their existence. At most we may say that the so-called earthquake tidal waves, such as those of Simoda (1854), Arica (1868), and Iquique (1877), have given occasion to researches. But the object in view was not so much to ascertain the causes of the phenomena as to draw from the movement of the waves conclusions as to the depth of the ocean. Recognising this deficiency in our knowledge of the seismic action of the earth's crust, Herr E. Rudolph, of Strassburg, has undertaken to collect all accessible records of seaquakes in a catalogue which extends to eighty pages. He characterises and classifies the seaquakes in accordance with the variable manner of their occurrence and their mechanical action, and explains the processes on the basis of the physical laws of wave-motion in solids and liquids.

This author gives the name of seaquakes to all agitations which have their origin in the bottom of the sea, and which, passing over to the mass of the ocean, are propagated as waves of elasticity. They are manifested to the observer by the shock which the ship undergoes, by a noise, and by phenomena on the surface of the sea.

A seaquake is felt by the sailors as if the ship had run aground, and was passing over it rapidly. According to the intensity of the shock, it may be merely a gentle but strange trembling in the ship, but in stronger shocks heavy objects are overturned, men are flung upwards, and ships even dismasted. In extreme cases the vessel itself may be lifted or thrown on its side, though its direction and speed are unaffected. As to the nature of the shock, both undulatory and succussory movements can be felt.

The atmosphere is not affected in seaquakes, save that there occur phenomena of sound which seem to have their origin in the sea, and which have been compared to a rumbling, or to distant thunder.

According to the action of seaquakes upon the water they are divided into two great classes. In the majority of cases the submarine shock passes over without exerting the least influence upon the mass of water. A change in the condition of the sea is not produced by the most intense shock in perfectly calm weather. This holds good alike in deep and shallow water, even along coasts. In some cases an ebullition was observed, and peculiar jets of water, like those produced by the impact and rebound of violent rain, were thrown up to the height of about fifteen inches.

From such seaquakes Herr Rudolph distinguishes those which raise up the water in mighty waves in all directions. At the same time the sea throws up abundance of bubbles, a roaring sound is heard in the depth, vapours are given off, and the water becomes distinctly hot.

As to the duration of these seismic movements under the sea, the extent and the limits of the region shaken, and the speed of the propagation of the shock, little can be said, as, for the most part, each seaquake is recorded by one ship only. Often many shocks succeed each other at brief intervals, but the duration of each shock is for the most part very short, and prolonged agitations are rare. An extensive region has been observed to be shaken in four cases only. The rate of propagation on the surface from the epicentrum was found to be 594 metres in a great seaquake in the Bay of Bengal.

The author attempts to explain the phenomena observed by a comparison with those produced in submarine blasting operations undertaken to remove a sunken rock in the harbour of San Francisco, and reported by the younger Le Conte in 1874. In this manner he very successfully refers the ordinary seaquakes, in which the surface of the sea is not disturbed, to submarine shocks. Those cases when huge waves are raised which dash upon the coasts in the manner of an exaggerated flood-tide are the result of volcanic outbreaks beneath the sea.

Seaquakes have been experienced in all seas, deep or shallow, and in their distribution they do not depend on the plasticity of the bottom. There are, however, certain regions in which they are exceptionally frequent, as in the Atlantic, in the seismic zone of St. Paul's Rocks and on their eastern side, near the Azores and the Lesser Antilles, near the Sunda Islands in the Indian Ocean, and along the greater part of the coasts of the Pacific. The "earthquake flood-waves" are almost peculiar to the Pacific coasts.

Rudolph forms the conclusion that the frequency and intensity of the manifestation of seismic and volcanic forces at the bottom of the sea is not connected with the distance from active or extinct volcanoes on the dry land.

If we except the few regions which are quite free from seaquakes, the bed of the ocean is, as compared with the land, a region of intensified seismic and volcanic activity.

Lastly, the author inquires into the causes of seaquakes. In four cases he shows a probable connection of seaquakes with dislocatory fractures, and two of these cases were accompanied by submarine eruptions. The numerous seaquakes of littoral zones he refers also to similar fractures. The desultory seaquakes occurring in all oceans, and especially in the deeper regions, are considered to be shocks produced by the injection of molten matter into the plastic substance of the deeper parts of the earth's crust.

General Notes.

New Minor Planet.—Dr. Palisa, of Vienna, discovered another minor planet (No. 280) at 1 30 a.m. on Nov. 1st. The position then was, right ascension 2 h. 2 min. 46 sec. (decreasing 1 min. 8 sec. daily); north Polar distance, 76 deg. 25 min. 31 sec. (increasing 1 min. daily). It is of the 12th magnitude.

The Microbia of Yellow Fever.—Dr. G. Sternberg (*Therapeutic Gazette*) argues that the microbia of yellow fever, unlike the bulk of disease-germs, flourish in an acid medium and that alkaline medicines are most likely to prove effectual in its treatment. It is right to add that this system has worked successfully in practice.

Glass Blowers' Cramp.—M. Poncet (*Popular Science Monthly*) describes a peculiar deformity of the hand occurring among glass-blowers, and known as glass-blowers' cramp. It consists in a permanent and decided flexion of the fingers, especially of the third and fourth finger of the hand, which comes on after a short practice in glass-blowing and increases progressively.

The Position of Timbuctoo.—M. Caron, the French officer who recently sailed down the Niger to Timbuctoo, took two observations near the city, which materially alter the position assigned to it by Barth, and laid down on many maps. He deduces from these observations that the latitude of the city is 16 deg. 49 min. N. and longitude 5 deg. 12 min. W. from Paris. Barth gave the former as 18 deg. 3 min. 45 sec., and the latter 4 deg. 5 min. 10 secs.

New Comet.—Mr. Barnard, of the Lick Observatory, announces the discovery of the sixth comet of the present year at 1 p.m. Greenwich time on October 31st. The comet at that time was in Right Ascension 9h. 43m. 22s. (increasing $1\frac{1}{2}$ min. daily), and North Polar Distance $105^\circ\ 18'\ 52''$ (decreasing $9'$ daily). The physical appearance is described as "11th magnitude, $1'$ in diameter, slightly elongated, strong central condensation." This is the second comet discovered by Mr. Barnard at the Lick Observatory.

Royal Geographical Society.—The two first meetings this season of the Royal Geographical Society will be of unusual interest. At the first meeting, on November 12th, Mr. H. H. Johnston, Her Majesty's Consul on the West Coast of Africa, will describe some of the results of his recent visits to the Cameroons and the oil rivers. At the second meeting, November 26th, Mr. Joseph Thomson will give an account of his recent visit to Morocco. A few days later he will leave for East Africa, probably to be absent for some considerable time.

Singing Sands.—Dr. A. Julien and Professor H. C. Bolton (*Science*) have communicated to the New York Academy of Sciences the results of their examination of sonorous sands. Such sands are always clean and free from dust, consisting of angular or rounded granules, between one-third and one-half of a millimetre in diameter. The chemical composition is not important. When such sands are moistened by rain or by the tide, and the moisture is afterwards evaporated, a film of condensed air is formed on the surface of each grain which acts as an elastic cushion, and enables the sand to vibrate when disturbed. Such sands can be rendered mute by heating, rubbing, or shaking.

Wood Creosote.—Captain W. H. Bixby, in the United States Forestry Department's Report, greatly recommends crude creosote for its antiseptic properties. It is an efficient poison for both animal and vegetable life, and its tarry acids possess the property of coagulating albumen and other fermentible matters. It forms an excellent insecticide, and is one of the best possible oils for preserving timber and piles. If painted upon wood or metal, it preserves from wet and dry-rot, rust, and the attacks of insects. If forced into wood by hydraulic pressure, it fills all the pores, and extends its coagulating and antiseptic effects to the very centre of the block.

The Prehistoric Race in Spain.—MM. H. and J. Siret (*Science*) have published the results of their archæological researches in South-Eastern Spain, and have traced the history of the early races inhabiting that country. The most ancient remains seem to belong to the neolithic age, the use of copper and bronze coming in subsequently. They fully confirm the recent view that in most parts of Europe the bronze age was preceded by a copper age. At the close of the bronze age, the use of silver is introduced and fortified villages occur. The principal result is that various races occur among the early inhabitants. A series of dolichocephalic skulls has been found, with an average cranial index of 73·8 and a long face. The nose is long and the orbit high. This is the exact counterpart of the northern inhabitants of Europe. Besides these, Jaques found a short-headed race also with long faces, high noses and orbits. This type also occurs in Northern Europe. A third race is also brachycephalic, but with a broad, flat face and prominent jaws.

The White Sea.—The hydrographers charged with an exhaustive inquiry into the depth and navigability in other respects of the White Sea, recently returned to Archangel. They began their investigations at the end of May in the Bay of Onega. One party of three officers made a special examination of the Gulf of Soroki. One discovery was that of a bank 11 ft. below water-line, where a depth of 35 ft. was marked on the chart. As there is a project mooted for a canal from Onega to the White Sea, it is observed by the explorers that a good port at Soroki is essential. Several deviations were also noted in the channels of the rivers Corelia and Dwina. The former will soon be dried up, while the latter promises to improve. A lighthouse is pronounced necessary on the island of Kü, and another is scarcely less needed at Cape Zetny Orlow. The reefs off Moutssalma island are also badly indicated, and the lighthouse at Orlow would be useful as indicating their precise situation. In support of these improvements the fact is put forward that Russian ships are wrecked by hundreds in the Arctic seas.

Cocoanut Fibre as a Defensive War Material.—In the last report of the curator of the Nilgiri gardens, attention is drawn to a new use for the refuse fibre of cocoa nuts. Dr. Lawson says that his attention was drawn to the subject by Mr. Money, a planter in the Nilgiris, who sent him an article in the *Revue des Deux*

Mondes for August 1st, 1886, by M. de la Barrière, entitled, "Bâtiment de combat et de la guerre," in which the author described how the refuse of cocoa nut, after the process of retting, might be used for backing the iron plates of ships of war. The method of proceeding was to take a quantity of the powdered refuse before it was quite dry, and subject it to pressure, when the natural viscidity of the macerated cellular substance of the nut caused the whole to cohere and to form a plate which in general appearance was like a mill board, only much more brittle. Owing to the hygroscopicity of this substance, if a hole be made through it, the parts adjacent to the puncture absorb water, swell up, and immediately close the orifice. Dr. Lawson got a sack of this refuse and made a plate 18in. square, by about ¾in. in thickness, which he placed between two boards, and then fastened it to one side of a box, which contained a head of one foot of water. A bullet half an inch in diameter was fired through it, but not a drop oozed out. This experiment was repeated three times with the same result. Then a ¾in. bullet was fired through the plate, when a few drops only made their way through. Lastly, a bullet nearly 1in. in diameter was fired through the plate, when a large jet of water shot through, but in the course of a few seconds the stream decreased in volume, and in less than a minute had ceased to flow altogether. "Whether or not this material could be advantageously used for the purpose which M. de la Barrière suggested, or for any other purpose, is a matter worth considering, for, as he truly says in his article, millions of tons float away annually down the rivers in India."

Men of the Stone Age in Central Brazil.—Dr. Karl von den Steinen, the explorer of Brazil, in a recent lecture before the German Scientific Association on the state of culture of the people of the Stone Age in Brazil at the present day, described the Indian tribes on the Xingu, a Brazilian tributary of the Amazon. These people, he said, still belong to the Stone Age; they know nothing of metals, and use only stone, teeth, bones, and shells for their weapons, implements and ornaments, which they know hcw to carve with great artistic skill. They are now as they were in the time of Columbus, and have not changed in any degree since they were first discovered. They are, however, by no means savages; their customs are decent, they are monogamists, although there are no marriage ceremonies, and have the most affectionate relations with their children. Their mode of life is simple, but not barbarous, and there is not the least immodesty in their lack of clothing. The different tribes live in villages containing at the most 250 persons, near to the rivers, and usually some days' journey from each other. There is little communication between them. They are acquainted with the notion of private property, but it plays no great part among them, as the difference between the capacity for production of individuals is of the smallest. Thefts are sometimes committed from other tribes, but not in the same village. A great hindrance to development is the absence of all domestic animals, even dogs. The people hunt and fish, and, in a certain degree, carry on agriculture, but this latter is most primitive. They regard themselves as in close consanguinity with animals; the Bakari trace their descent to the jaguar, and the Trumai people, whom they hate, and who are expert swimmers, are believed to be a species of alligator, and to sleep at night at the bottom of the stream. The sun is to them a ball of the feathers of the red *ara* enclosed in a pot, the cover of which is raised in the morning and closed in the evening, and the other celestial phenomena are all connected in a similar way with the animal world. The sorcerer among them is a physician rather than a priest, he has no divine position, and indeed they have no notion of a Supreme Being. Soul and body are regarded as separate, for during sleep the latter is at rest, while the former wanders about at will. Hence a sleeper must not be awakened suddenly lest the soul should not have time to return. The language is not poor in expressions, and is scarcely narrower, says Dr. von den Steinen, than the speech of a German peasant in a remote place, but structure or system does not exist.

The Public Health.—The Registrar-General's return of births and deaths for the week ending Saturday, October 27th, states that the deaths registered in 28 great towns of England and Wales corresponded to an annual rate of 21·8 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The six healthiest towns were Birkenhead, Brighton, Bristol, Derby, Leicester, and Norwich. The highest annual death-rates, measured by last week's mortality, were, from measles, 1·4 in Leicester, 1·5 in Liverpool and in Leeds, 1·7 in Huddersfield, 2·2 in Portsmouth, and 3·8 in Cardiff; from scarlet fever, 1·0 in Leeds; from whooping-cough, 1·1 in Norwich; from "fever," 1·1 in Derby, 1·2 in Salford and in Sunderland, 1·3 in Halifax, and 1·9 in Cardiff; and from diarrhœa, 1·3 in Brighton, 1·5 in Portsmouth, and 2·0 in Preston. The 47 deaths from diphtheria in the 28 towns included 31 in London, 5 in Manchester, 2 in Nottingham, and 2 in Halifax. Small-pox caused one death in London and one in Preston, but not one in any of the 26 other great towns. In London 2,665 births and 1,737 deaths were registered. Allowing for increase of population, the births were 184 below, while the deaths exceeded by 104, the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had increased in the five preceding weeks from 15·8 to 20·0, further rose last week to 21·2, and exceeded the rate recorded in any week since the middle of March last. During the first four weeks of the current quarter the death-rate averaged 19·1, and was identical with the mean rate in the corresponding periods of the ten years 1878-87. The 1,737 deaths included 1 from small-pox, 100 from measles, 25 from scarlet fever, 31 from diphtheria, 18 from whooping-cough, 17 from enteric fever, 2 from ill-defined forms of continued fever, 30 from diarrhœa and dysentery, 1 from infantile cholera, and not one from typhus; thus, 225 deaths were referred to these diseases, being 26 above the corrected average weekly number. Different forms of violence caused 57 deaths; 53 were the result of negligence or accident, among which were 24 from fractures and contusions, 8 from burns and scalds, 4 from drowning, and 12 of infants under one year of age from suffocation. In Greater London 3,480 births and 2,102 deaths were registered, corresponding to annual rates of 32·9 and 19·8 per 1,000 of the estimated population. In the outer ring 11 deaths from diarrhœa, 9 from measles, 7 from whooping-cough, and 4 from "fever" were registered. Three fatal cases of measles and two deaths from "fever" occurred in Tottenham sub-district.

MARS AND ITS "CANALS."

(Concluded from page 453.)

(Concluded from page 453.)

WE have now to search for a rational explanation ot the phenomena described and figured. Not a few authorities, or at least authors, consider the canals as artificial. In their opinion these canals are immense engineering operations which have been executed by the inhabitants of Mars. All these canals, it will be perceived, form direct communication in a straight line between the seas, or between seas and other canals.

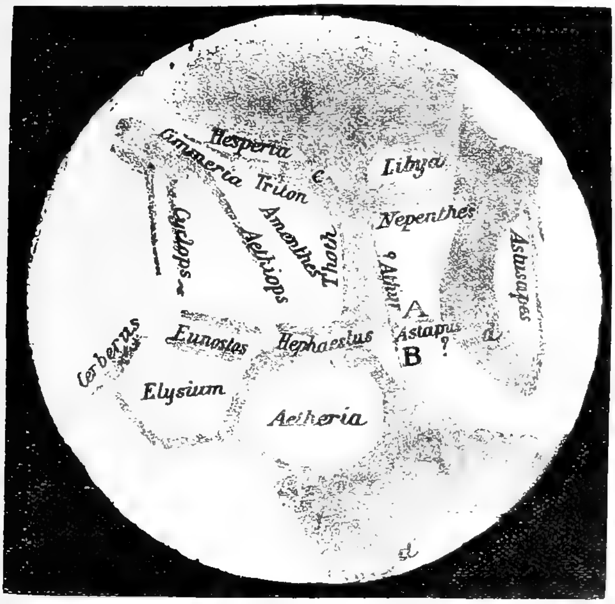

FIG. 4.—MARS AS IT APPEARED ON JUNE 12TH, 1888. (AFTER PERROTIN.)

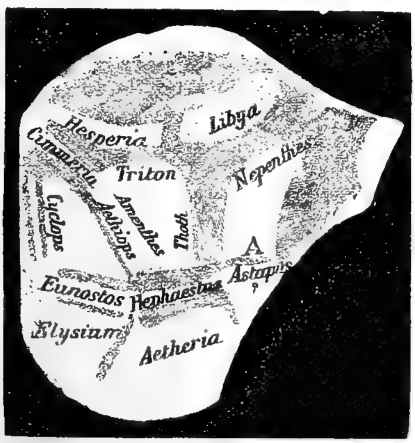

FIG. 6.—SKETCH OF MARS AS IT APPEARED ON MAY 8TH, 1888. (AFTER PERROTIN.)

None of them ever come to an end in the interior of a continent. Mars has for some years accustomed us to such extraordinary surprises that we do not protest against such an hypothesis, improbable as it may seem. For others the canals are gigantic rivers, but rectilineal rivers, passing invariably from sea to sea or from one watercourse to another, and never taking their rise in the continents! Men of science in our day are chary of using the word *impossible*, but here it almost appears justified. The late Proctor thought that the twin canals might be a phenomenon of diffraction, produced when fogs are suspended above the beds of the rivers of Mars. But this hypothesis leaves unexplained the difficulty of rectilinear rivers passing through the continents from sea to sea!

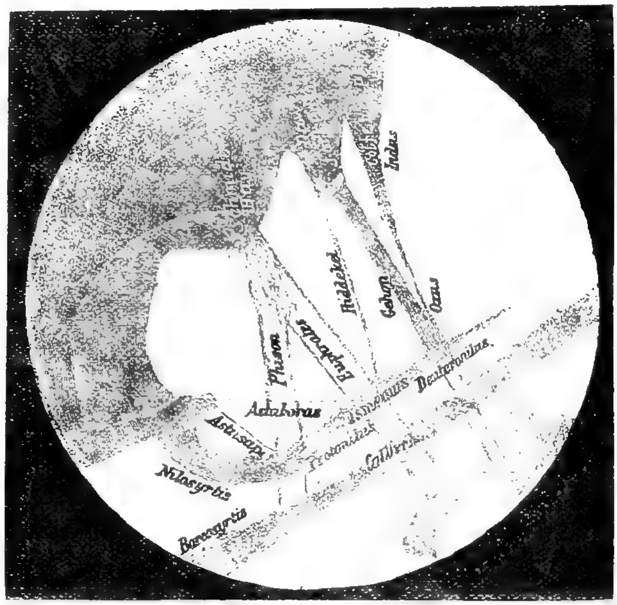

FIG. 5.—MARS AS IT APPEARED ON JUNE 4TH, 1888. (AFTER PERROTIN.)

M. Fizeau regards these canals as colossal *crevasses*, or chinks, in the glaciers of the planet. For him a glacial epoch reigns over the whole surface of the planet. The illustrious physicist has been led to this hypothesis by the presence of a dark line in the polar cap, as we have

FIG. 7.—SKETCH OF MARS AS IT APPEARED ON MAY 21ST, 1886. (AFTER PERROTIN.)

mentioned above. This canal seems to him to be a *crevasse*, such as we find in terrestrial glaciers; and as this fissure seems analogous to the other canals, these also would be fissures in an immense glacier.

M. Flammarion has shown various objections to the hypothesis of Fizeau. We believe we may conclude with him, from the melting of the snows at the poles, and from the difference between the polar regions and the rest of the surface, that Mars is not in a state of glaciation.

It may further be asked whether the system of canals and the great spots are sufficiently variable for this explanation. Changes have certainly been observed. In 1881-1882 the island Cimmeria was totally separated from the region. Amenthes now communicates with this latter between Ethiops and Lake Triton. Fig. 7 shows how M. Perrotin represented these details in 1886. Another change, apparently incontestable, is the enlargement of Lake Triton in 1888. The same may be said of Thoth. This canal in 1886 (fig. 7) is represented only by a small point prolonging Lake Mœris.

Still, these changes do not affect the grand network of canals. It is the same with the spots which, in their general configuration, are still what they were in 1659, when Huygens first described them in a characteristic manner.

However, as Schiaparelli very justly says at the end of his third Memoir, "To seek to found an explanation of these singular phenomena upon the scanty and incomplete data which have hitherto been collected would be rashness unparalleled and reprehensible. Yet we may notice that a tendency to gemination or doubling is manifested also in another manner on the surface of Mars. The division of Lake Ismenius, and that which separates Lake Niliacus from Mare Acidalium, seem to be instances of gemination. In like manner the existence of two bays of the Sinus Sabæus (Dawe's forked bay) and the two Atlantides belong to the same category of phenomena.

We may add some further details, such as the parallelism of the Sea of the Syrens, of the Cimmerian, the Tyrrhenian, and the Adriatic Seas; that of the Atlantides, of Cimmeria, Hesperia, Ausonia, and the lands of Japhet, Deucalion, and Pyrrha.

We even find two countries in Mars which seem to be copies one of the other. The Great Syrtis corresponds to the Gulf of Pearls, the Nilosyrtis to the Indus, the Astusapes to the Hydaspes, the Phison to the Jamuna, the Typhonius to the Hydraotes, the Horn of Ammon to the Promontory of the Aromes, Œnotria to the region of Pyrrha, Libya to the land of Deucalion. We may say that Tempe is modelled after Elysium, Styx corresponds to the sea Acidalium, Cerberus to Nilokeras, Eunostos to Nilus, Hyblæus to Ceraunius, Galaxias to Issedon, Cyclops to Ganges, Antæus to Hydraotes.

What should we say if we could be transported to Mars, and on observing the earth through a powerful instrument, could see, instead of a single Europe, two European continents, each exactly of the same form, traversed by rivers so identical that the two continents seemed copies the one of the other?

A. M. F. Serly says, "Never was a mystery more profound, an enigma more extraordinary, submitted to the human intellect."

Professor Holden, in a paper entitled *Physical Observations of Mars*, made during the Opposition of 1888 at the Lick Observatory, published in Gould's *Astronomical Journal*, denies the existence of these double canals, but as it seems impossible that so many skilled observers should have been deceived, we await, with great interest, the observations which will doubtless be made during the favourable opposition of 1890-1892, as they will probably assist in clearing up the mystery attached to these markings.

THE CONDUCTIVITY OF A VACUUM.

DR. E. EDLUNG has recently replied in Wiedeman's *Annalen* to the memoir of Dr. Foeppl on the electro-conductivity of a vacuum. He decidedly contests the cogency of Foeppl's experiments. His views are the following: Foeppl surrounded a spiral composed of glass tubes, and containing air highly rarefied, with a spiral of copper wire, through which a powerful electric current was transmitted. With this combination Foeppl was unable to recognise an induction-current in the glass spiral, whence he concluded that the highly rarefied air was not capable of conducting electricity.

Edlund cannot accept this conclusion. He writes: "It is proved experimentally that the electro-motive force excited in metals by voltaic or magnetic induction does not depend on the nature of the metals. This law holds good also for conductors of the second order; at least, it has been experimentally proved in the case of solutions of sulphate of zinc. The question now arises whether the same law extends to gaseous bodies—a question which has hitherto received no answer. Electrically, gases behave in a quite different manner from conductors of the first and second orders. In such conductors the potential difference between two points is proportional to the resistance between these points multiplied by the strength of the current. In gases, on the contrary, this difference is independent of the strength of the current. In metallic and liquid conductors the resistance is inversely as the section, but in gases it is equally great, whether the section is larger or smaller. Hence it appears very hazardous to ascribe to the constant of induction for gases, the same value as that for solid bodies, in default of any evidence, whether theoretical or experimental. Yet Foeppl's conclusion is based upon such an assumption.

Moreover, Foeppl calculates the strength of the current according to Ohm's formula, which is not valid for gases.

In favour of the conductivity of a vacuum, Edlund cites the fact that the strength of a current remains unchanged when the distance of the electrodes is increased from 1 to 30 centimetres. Further luminous phenomena can be elicited by influence in highly rarefied air, when the resistance decreases progressively to the utmost rarefication. The negative results obtained by Foeppl are due to the fact that the induction-constant of gases is too minute, as also that the electro-motive force of 5,000 volts which he calculates is non-existent.

THE TWINKLING OF THE STARS.—According to *Ciel et Terre*, in all parts of the sky the scintillation is strongest in winter and weakest in summer. In every season of the year it is more marked in the north than in other directions. Except in summer, it is stronger in the east than in the south and the west. The mean intensities of scintillation corresponding to the four seasons follow regularly the variations of their mean temperatures.

DEEP SEA FISHING.— M. Fol (*Comptes Rendus*) has attempted to fish at the depth of 800 metres by sending down nets fitted with tubes charged with phosphorescent sulphide of calcium. Unfortunately, the pressure had broken almost all the tubes, and the experiment has thus miscarried. M. Fol proposes to renew the attempt.

Natural History.

NATURAL SUCKERS.

ALTHOUGH we do not meet with it among the mammals or the birds, the sucker in some of the lower forms of life is of considerable importance, not only in the capacity of a weapon, but also in that of an organ of locomotion, as well as of a means by which locomotion may be checked. Thus, to adduce but one example in illustration of each method of employment, the suckers of the cuttle-fish are weapons of offence, those of the gecko render possible the employment of the limbs under unusual circumstances, while a similar organ in the gobies serves as an anchor, by means of which its possessor may defy the fury of the waves. And in each of these cases the construction of the sucker, and of the apparatus connected with it, is well worthy of examination.

Let us take, in the first place, the tentacles of the common octopus, or poulpe, by means of which it seizes its victims, and drags them closely and more closely to its body, until its strong curved beak can be plunged into their flesh. Each of these tentacles is studded with an array of no less than one hundred and twenty pairs of suckers, every one of which constitutes a most perfect air-pump, the more powerful and effective by reason of its employment under water. And all these manifold suckers are entirely under the control of their owner. The principle upon which they are constructed is very simple. "The adhesive disc itself," says Rymer Jones, "is composed of a muscular membrane, its circumference being thick and fleshy, and in many species supported by a cartilaginous circlet, so that it can be applied most accurately to any foreign body. In the centre of the fleshy membrane is an aperture leading into a deep cavity, at the bottom of which is placed a prominent piston, which may be retracted by muscular fibres provided for the purpose. No sooner, therefore, is the circumference of the disc placed in close and air-tight contact with the surface of an object, than the muscular piston is strongly drawn inwards, and, a vacuum being thus produced, the adhesion of the sucker is rendered as firm as mechanism can make it."

GECKO.

In some of these singular animals the ordinary suckers, powerful as they are, do not seem to be sufficient, and are reinforced by others of a different character, situated upon two additional tentacles. Each of these bears a strong and sharp hook, which is forced deeply into the flesh of the victim by the mere pressure of the sucking-disc, and thus the sucker practically consists of two wholly distinct weapons, each of a highly formidable character. This structure is especially noticeable in the *Onychoteuchis*.

And there is another point connected with these additional tentacles which must not be overlooked, for each is provided with a small group of adhesive discs of the ordinary character. And for this reason: Sometimes a victim is seized which, although it cannot break away from the hook-armed suckers, yet struggles so violently that it cannot be drawn sufficiently near to the body for the employment of the beak. In such cases both the long tentacles are brought into use, and, adhering closely *together* by means of the simple sucking-discs at their extremities, supplement one another, just as we ourselves employ both arms to drag to us an object which neither alone is sufficiently strong to move. And after the victim has been drawn up for a little distance, the shorter tentacles also are employed, and its doom thus sealed.

These singular suckers—those of the simple kind, that is—combine in themselves all three of the functions referred to at the commencement of this paper, for not only are they employed as weapons, and weapons of the most formidable character, but they are also used both in locomotion and as anchors by which their owner may cling to a rock or stone.

What the precise function of the sucking-disc of the Remora (*Echeneis remora*) may be is still altogether unknown; but it is nevertheless a most singular piece of mechanism. Lying on the upper surface of the head, it consists of a number of flat, bony laminæ, arranged side by side very much after the manner of the laths of a Venetian blind, and capable of being raised or depressed at the will of their owner. The edge of the disc itself is soft and fleshy, and when this is placed in contact with any smooth surface, and the laminæ are depressed, a vacuum is formed, causing the fish to adhere so tightly to its hold that scarcely any amount of force will detach it. In this manner the fish will affix itself to whales, turtles, sharks, and many other of the larger inhabitants of ocean, being carried by them for immense distances through the water, apparently in total ignorance of its presence.

This strange sucking organ would appear to be a modification of the first dorsal fin, the bony laminæ by which the vacuum is caused exactly corresponding in number to the spines. But as regards the object of its presence we are altogether in the dark. It cannot be merely an aid to locomotion at the expense of other fish, etc., for the remora is a good swimmer, and is at least as swift and active as are many of its fellows; and there seems to be no reason why it should wish to pass through the water with unusual speed. Nor does it appear to find any difficulty in procuring food, for when a specimen is killed and examined its stomach is nearly always full. Possibly the disc is employed as a means of *defence*, the fish attaching itself, when in danger, to some creature of far greater size, and thus putting itself, as it were, under protection. We do not know. One would think, from its highly developed condition, that the organ in question must have some special function, but of what nature that function may be has so far passed the wit of man to ascertain.

The *Discoboli*, or quoit-fishes, are provided with a somewhat similar sucker upon the ventral surface of the body, formed by a modification of the ventral fins, and capable of holding so firmly that one of these fishes which had affixed itself to the bottom of a pail of water still retained its hold when lifted by the tail, though it was consequently obliged to sustain the weight both of the pail and the water. The ventral fins of the gobies are modified in very much the same manner.

The lamprey possesses an excellent sucking organ in its mouth, and employs it not only for mooring purposes when the current is strong, but also for removing stones, etc., from the spot in which it wishes to lay its eggs. And the leech, although so widely removed in the zoological scale, has a mouth of very similar character, but armed with teeth capable of penetrating the skin of any animal to which it may affix itself.

The suckers upon the foot of the gecko, which terminate each of the toes, are employed solely as aids to locomotion, enabling their owner to ascend a perpendicular wall, or to creep head downwards across a ceiling, with perfect ease and safety. And thus the animal is able to capture its insect victims under conditions which would place them in almost absolute safety from all other foes. Something of the same kind we find in the feet of the house-fly and its allies, but in these true suckers are wanting, and the flat disc of the foot adheres to a wall or ceiling merely by reason of a strongly glutinous fluid which it secretes; and, as the feet are lifted obliquely, they can be removed from their hold without the slightest difficulty.

Quite an array of true suckers, however, we find in the anterior feet of the male great water-beetle (*Dyticus marginalis*). These are of two kinds, two large ones being situated upon the foot itself, while the remainder, which are very numerous and much smaller, are set at the extremities of slender foot-stalks, and look something like inverted mushrooms. Upon the intermediate feet, also, there are a few of these suckers, although the basal joints of the tarsi are not swollen into large fleshy pads, as are those of the front pair. In the female insect they are altogether wanting.

Finally, we have examples of the sucker structure in the bases of sea-anemones, by means of which they attach themselves to rocks, and also in the "feet" of to such molluscs as the limpet, which can cling so firmly their hold that it is very difficult indeed to remove them.

It will be noticed that in the great majority of cases these natural suckers are possessed by aquatic creatures, to which they would obviously prove more useful than to those living upon dry land; for the employment of a sucker under water signifies not only the atmospheric pressure of fifteen pounds upon the square inch of surface, but also the pressure caused by the water itself. And it also follows that the greater the depth at which they are employed, the greater the force involved. Thus the cuttle fish is able to hold creatures which in the air above would easily break away, and the remora to withstand force which, were it lifted from the water, would suffice easily to drag it from its hold. But the suckers even of such creatures as the gecko are tolerably powerful, and cannot be detached save at the expense of some little force.

Edible Birds' Nests.—Mr. Steere, a traveller in the Philippine Archipelago, in the course of a paper in the *American Naturalist*, descriptive of the central islands of the group, refers to certain caves in the Island of Guimaras where edible birds' nests are found. The bird which builds these nests is a species of swallow or swift, and the caves are not found opening on the sea, but far inland where the cavities are covered by vegetation. Guided by an old Indian whose livelihood was obtained by gathering nests, and provided with a torch of native gum and another of the ribs of cocoa palm leaves, Mr. Steere started for the caves. After half an hour's rapid tramping through the steep, rocky valleys, he came to a low ledge of rock, 8 feet or 10 feet high, covered with vines and bushes, at the foot of which was a black hole, just large enough to crawl through, leading down into the earth. After lighting the torches, the party crawled on hands and knees down a steep, rocky, narrow passage, the channel of a stream in the rainy season. It was simply a rift in the rocks, produced, perhaps, by an earthquake. Gradually all light except that from the torches disappeared, and when about 100 feet below the ground and several hundred from the entrance, the weak, faint twittering of little birds as they flew about overhead was heard. When the Indian raised his torch, shallow hollows were seen in the roof of the cave, in which, partly supported by the sides, were the little cup-like nests. They were pure white in colour, made of little fibres interwoven with each other, and were still soft and damp. It was surprising how the birds ever found out a place so far from the light, with a dry face of rock and suitable depressions, or how they could build the nests in such utter darkness. A second cave, not far off, was entered by a kind of well, and the curious, faint noise of the birds underground is described as "more like the sounds spirits make than the notes of anything earthly." Near the mouths of the caves were rougher nests, built also of the same edible gum, and said to be those ot birds who gave warning of danger to those within. The young frequently attach their nests to those of their parents, and the same nest is used year after year. In these caves the nests are collected and sold to the Chinese in Ho Ho. It should be added that the caves here described by Mr. Steere are of quite a different character from the far-famed Gomanton caves in British North Borneo, which are the principal source of the supply of edible birds' nests. These stupendous caves are quite open, and are as lofty as a cathedral aisle, so that the nest-gatherers have constructed ladders and galleries of rattans to reach the nests in the roof. A curiosity of these caves also is that they are inhabited by myriads of swallows by night and of bats by day, the latter swarming out in clouds as the former swarm in, and *vice versa*.

The Great Lacewing Fly.—This beautiful insect, which is known in scientific parlance as *Osmylus chrysops*, is the largest of the British *Planipennia*, which includes the lacewing flies, scorpion flies, and stone flies, generally called true neuroptera (*Neuroptera genuina*). They are principally distinguished from the *Pseudo neuroptera* (the dragon flies, day flies, and the white ants, etc.) on account of their metamorphoses, which are complete or perfect, while in the latter they are imperfect. The insect under consideration measures about an inch and a half to two inches in expanse of its wings, which are beautifully veined and reticulated with a few brownish patches in different places. Its general appearance much reminds one of a small Anthori, or *Myrmelion*, several species of which abound on the Continent. The *Osmylus chrysops* is generally a local insect in this country, occurring only in the vicinity of streams, particularly in woods. It usually flies during the sunshine, which is not universally the case with lacewing flies. About half a century ago this species was considered such a rarity that the price for it in dealers' shops in London was half a sovereign for a pair. A very excellent illustration of this interesting insect is given in Donovan's "British Entomology."

Sorting Coloured Wools when Blindfolded.—Under this title a correspondent of *Science* writes: Your reviewer considers that the experiments of Professor Fontan, in which a hypnotised subject sorted coloured wools with his fingers when his eyes were completely covered, are simply incredible. It is true that they are so hard to believe in that a single instance can produce scarcely any effect at all, but they cannot be considered as absolutely incredible in view of the fact (?) that Professor Vitus Graber has shown *that so thick-skinned an animal as the cockroach reacts to colours when his antennæ have been removed and his head has been covered with a thick coating of black sealing-wax.*

The Great Skua.—Twelve eggs of the great Skua (*Lestris catarractes*) known as the Bonxie, were recently exhibited in a shop window in Kirkwall. The bird is believed to be nearly extinct. The eggs are a light brown, with dark chocolate spots; length of eggs, 2¾ in.; breadth at broadest part, 2 in. This bird is known to breed nowhere in Scotland but in Foula, near the Shetland Isles, and there they are very scarce.

Horse Protecting a Goat.—The following remarkable illustration of the sagacity of the horse comes from the *Birmingham Mail.* A man named Gilbey, a coal dealer and haulier, rents a field adjoining Gillott-road, Edgbaston, in which a horse and goat have been in the habit of grazing. Recently a gang of young roughs from the Icknield Port Road have amused themselves by throwing stones at the goat, and some of the more cowardly of the ruffians beat it with a stick. Whenever the goat has been attacked in this way the horse has always raced to its rescue, and a few days ago he seized one young rascal by the collar and flung him over the hedge into the road.

Tasmanian Earthworms.—Mr. Morton, at a meeting of the Royal Society of Tasmania, exhibited some splendid earthworms ranging from 2 to 3 feet in length. They are considered to be of a new species, and probably to represent a new genus.

The Egg of the Echidna.—Mr. A. Morton (Royal Society of Tasmania) gives an elaborate account of the anatomy and ontology of this curious animal, confirming Mr. Caldwell's description, and showing that in 1849 the aborigines were perfectly aware that the *Echidna* produced eggs. The egg is described as being three-quarters of an inch in length.

An Eighth Sternal Rib.—Dr. Lamb, of the United States Army Medical Museum (*Science*), has observed in a number of human specimens an eighth rib, the cartilage found below the seventh rib being fully developed into an eighth rib. This abnormal (or reversionary ?) phenomenon occurs, as far as Dr. Lamb has observed, among negroes. One case has been found in a Red Indian.

The Periodicity of Insect Ravages.—Mr. A. H. Swinton has pointed out that the years notable for swarms of locusts are identical with those when the sun-spots are at a minimum.

Reviews.

Proceedings of the Royal Society of Edinburgh. Session 1887-88. No. 126.

In the Chairman's opening address we observe the statement that the library of the Society is "the most complete collection of its kind in the United Kingdom; more complete even than that of the Royal Society of London."

We observe with pleasure the creation of a Victoria Jubilee Prize by Dr. Gunning. This prize is to be awarded every three years for scientific research, either done during the past three years, or to be conducted during the three years ensuing.

Referring to the defective state of the Edinburgh Observatory, the speaker regretted that work similar to that which is now being done for the southern heavens at the Cape Observatory is at present not in hand either at Edinburgh or London.

Mr. Piazzi Smyth calls attention, with particular reference to the service of the Edinburgh Observatory, to the scanty remuneration awarded to scientific servants of the British Government, in comparison with the salaries allotted to mere "quill-drivers." In an advertisement the salary of £100 yearly is offered to a second assistant astronomer at the Royal Observatory at Edinburgh—who, in addition, is to be chosen, not *rebus gestis*, but by the absurd scheme of "open competition"—whilst in another announcement appearing on the same day, £250 yearly, rising to £600, is offered to each of two junior clerks in the Colonial Office!

We find here the second part of "Researches on Micro-Organisms, including ideas of a new Method for their Destruction in Certain Cases of Contagious Disease," by Dr. A. B. Griffiths, F.R.S.E.

In this most valuable memoir, the author draws the following conclusions, which seem legitimate inductions, from the facts described. It has been proved beyond doubt that microbes are the real cause (we add here, "direct" or "indirect") of certain contagious diseases. In many cases these microbes are capable of being destroyed by various germicides. Therefore, by further investigation, we ought to find a germicidal remedy for such terrible scourges to humanity as consumption and syphilis. The vitality of *Bacillus tuberculosis* is considerable, and it is capable of being dried up in the atmosphere for many weeks without its vitality being impaired. It is even capable of being disseminated by envelopes coming from phthisical patients. The electric current destroys the vitality of certain microbes. The soluble zymoses secreted by living microbes are capable of being destroyed by germicidal agents. The germicidial agents used for injection must not produce poisonous actions upon the blood and tissues, yet they must be powerful enough to destroy the vitality of the microbes and their spores.

Professor R. Wallace communicates a memoir on the "Colour of the Skin of Men and (Lower) Animals in India."

The author notes that in India, cattle, sheep, pigs, buffaloes, and horses, whatever the colour of their hair, have black skins, and of this fact he seeks the explanation.

New Fibre from the Stalk of the Cotton Plant.—According to *Science*, the stalk of the cotton plant yields a fibre fit for all the uses to which hemp is put.

Abstracts of Papers, Lectures, etc.

LIVERPOOL SCIENCE STUDENTS' ASSOCIATION.

The opening meeting of the winter session of this Association was held at the Royal Institution on the 19th ult., After the introductory business had been concluded, Mr. F. P. Marrat exhibited a case of specimens from his fine collection of agates, and described the various modes of formation of these beautiful silicious minerals.

Miss E. N. Wood next gave a *résumé* of the botanical work of the summer session, which had been fruitful in the acquisition of several floral rarities by those members who attended the various field meetings.

The President (Mr. Osmund W. Jeffs) then delivered the annual address, alluding in the first place to the work already accomplished by the Association, and indicating several directions in which its future vigour and usefulness might be developed. The study of biology was referred to as possessing a wide range amongst the natural philosophies. It was the *raison d'être* of the naturalist, and interested alike the student of to-day and of the long past. There was scarcely a spot which did not yield some vestige of the presence, at some time or other, of that active principle called "life," and a study of this science opened our minds to some of the highest and most reverential ideas of which the human intellect was capable. Anthropology, or the natural history of the human species, also deserved careful study, for the furtherance of which special facilities existed in Liverpool, where the different racial types from all quarters of the globe met together; and closely connected with this was archæology—the science of ancient things—a kind of *via media* between anthropology and what was generally classed under the term of "history." Both in connection with this subject and with natural science much assistance could be obtained by students from the admirable collections displayed in the Free Public Museum. There was a growing feeling that a museum should be something more than a storehouse of curiosities; it should be a more direct means of conveying knowledge. Viewed in this light, the educational value of a museum became much enhanced, a fact which doubtless had its share in inducing the local authorities to open the Public Museum on Monday evenings. The remainder of the address dealt with the geology of the Cheshire hills. The subject of the origin of hills and mountains had lately received renewed attention at the hands of geologists, with the result that one more magnificent conception had been added to the list of geological theories. The author of the new theory was Mr. T. Mellard Reade, F.G.S. Discarding the old hypothesis that mountain ranges were caused by contractions of the crust following upon a shrinking nucleus —a hypothesis which on mathematical grounds was demonstrated to be insufficient—Mr. Reade urged local expansions in those parts of the crust subject to a rise of temperature through sedimentation. In the limits of an address it was impossible to do justice to Mr. Reade's theory, which was borne out by an exhaustive series of original experiments, but it was suggested that a reference to the work itself would convince students of the importance of the physical effects pointed out by the author. Our local hills were rather the result of denudation acting upon little disturbed strata of the triassic age. The President remarked that the observer of scenery could not fail to be interested in the question of the origin of our hills. For the history of their formation they must look to those physical operations slowly, but surely, changing the form of the earth's surface. The older theories of violent upheavals could now no longer be admitted. The history of the opinions held regarding denudation was then traced from the early "cataclysmal school" to Lyell's marine theory, and the more modern views of the sub-aërial geologists (really the result of Hutton's teaching in 1795, the application of which has long lain dormant), who had shown that the ordinary operations of rain, rivers, and ice—slow in progress, but constant in action—were sufficient to account for the formation of hills and valleys, without having recourse, on the one hand, to violent disturbance of the strata, or, on the other hand, to exclusively marine action. The theory of escarpments and of longitudinal and transverse valleys was then touched upon, and local instances cited in illustration. A line of escarpment extends from Overton Hill, above Frodsham, to Helsby Crag. The steep sides face the north-west, the gentle slopes of the hills being in the direction of the "dip" of the rocks. A miniature instance of a "transverse gorge" is also seen here. The scarped faces of the Peckforton Hills, so prominent a feature in the scenery of the district, were shown to be due to ordinary sub-aërial operations, aided by faults which have brought down the hard keuper basement beds, leaving the softer beds of the upper bunter exposed to denuding influences. The softer rock being more rapidly worn away, the hard keuper rock falls down. This process can be seen in action. In many places on the hills the uppermost keuper beds overhang the bunter rocks, of which the slopes of the range are composed. The important influence of faults in modifying the shape of the ground was explained, but the speaker opposed the theory that valleys always coincided in direction with faults and fissures in the crust of the earth. Referring to the marine theory of denudation, which some writers had brought forward to explain the origin of these escarpments, it was pointed out that the hills of Peckforton present all the features of escarpments due to sub-aërial denudation; and when that was known to be sufficient to produce the effects which we now see there was no necessity to bring to our aid supposed prevalent winds or extraordinary powers of marine breakers. In considering the origin of surface features, it should be remembered that the existing configuration cannot have been of long duration, geologically speaking. The present surface is connected with former systems of hills and valleys, which (if only they could be reconstructed) would help us to understand how the existing outlines attained their shape. Since the deposition and upheaval of the triassic rocks, immense masses have been removed from the surface, the shape of which must have constantly been altered, so that the original lines have been lost for ever. Some geologists are apt to forget this, and they construct maps to show the positions of land and sea during various periods of the earth's history upon evidence which is insufficient to entitle them to pronounce so positively on what is a purely speculative matter. The hills of Wirral were then described, including Storeton Hill (famous for its labyrinthodent footprints), Bidston Hill, Flaybrick Hill, and on the other side of the peninsula Thurstaston Hill, where there is another instance of an escarpment the formation of which can be seen in progress. Near the top of the hill a well-defined band of hard quartzose rock is seen. Underlying this is a bed of soft sandstone, which is rapidly worn away, and in course of time a further scarped face will be apparent, resembling those of Delamere and Peckforton. Thurstaston Hill is intersected by numerous faults, to which may, in all probability, be attributed the isolation of that rectangular block of sandstone to which archæologists have given the name of "Thor's Stone." In was pointed out, in conclusion, that the district around Liverpool was not so devoid of geological interest as many supposed. In geology there was still much to be learnt, and there were many difficulties yet to be explained. It was only by the patient observation of ever-acting nature that they could hope to decipher the past physical history of the earth; and when they reflected upon what the energy and labour of their local workers had already accomplished they might rest undisturbed by conflicting theories, and look forward with increased confidence to the discoveries of the future.

LIVERPOOL GEOLOGICAL SOCIETY.

THE annual meeting of this Society was held on the 9th October, in the small lecture-hall at the Royal Institution, the presidents, Mr. H. C. Beasley, in the chair. After the transaction of preliminary business, the usual balloting for the Council took place. The President (Mr. Beasley) and ex-President (Mr. G. H. Morton, F.G.S.) do not retire this year. The remaining officers elected for the ensuing session were—Vice-President, Mr. F. P. Marrat; Hon. Treasurer, Mr. E. M. Hance, LL.B.; Hon. Secretary, Mr. W. Hewitt, B.Sc., and members of the Council, Messrs. J. J. Fitzpatrick, C. Ricketts, F.G.S., T. Mellard Reade, F.G.S., O. W. Jeffs, and the Rev. S. Gasking, B.A.

The President, in his annual address, dealt in a very graphic and interesting manner with the geology of the district around Liverpool. After congratulating the Society on the work of the last twelve months, he proceeded to show that a large number of unsolved questions relating to our local geology awaited the attention of members of the Society. There was, he said, no ground for the statement so often expressed in the past that the neighbourhood of Liverpool afforded few features of interest to those whose aim it is to investigate the strata upon which we live. On the contrary, Liverpool formed an admirable centre for geological field work, and was especially rich in facilities for the study of the glacial and post-glacial beds and the phenomena connected with them. In the triassic strata of Lancashire and Cheshire, again, there were abundant opportunities for studying a series of formations about which a great deal has been written, but which presented many points of interest still comparatively unworked. Referring to the paucity of remains of animal or plant life in the triassic rocks, the President counselled further and more minute investigation of the keuper strata, with a view to the discovery of the fossilised remains of the bones of those Saurians and other animals whose footprints are found recorded in the rocks at Storston and many other places in the district. So far no remains of the animals themselves had been found in local strata nearer than the keuper sandstone of Shropshire. With regard to the bunter rocks, there was little hope of any such remains being found. A question which had been agitating physical geologists for some time was that of the origin of the new red sandstone. The beds, as developed around Liverpool, might be divided into four divisions—marine, estuarine, lacustrine, and riverine; and some points recently brought forward by Professor Bonney would seem to indicate that many of the bunter rocks may not have been deposited in deep water. Throughout the pebble beds the pebbles are of a peculiar character, being well rounded, and usually differing entirely in composition from rocks of local origin. At a section exposed on the west side of Hilbre Island a conglomerate bed of remarkable character was found, many of the pebbles in which appeared to have been derived from the carboniferous rocks. There had recently been some difference of opinion expressed as to the age of this bed, which the survey regarded as a part of the bunter, though it had lately been classed as a basement bed of the keuper. The speaker invited the attention of members to this interesting section, and proceeded to refer to several local indications of sandstone beds having been accumulated as æolian deposits by the action of wind. Attention was also drawn to the strata as exhibited at Flaybrick Hill, where the junction of the lower keuper and the upper bunter is well developed. The address concluded with an appeal for members to take advantage of the many opportunities constantly occurring in the opening of new railway and canal cuttings, borings for water, and other sections, a careful study of which would frequently be found to throw new light on what has been previously learnt as to the stratigraphy and physical features of the country around our own homes.

NEWCASTLE SOCIETY OF ANTIQUARIES.

At the meeting held on Oct. 31st, the Rev. Dr. Bruce presiding,

The Chairman called attention to Hodge's account of the Abbey Church of Hexham. He said that he had long been acquainted with that very beautiful structure, the Hexham Abbey Church, which was one of the finest specimens in England of the early British style, a style which to his mind was better adapted for the construction of places of worship than any other. This very interesting structure had met with one who could really reveal to them its beauties. In the work he had mentioned they had very magnificent drawings of this very elaborate structure, and an account of all the beauties of it which would afford to any one who studied it an amount of interest and instruction that could rarely be met with. He did not believe there was any architectural structure in Britain that was so well and so fully described both by letterpress and by plates as this one, and he was glad to say that the work was the work of one of their members. He would strongly recommend every architect and every antiquary to get a copy of it.

Mr. John Philipson read a paper on *Vitality of Mummy Wheat and Seeds taken out of the Wrappings of Egyptian Mummies.* He said: It may be remembered that at the monthly meeting of our society on September 28th last year, some conversation which passed between the chairman and the late Captain Robinson came near reviving the far-famed controversy respecting the germinating possibilities of mummy wheat, in the same manner that it had been renewed by Professor Judd at the Geological Society, early in the summer of 1886. I confess to a more than ordinary interest in the subject, as I was aware of some instances of reputed mummy wheat having been successfully grown in our own locality; but as I am not one of those who venerate the story simply because it is old, I set to work to collect such evidence as might explain two problems that presented themselves, viz.: 1st. Would seeds retain their germinating powers during a period of 2,000 or 3,000 years? and 2nd, have plants ever been raised from such seeds? The whole matter turns upon the character of the seeds which have been discovered in the folds of mummy wrappings. I have ample proof that plants have been raised from such seeds not only in the south of England, but in this neighbourhood, and it only remains for the spurious or genuine nature of these seeds to be decided to set the matter at rest. It is, of course, impossible to obtain *absolute* proof in such a matter; but there are those who have not hesitated to assert that the Arab, with his characteristic cunning, has placed modern seeds within the folds of the mummy cloths. Nothing s easier than to make a declaration of this kind. Crafty, though he may be, the Arab would not take this trouble until he knew that there was something to gain by it—*i.e.*, until he had heard of the finding of *genuine* seeds, and the interest evoked by their discovery. There were, however, three cases in which the receptacles—two sarcophagi and a vase—could not possibly have been tampered with, and the knowledge of these instances have encouraged me to follow up the subject, with the result that I am able to lay before you what I consider sufficient evidence to prove that what is known as mummy wheat has been raised from seeds more than 2,000 years old. Mr. Philipson then entered in detail into the evidence referred to.

CAMBRIDGE ANTIQUARIAN SOCIETY.

At the meeting held on the 29th of October, Professor A. Macalister, M.D. (President), exhibited some specimens of Roman pottery found in the excavations made for building purposes in the Madingley Road. The most perfect of these was a fragment of Samian ware with a figure of a deer. Nearer the surface a silver halfpenny of Edward III. was found. Most of the pottery was found in a pit of black earth, evidently the trace of an old excavation in the gault.

Mr. J. W. Clark exhibited a skeleton of a Red Deer (*Cervus elaphus*), lately mounted by his assistant, and placed in the Museum of Zoology and Comparative Anatomy. The bones were found in December last in a deposit of peat at Manea, on the estate of William Wiles Green, Esq., who kindly presented them to the University. This skeleton is the largest, of a full-grown animal, yet found in a complete state, measuring four feet from the ground to the top ot the dorsal spines. A skeleton of an adult Scotch stag, exhibited by the side of it, measured only three feet four inches.

The President remarked that the late Professor Jukes described and figured in the proceedings of the Geological Society of Dublin a skeleton of a red deer of unusually large size from Bohoe, Co. Fermanagh, and with fourteen pairs of ribs. Another very large red deer skeleton from Co. Limerick is in the National Museum of Dublin. Mr. Green mentioned that a bronze coin of Vespasian had been found in the immediate vicinity of the deer-bones, and invited members of the Society to come and co-operate with him in investigating the spot.

The Rev. E. G. Wood read an elaborate memoir upon the University at Stamford.

Highbury Social Guild.—On October 30th the first lecture delivered in London on the "Perfected Phonograph" was given under the auspices of this guild by Sir Albert K. Rollit, LL.D., F.R.A.S., M.P. The Rev. Dr. Allon presided, and amongst those present were Colonel Gourand and Mr. Hamilton (representing Mr. Edison. The lecture was illustrated throughout by interesting and successful experiments in acoustics, with sensitive and manometric flames, microphones, telephones, various phonographs, etc. Sir Albert, after sketching the career of Edison, and explaining the principles which Edison had practically applied in the invention of the phonograph, said it was in 1877 that the magnificent step had been taken which had led to the evolution of the new instrument. Its purpose was to register the different vibrations produced by speech, and to reproduce the words in correspondence with the registered tracings. Phonograms would become, he did not doubt for a moment, a matter of ordinary correspondence through the penny or parcels post. The phonograph as a medium of correspondence was always audible and legible. One could not say the same of personal handwriting. Immense possibilities were opened up by the belief of Edison that there would ultimately be a combination of the telephone and phonograph with which they would have a messenger or clerk who could make no mistakes.

Essex Archæological Society.—On October 26th the members of this Society paid a visit to Coggeshall. Mr. G. F. Beaumont exhibited a number of Saxon relics found at Kelvedon in March last. These included a knife, a fork prong, hair pin, ring, and hinge, all highly oxidised, together with a small Saxon javelin head and a straight sword heavily embossed with the rust of centuries. Mr. Beaumont also exhibited a small bronze Virgin and child; a square red drain pipe, possibly as old as a Roman aqueduct, found near St. Nicholas' Chapel, Coggeshall; two cinerary urns, and a weaver's shuttle. Major Hamilton produced two handsome stone axes, found near Kelvedon. Mr. G. F. Beaumont followed with an interesting description of relics which have been found near Coggeshall and Kelvedon; after which Major Hamilton referred to the many Roman remains which have been found near Rivenhall Church and on Crane's-hill, between Witham and Kelvedon.—Major Hamilton said recently, at Braxted, he saw a lady executing some needlework, the pattern of which had, she stated, been copied from that of the tiled pavement in Prior Cranden's Chapel at Ely. He recognised that the pattern corresponded with that of the pavement in the Pilgrims' Chapel at Little Coggeshall. Now, he found that about the 13th century the Bishop of Ely came to Coggeshall to settle some dispute about tithe, and he probably carried back with him to Ely some of the pavement of the Pilgrims' Chapel. It was a Cistercian pattern, plain, and with little ornament.

Physical Society of Glasgow University.—At a meeting held on October 26th Mr. G. G. Henderson, M.A., B.Sc., read a paper on "The Determination of Molecular Weights," in which, after referring to the well-known methods, he directed special attention to the important researches of Raoult on the laws governing the freezing-point of dilute solutions, the outcome of which is a new process for determining molecular weights, which is of almost universal application to organic substances. The great value of Raoult's method lies in the fact that by its application it is now possible to determine the molecular weights of substances whose character renders a determination of vapour density impossible —the carbo-hydrates, for example. The process is based on Raoult's general law of congelation—viz., "If one molecule of any substance be dissolved in one hundred molecules of any solvent the freezing-point of the latter is lowered 1·63° C."—and is a very simple one, involving the use of no complicated apparatus. Till recently chemists have not given this discovery the attention which it deserves, though it is, without doubt, one of the most important additions to the supply of physical methods applicable to chemical research since the enunciation of the law of Dulong and Petit.

Bristol Microscopical Society. — The forty-fifth annual meeting was held on October 5th, when the following officers were elected: Dr. Harrison, president; Professor Leipner, F.Z.S., and Mr. E. B. L. Brayley, F.R.M.S., vice-presidents; Mr. C. K. Rudge, hon. librarian; and Mr. H. A. Francis, hon. secretary. The retiring president, Dr. Hudson, Pres. R.M.S., in his annual address, congratulated the Society upon its flourishing condition, and also read a letter of thanks from the Bath Microscopical Society to the Bristol men for the great assistance rendered to Bath on the occasion of the soirée given to the British Association. Several members exhibited rare and interesting specimens, Mr. C. K. Rudge showing discs of *Liparis Montagni* and *Cyclopterus*, also epizoa of dogfish, Mr. F. W. Stoddart a section of wall of subcutaneous abscess in glanders, Mr. Brayley a very rare mite, *Glyciphagus plumiger*, and Dr. Hudson a very rare rotifer, *Esplanchna ebbesbornii*, found only near Salisbury, England, and at the Botanical Gardens, Sydney, Australia.

The Leeds Naturalists' Club and Scientific Association.—At the meeting on October 22nd the subject of the evening—"Plant Structure"—was entered upon, under the chairmanship of Mr. F. W. Branson, F.C.S., who gave some account of the structure of *Pilularia globulifera*, an interesting cryptogamous plant, the reproduction of which is effected by spores. The sporocarp and the macrospores and microspores were very beautifully shown in section, as was also the structure of the stem, and attention was called to the species as being the only British one possessing both classes of spores.

Leyburn Literary and Scientific Society.—On October 19th this society held its annual meeting. The president, Mr. H. Arthine, sen., occupied the chair. The secretary (Mr. F. Potter) produced his report, which stated that during the past session nineteen papers were given embracing different subjects, while in the previous session only twelve papers were read. The meeting then elected Colonel Wray, hon. president; Mr. H. Arthine, sen., president; Mr. W. Horns, F.G.S., vice-president; Rev. P. K. Bircham, Mr. C. Horner, and Mr. L. Paisley, members of the council; Mr. H. Horne, treasurer; and Mr. F. Potter, secretary.

Old Kirkpatric Naturalist and Antiquarian Society.—A very successful conversazione was held by this Society on October 26th.

The Bradford Philosophical Society.—On October 25th the session of the Bradford Philosophical Society was inaugurated with a lecture by the president, Mr. A. R. Binnie, on "Heat in Relation to Coal."

LIVERPOOL NATURALISTS' FIELD CLUB.—On October 26th this club held a conversazione which proved a great success. Amongst the exhibits were two yellow love-birds, shown by Mr. William Cross, and some living Longicorne beetles.

LIVERPOOL GEOLOGICAL FIELD CLASS.—On October 27th the members of this class, under the guidance of Mr. Lomas, lecturer on geology at the University College, and Mr. H. C. Beasley, President of the Liverpool Geological Society, visited Wallasey and Poulton.

ISLE OF MAN NATURAL HISTORY AND ANTIQUARIAN SOCIETY.—At the monthly meeting held on October 11th, Deemster Gill, the President, read his report, as delegate, of the British Association meeting at Bath. The question of publishing a quarterly report was considered, and a list of Manx land and fresh-water shells, taken by Mr. Lionel E. Adams, was read.

FALMOUTH NATURALIST SOCIETY.—The annual conversazione in connection with this Society was held in the Town Hall, Falmouth, on Monday, October 29th.

KIDDERMINSTER.—Sir R. S. Ball delivered a lecture on "Comets and Shooting Stars," in the Town Hall, on October 29th.

AUSTRALIAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

WE abstract from the columns of the *Sydney Morning Herald* the following report of the proceedings :—

SECTION A.—ASTRONOMY, MATHEMATICS, PHYSICS, AND MECHANICS.

In this section Mr. R. L. J. ELLERY, F.R.S., F.R.A.S., presided, and delivered the presidential address on *The Present Position of Astronomical Knowledge*. After a very exhaustive review of the solar system and the wonders of the universe, he said,—"Owing to the nearness to which the planet Mars often approaches us, and to the earth-like character of its telescope appearance, it naturally presents a most interesting study to the astronomer. It is seen to be marked out as if in continents and seas, the marking often appearing as if obscured by clouds. Very considerable changes in the features have been observed from time to time, and recently appearances as of narrow channels or canals have been seen, which have changed and split, and been joined by cross-channels. These observations have been dilated upon by popular scientific writers, who have suggested that the canals and channels are the work of martial inhabitants for irrigation or other great engineering purposes. The writers must have imagined stupendous works by stupendous beings, when canals and irrigation channels are as wide as the Mediterranean Sea. The mapping of Mars has been pushed to a minuteness that many astronomers cannot follow, but the soaring imagination of one popular writer brooks no bounds, and where we have canals and artificial channels this year we may discover barges and steamboats next. My own experience leads me to regard many of the drawings and speculations concerning the martial surface as being a little in advance of ascertained facts. It is undoubtedly very earthlike in character, and it is very probably nearer the same stage (as regards cooling) of our planet than any other. It also appears to be endowed with an atmosphere often cloud-laden, obscuring the features of the planet's surface. We wait for increased powers of observation at the future near approaches of this planet for further developments. The most interesting fact in connection with this planet is the comparatively recent discovery by Hall, in 1877, in America, of his two satellites, whose existence had not hitherto been even suspected. The remarkable features of these bodies are their nearness to the parent planet, their smallness, and their rapid motion. They have been named Deimos and Phobos (fear and panic). Phobos is only 3,760 miles, and Deimos 12,500 miles, from Mars' surface. The former goes round the planet in a little over seven hours and a-half, and latter in about thirty hours and a-quarter. The actual dimensions can only be estimated from light measures, which give diameters of about nine and eleven miles. Some very important suggestions by Mr. Norman Lockyer, upon the classification of heavenly bodies, and I may almost say a new theory of the universe, have been laid before the scientific public through the Royal Society of London. In brief, it may be stated as follows—Space is a *plenum* of meteoric matter. All self-luminous bodies in the celestial spaces are composed of meteorites or meteoric vapour produced by heat from condensation of meteor swarms due to gravity. He assumes some at least of the meteoric matter to have orbital motion. Some may be in motion, some at rest, but all visible evidence of this matter appears as stars, comets, or nebulæ, between which no distinction can be made on physical grounds. Visibility is brought about by collisions of meteoric particles, and according to the profusion or sparseness of the meteoric particles in space where collisions occur by intersection of orbits with matter at rest, or with bodies in other orbits, we have nebulæ of the several kinds, comets, nebulous stars, and even concrete stars themselves. This may be called the meteoric hypothesis, and as the conception has for its foundation a mass of indisputable facts, the result of long and laborious research with the spectroscope in the laboratory, compared skilfully and patiently with facts, revealed by spectroscopic examination of all classes of celestial objects, I can but regard it as a most important step in physical astronomy, destined, I believe, to mark a new epoch in the science. The idea that meteoric matter or bodies pervade all space is not in itself a new one, for when we consider, accepting Professor Newton's estimate that twenty million meteorites fall to our earth daily, it is evident that space is, astronomically speaking, full of them. Nevertheless, by the same calculation by which Professor Newton arrived at the foregoing number, he ascertained their sparseness to be such that the meteorites must be 250 miles from each other in space. As regards the effects of collision of meteorites, the speed of visible meteors can be measured, and it is reckoned to be at an average thirty miles a second. If then the specific heat of the material of which they are composed be ·10, the increase of temperature when their motion was arrested by a full collision would amount to 2,700,000 degrees centigrade, steel being fluid at 2552° Fahrenheit."

Mr. W. SUTHERLAND read a paper on *The Law of Molecular Force*, and in this paper he further discussed the hypothesis already discussed in the *Philosophical Magazine*, viz. :—That molecular bodies attract one another with a force varying inversely with the fourth power of the distance between them.

He also read a paper on *Molecular Refraction*. This paper was devoted to the question of showing that the formula of the English physicist Gladstone for the connection between the index and the density is the best formula yet proposed, and it had a theoretical foundation.

Mr. H. C. RUSSELL read a paper on *Contributions to the History of Astronomy in Australia*. The paper was a long and exhaustive research into the records of the past, and gave facts and figures relating to the astronomy and meteorology of the early observers. He also read a paper on *A Proposed Method of Recording Variations in the Direction of the Vertical.*

Professor THRELFALL read a letter which had been received from Professor Rucker in relation to the effect rocks containing iron had upon the magnet.

Some discussion took place, which was closed by Professor Threlfall remarking that he did not consider the subject of very great importance, as people did not "steer" by the compass when on land.

Mr. GRAYDON read a paper on *The Diurnal Variation of Atmospheric Pressure and Wind.*

Professor THRELFALL also read papers on *The Measurements of High Resistances, and on Galvanometers Suitable for the Purpose. McArthur Pollock on the Clark Cell as a Means of Obtaining Standard Currents, and on its Application to the Construction of a Graded Galvanometer for the Prince Alfred Hospital.*

SECTION B.—CHEMISTRY AND MINERALOGY.

This section met under the presidency of Professor Black, who delivered the presidential address dealing with general chemistry in relation to education, and contended that chemical knowledge should be taught in all branches of education, especially in the higher schools. In this respect a great improvement might be made from a practical point of view.

The first paper read was on *Butterine as an Article of Food,* by Mr. CHARLES A. SMITH, F.I.C., F.C.S. An interesting discussion followed, in which the president, secretary, and Mr. Pond took part.

Mr. JOHN MINGAYE, F.C.S., assayer to the Mines Department, read a paper on *Discovery of Tellurium in New South Wales, in certain Bismuth Ores, found near Captain's Flat.*

Mr. POND announced the fact that he had found tellurium in New Zealand in the year 1885, in silver ores, through the suggestion of Sir James Hector, in examining some minerals. He thought that Mr. Mingaye had omitted to note the date of the discovery.

Dr. LEIBIUS suggested that a paper on Mr. Pond's research would be valuable, and this was promised for a future meeting.

Mr. HAMLET read a paper, in the absence of the author, by Mr. EDGAR HALL, F.C.S., of the Sunny Corner Silver Mine, on *Silver Smelting, Rich Silver Mattes, and their Treatment, and on Kernel Roasting.*

Mr. POND, in discussing the paper, said that if the section had done nothing more than produce this one paper it had done valuable work. He thought the matter was so important and the treatment so original that it ought to be published in the proceedings. A lengthy discussion followed, in which the secretary, Dr. Rennie, Dr. Leibius, and the president took part.

Mr. W. A. DIXSON read a paper on *Some Considerations in regard to the Formation of Coal.* He said that the examination of some coal from New Zealand and the other colonies had led him to the conclusion that the chief differences in coals were due to the original formation of the vegetable of which they were composed. The best *ligno-cellulose* was largely composed, originally, of resin from vegetation, and cannel coal, appeared to be derived from *adipo-cellulose* mixed with *ligno-cellulose.*

A paper was also read by Mr. HAMLETT, for Mr. F. Ratte, on *Some Means of Popularising the Study of Crystallography.*

Other papers read were :—On *The Occurrence of Silver in the Lodes of the Cape Colville Peninsula, Thames, No. 2,* by Mr. Pond, Government Analyst, Auckland, New Zealand. *On the Dissolved Matter contained in Rain Water collected at Lincoln, New Zealand,* by Mr. George Gray, F.G.S. *On the Origin of Vein-Gold and the Growth of Nuggets,* by Professor Black. *A Contribution to the Solution of the Problem—How Gold came into the Reefs?* by Mr. J. R. Don, M.A. (1) *Notes on the Proposed Chemical Laboratory, University of Sydney,* (2) *Notes on Some New South Wales Minerals,* (3), *Notes on Moss Gold,* by Professor Liversidge, M.A., F.R.S. *Gold, its Formation in our Reefs, with Notes of some of its Newly-Discovered Reactions,* by Mr. W. Skey. *Notes on the Composition of New South Wales Fahlerz and Embolite,* by Dr. G. S. Mackenzie. *Bibliography of the Chemistry of Indigenous Australian Vegetable Products,* by Mr. J. H. Maiden, F.L.S , F.G.S. ; *On the Action of Nepean Water on Tubes and Boiler Plates,* by Mr. Hamlet.

SECTION C.—GEOLOGY AND PALÆONTOLOGY.

The President, Mr. JACK, F.G.S., delivered his presidential address on *Some Salient Features in the Geology of Queensland.* He said that it seemed to him that some vague term, such as "Devonian," would best express the present state of their knowledge of a great part of the region hitherto regarded as "paleozoic." Their knowledge was extremely fragmentary, for it had been shown that formations of widely different dates may, under similar conditions of disturbance and pressure, assume the same lithological characteristics; one portion, for instance, may be a goldfield and another part a coalfield. He thought they would have to look for help in unravelling the structure of Queensland to the workers in other lands and to such meetings as the present.

Mr. S. H. COX, F.C.S., F.G.S., read a paper on *The Development of Mining in Australasia.* He said that as regards gold, by far the greater returns had been obtained from alluvial deposits. In early days, when alluvial gold was easily got, the deposits in some cases were surprisingly rich. The large returns in Victoria during the period from 1852 to 1862 were of gold almost exclusively alluvial. In those days men squandered their money in a reckless manner. There was one instance on record of a man having his horses shod with gold when a successful member of Parliament was brought into the town. The same individual was reported to have spent £200 in drink for the men every time he visited the claim. The copper ores, which had hitherto been worked in Australia, appear to have been always associated with rocks of the Silurian age. From a productive point of view, the collieries were no doubt steadier-paying mines than the metalliferous ones, although there were no sensational returns; nor was the value of the coal raised so high as would be anticipated by the stress which is frequently laid upon the value of the coal-mining industry. Australia was essentially a mining country, and was a place where all classes of ores are to be found. It was a country which offered every inducement for the further development of its resources. There was no doubt that they had every source of wealth, but the future of Australia was very largely dependent on the minerals raised. There was, perhaps, no part of the world where the valuable ores are so evenly distributed throughout the ground, but the success of the mining industry would greatly depend upon the skill that is brought to bear upon the extraction of the mineral and the treatment of the ores.

Mr. A. W. HOWITT read a paper on the *Metamorphic Rocks of Gippsland.* His deductions were to the effect that the rocks referred to were clearly connected with the vast earth movements which occurred at the close of the Silurian age.

The Rev. J. E. TENISON-WOODS read a paper on the *Desert Sandstone of Australia.* He said that the term "Desert sandstone" had been loosely applied in Australasia. He considered that the whole formation belonged to the tertiary period, but differed much in point of age.

Mr. T. W. EDGEWORTH DAVID read a paper on the *Origin of the Laterite in the Vegetable Creek District of New South Wales.* He said that the term "laterite," as used, is defined as a rock consisting of silicate of alumina and peroxide of iron. The colour is of a prevailing brick red, passing into ocherous, and the rock shows every gradation from a soft ferruginous clay, resembling lithomarge, to a hard pisolitic ironstone. Laterite is found in New South Wales, associated with the basalts and auriferous and stanniferous gravels of the tertiary age. Mr. C. S. Wilkinson has described this rock as "a sandy concretionary ironstone, which sometimes assumes a pisolitic structure." At Emmaville, in the Vegetable Creek district, the laterite has a thickness of from a few feet to 40 ft., and occurs in oval patches from half-a-mile to two miles wide, situated chiefly at the sources of the lava sheets, and forming the material of which a number of small basaltic craters are composed. Some of these craters retain so much of their original shape as to leave no doubt as to their true nature, while others have suffered so much from denudation as to preserve no vestige of their original crater rings. In two places at Vegetable Creek cavernous spaces 2½ ft. high and several chains wide were found to separate the under surface of the laterite from the underlying decomposed basalt. These are compared to the lava caves at Laurel Hill, near Tumberumba, New South Wales, and to those described by Darwin in islands of the Galapagos Archipelago. The conclusion is that the greater part of the laterite is an altered basalt tuff belonging to the earlier basalt eruptions, of Eocene age, or possibly to a time intermediate between that of the older and newer basalts. That water has played an important part in altering the tuffs, and possibly in redistributing them is proved by the occurrence, though exceptional, of small fragments of plants intermixed with the laterite, and of lenticular beds of limonite occupying local depressions on its surface.

Papers were also read by Professor Tate, on the *Secondary Rocks of Lake Eyre Basin, The Census of the Older Tertiary Fauna of Australia,* and *Glacial Phenomena in South Australia ;* by Mr. H. T. L. Brown, on the *Mesozoic Plains of South Australia ;* by Professor Hutton, *On the Rocks of the Thames Goldfields, U.L. ;* by Mr. F. W. Edgeworth David, B.A., F.R.G.S., on *Micropetographical Notes on some of the Hydrothermal Rocks of New South Wales,* and *On the Copper Shales of the Passage Beds between the Hawkesbury Series and the Upper Coal Measures of New South Wales ;* by Mr. H. T. Wilkinson, J.P., on *The Geology and Physical Geography of Norfolk Island;* by Mr. T. Mitchell, on *The Geological Sequence of the Bowring Beds.* Other papers were read on *On the Advisability of Establishing a Mining Institute in New South Wales, especially from a Geological Point of View,* by Mr. F. Ratte ; *On the Discovery of Fossils at Rockhampton,* by Mr. James Smith, F.G.S. ; *How Far can Australian Geologists safely Rely upon the Order of Succession of the Characteristic Genera of Fossil Plants of a far Distant Region, in the Determination of the Order and Relationship of Australian Terrestrial Formations?* by Mr. R. M. Johnson, F.L.S. ; *On Certain Boulders met with in the Beds and Reefs of the Gympie Goldfield,* by Mr. W. H. Rands ; and *On Metamorphism, and the Rocks of the Bathurst District,* by Mr. W. J. Clunies Ross, B.Sc.

SECTION D.—BIOLOGY.

The President, Professor RALPH TATE, F.G.S., delivered the presidential address, taking for his subject *The Influence of Physiographic Changes on the Distribution of Life in Australia.* The address consisted of an account of the influence of certain changes in the conformation of the land, and the distribution of land and water with concomitant and resultant changes of climate which have probably taken place in the later geological periods on the distribution of life, both plant and animal, on the surface of the continent. He traced more particularly the distribution of the flora over the various regions, and sought to account for its present peculiarities by reference to such changes in the level of the land and the like as seem to have taken place since the Cretaceous period. He pointed out the fallacy of the idea popularly entertained that there was evidence of the existence in Tertiary times of an extension of the sea through Central Australia, the Tertiary beds of that region bearing evidence that they were not of marine but of lacustrine origin, containing remains of fresh or brackish water or land animals, but of no marine forms. He showed that this region was, at the time when other parts further south were subjected to the action of glaciers, a region of great rainfall and consequent formation of great valleys and great accumulations of fluvialite deposits. He followed out the effects of these conditions and of various oscillations of climate which Australia had undergone in more recent periods in determining the leading peculiarities in the geographical distribution.

The first paper read was one by Mr. W. M. HAMLET, F.I.C., F.C.S., *On the Action of Metallic Salts in the Development of Aspergillis nigrescens*. Certain samples of bread submitted to Mr. Hamlet for analysis were found to be densely crowded with the hyphae and conidia of a mould-fungus—*Aspergillus nigrescens*—and, on analysis, a small quantity of zinc was found in the bread, to the presence of which, probably derived from galvanised iron tubs or vessels used in the baking, the specially active growth of the mould was ascribed.

Dr. JOSEPH BANCROFT, of Brisbane, read a paper and gave a demonstration of the respiration in the roots of shore plants that inhabit the undrained mud-banks of the coast of Queensland. It appears there is a remarkable organ that springs up from the roots of avicennias covered with circular pores. The pores throw off flakes of white corky cells. This action of the plant opens up air communication with the pithy roots, that live permanently in fœtid mud. These organs he calls "breathers." They are 18 in. high in Avicennia and in Sonneratia, brought from the Johnson River by Dr. Tom Bancroft, are upwards of 6 ft. in length, and 6 in. in diameter, tapering to a point. The breathers never throw out leaves, but when wounded will become forked. In Brugueira, another shore plant, knees are thrown up on which lenticels are developed. Mangroves show lenticels on their many-legged stems. The Swamp cypress of the Southern States of America throws up knees which are cut off and used for buckets. Dr. Bancroft believes the function of the cypress knees will be found analogous. Roots of the shore plants were immersed in water, and on air being forced through them, it appeared in bubbles at all the lenticular apertures. Dr. Bancroft is of opinion that gardeners will profit by the understanding of the value of these lenticels being kept clean and free from lichenous growth on the stems of their fruit-trees.

A lengthened discussion, in which Mr. Tyron, of Brisbane, Professor Baldwin Spencer, Professor Anderson Stuart, and the President took part, then followed on the nature of these lenticular openings and the office they performed in the economy of the plant.

Papers were read by Mr. Arthur Dendy, M.Sc., F.L.S., bearing the following titles: *Preliminary Notes on the Structure and Development of a Honey Sponge* (Stelospongus flabelliformis); *On the Minute Anatomy of an Australian Land Planarian.* Papers were also communicated by Mr. W. J. M'Kay, B.Sc., on *The Development of the Pineal Eye in some Australian Lizards;* by Mr. A. Fletcher, B.Sc., *On a Myxosporidium infesting Australian Frogs;* by Mr. W. A. Haswell, M.A., D.Sc., *On the Striated Muscular Fibres in nvertebrates and in the Muscular Tissue of Peripatus.*

SECTION E.—GEOGRAPHY.

The section met under the presidency of the Hon. John Forrest, C.M.G., Commissioner for Crown Lands of Western Australia. The President did not consider it advisable on this occasion to confine his remarks to a particular geographical subject, as is usual in old-established societies, as he thought a few general observations on subjects within the wide scope of the geographical section of the Association would be more useful on the present occasion. He proceeded to remark on the territorial divisions of Australia, and made a graceful allusion to the work of explorers who have passed away. He made a plea for the systematic teaching of Australian exploration in our schools, and what more useful work would there be than teaching the rising generation the way in which the Continent we live in and love so well has gradually been opened up to the enterprise and commerce of the world. After briefly, but eloquently, describing the changes which civilisation has wrought in Australia within the space of the past 100 years, the question might arise in our minds as to what Australia would be like in another century, and that such thoughts should stimulate us to great exertions. The old way of travelling by cart and coach has given way to the railway, and the old way of shepherding our stock is fast disappearing; in fact, our present ways are not the old ways; and so it must be with the work of exploration. The old way must be superseded by the new; no longer must it be the love of adventure, and the fascination of discovering new mountains and new rivers, but our aim must be to examine and map the treasures of the earth. The man of science must now with care and with skill, and with slow but sure steps, follow on the steps of the early geographical traveller, and the prosecution and accomplishment of this great work be commended to the Governments and people of Australasia. As a rule, expeditions have been badly provided, have received but scant encouragement, and have had but small Government support. It therefore has frequently happened that fertile tracts of country have remained unknown and unutilised for years, just because a Government has not had sufficient knowledge and enterprise to have it examined and reported upon. As far as pastoral pursuits are concerned, the enterprise of the squatter has done good and lasting work. The question of federation must also occupy attention. At present the people of Australia were in many respects as foreign people to one another.

Papers were also read by Mr. James Stirling on the *Physiography of the Australian Alps*; by Sir Edward Strickland on *Emin Bey;* by Mr. H. G. M'Kinney, M.E., on *The Rivers of New South Wales;* by Mr. James Panton, P.M., on *Supposed Further Traces of Leichhardt;* by Mr. G. S. Griffiths, F.G.S., F.R.G.S., on *Antarctic Exploration the Duty of Australasia;* and by Sir Edward Strickland, K.C.B., F.R G.S., *Epitome of the State of our Geographical Knowledge of Australasia.*

SECTION G.—ANTHROPOLOGY.

Dr. A. CARROLL delivered his presidential address on the *Movements of Races from Asia to America and Australia.* The paper dealt with the little progress hitherto made in the progress of anthropology in Australasia or the Pacific since the entrance of the Spaniards to these regions; how little true advancement has been made in the study of the Pacific islanders in comparison with the peoples of other regions, and their ancient history, especially the Egyptians, Babylonians, etc.; the movements in High Asia 4,000 years ago of the various races and mixed peoples; the reactions of these upon the Davidians, the "Kush," and the various Babylonian colonisers and Syrian peoples, and the obliteration of the "Kush," who were afterwards absorbed by the "Shemites," etc.; the earlier natives of China—the "Mon," the "Lo," the "Yun," the "King," the "Mao"—some of whom were long before this immigration civilised nations; the quarrels of the Aryans, their separation, their advance towards India and to Media, Persia, etc.; the introduction of their dialects, myths, poetry, hymns (as the "Rig" and other "Vedas"), their native worship and their sun, etc.; myths and the families of these; and the history of the races of the world to the present era.

Mr. J. J. WILD read a paper on *The Outline of Anthropological Science,* which he explained was a new science developed by the intense intellectual activity of the 19th century. It was the science of man, and had led to a series of most surprising discoveries of the pre-historic race. The instruments of discovery had been the pick and the spade in turning over the soil of Italy, Greece, Syria, and Egypt. In all the terrible catastrophes which had overwhelmed man he had always come forward in a higher type of humanity and rising toward the higher destiny.

The Rev. G. PRATT read a paper on *The Genealogy of the Sun and an Ancient Samoan Legend,* which described the intercourse between the inhabitants of heaven and earth, and related the uplifting of the sky.

Among the other papers were: *A Comparative View of the Customs of the Papuan and Malay Races of Polynesia,* Rev. S. Ella; *Some Niceties of Expression in the Languages of the New Hebrides,* Rev. J. Copeland, M.A.; *Maori Art,* Mr. A. Hamilton; *Notes on the Last of the Tasmanian Aborigines,* Hon. Dr. Agnew.

SECTION H.—SANITARY SCIENCE AND HYGIENE.

Dr. BANCROFT, of Brisbane, delivered the presidential address, choosing for special reference the various hygienic aspects of Australian life. The many difficulties with which sanitary science had to contend were referred to, especially the slowness of the recognition of its paramount importance. He then adverted to the question of longevity, and pointed out that while these warmer countries are favourable in many respects to long living, the death-rate among children under the age of five was rather startling. He then proceeded to remark upon certain conditions of life which may have influence in the production of such a result. If, he continued, "this high rate of infantile mortality is to be reduced, more care—at least in Queensland—will have to be taken in improving the dwellings." The improvements suggested were in the direction of increased size, and of improvement in the corrugated iron roof by duplication with suitable intermediate packing so as to diminish the extremes of heat and cold, which are permitted by the single roof. Then the planting of trees to moderate the aridity of the air was advocated, and it was pointed out that though sanitary science can do little to mitigate the severity of climate, it ought at least to guide the choice of healthy sites for habitation. The hygienic conditions of country life were next touched upon, and the characteristics of a favourable site were described. The question of milk was next considered, and the value of substitutes referred to. Simple measures for the reduction of the house-fly nuisance attested by the author's experience, were given, as well as for other insect pests. The difficult questions of sewage and nightsoil disposal were also treated of. Dr. Bancroft warmly invited the attention of botanists to the problem of the cultivation of soil fertilised by sewage, when the fertilising agent so greatly exceeds the necessities of the land itself, and he himself indicated some probably valuable lines of cultivation. The vexed question of the mode of dissemination of typhoid came next for attention. The principles laid down may be thus summarised. The European idea of the spread of typhoid, almost entirely by sewage infection of drinking water, comes far short of the facts as we know them here.

SECTION J.—ENGINEERING AND ARCHITECTURE.

This section was presided over by Professor Kerney, of Melbourne. It was opened by a paper on *The Deep Drainage System of Adelaide: Its Results and Mistakes*, by the Hon. Dr. Allan Campbell, M.L.C., Adelaide. The paper elicited a considerable discussion, as the question is one in which the public interest in Sydney and Melbourne at this moment is deeply centered. Professor Warren; Mr. Jones, hydraulic engineer; Hon. Dr. Garran, M.L.C.; Mr. Helmsley, and others, took part in the debate. In the majority of instances the views put forward by the writer were endorsed by the speakers. The suitable situation of Adelaide for economical drainage was pointed out, its previous unsanitary state detailed, and the assertion was made that it is now the cleanest, and has the lowest death-rate of any of the Australian cities. Mortality returns were given to show this. A description, from an engineering point of view, was given of the system, and also a detailed account of the result when the system was first brought into operation. It was here where the writer pointed out the rock on which the system split, and which had led not a few sensible people in Adelaide to declare, in that new country, a great practical blunder had been committed. The ventilation of the street sewers was so imperfect that a greater nuisance appeared to have been created than the one the system was intended to remove. It was pointed out that the use of the "boundary" or "disconnecter" trap divided the system, so far as its ventilation was concerned, into two parts—the one next the street sewers unventilated, the other next the dwelling-houses ventilated by what the writer called the principle of through ventilation. The latter had never given rise to any annoyance, while the former was an unmitigated nuisance. Improvements on this portion of the system had to be made, and the principle of through ventilation partially applied. The result had been so satisfactory that Dr. Campbell claimed that the same principle should be applied throughout, and the only means of doing this was to abandon the use of this "disconnecter" or "boundary" trap. The object of this trap is to bar the way of foul sewer air towards the dwelling-house, but it was shown clearly and comprehensively that barring the way was simply creating a lodgment for foul air. The best thing to do was to make sure that foul air would not be permitted to form, but every instant would be swept out of the way. It was pointed out that the sewers were small in size, they discharged their contents with great ease and rapidity, and they were easily ventilated. It was also shown that no pipe from the inside of any dwelling stood in direct connection with any drain, but the flow from all pipes fell into a receptacle or trap, which had on its drain side a ventilating tube led high above the eaves of the house. By such means no pressure could bear against the water seal of this trap. Join this further fact to what has already been said, that periodical compulsory examinations of all house drains are made with the smoke test, and it was contended that the danger which the "boundary" trap was employed to prevent could not actually exist. It was urged that we ought not to import conceptions derived from a system of sewers such as had been employed in the old country and elsewhere. We must view the new mode of construction scientifically, that is, as it actually stands, losing sight of no factor in the system; and if we did so, the whole was simple and clear on the question of ventilation. In closing an animated debate, Dr. Campbell quoted the opinion of an engineer of some eminence (Julius W. Adams), who advocated the ventilation of a sewerage system on the same lines as he did, that all that was required was to "enable the sewers to breathe and ventilate themselves."

SECTION J.—ARCHITECTURE AND ENGINEERING.

Professor KERNOT introduced the subject of waterways of culverts and bridges. He remarked that the question was one of the highest practical importance to the road and railway engineer. He quoted a considerable number of rules and formulæ proposed by English, American, Indian, and Victorian engineers, and gave his preference to a modification of Colonel Dickens's rule. He showed that the proposed rule corresponded fairly well with a large number of successful structures of long standing in New South Wales and Victoria, and that the proportions that departed farthest from it on the side of efficiency had coincided with the scenes of disastrous failure and costly reconstruction. These cases were:—1. Bridgewater, Tasmania, 13 square feet waterway to 2 1-3rd square miles drainage area. 2. Bendigo Creek, Sandhurst, Victoria, 190 square feet to 16 square miles. 3 Cootamundra, New South Wales, 53 square feet to 20 square miles. 4. Plenty River, Victoria, 440 square feet to 60 square miles. 5. Barwon River, Geelong, Victoria, 4,000 square feet to 1,700 square miles. The rule given by Professor Kernot required for the Bridgewater case about 110 square feet instead of 13, for the Bendigo Creek rather over 300 instead of 190, for Cootamundra 380 instead of 53, for Plenty River 860 instead of 440, and for the Barwon 10,000 instead of 4,000. On the other hand, it agreed fairly well with numerous important bridges over the Bendigo Creek, Moonee Ponds, Yarra, Saltwater River, and Barwon in Victoria, that have been often tested by heavy floods during the past 30 years, and have proved sufficient but not excessive; and also with the bridges at Bathurst and Wellington in New South Wales. The paper was illustrated by large diagrams, and the author concluded by requesting the members to send him particulars of any cases of sufficient but not excessive waterways of old standing, also cases of notable failure, whereby further to confirm or, if necessary, slightly modify the rule proposed by him.

Mr. C. O. BURGE read a paper on the *Recent Progress in Sinking Deep Foundations for Engineering Work*—in the first place, with the partial substitution of iron for timber in pile work; several instances were given of the use of screw piles on a large scale, and of the failure of them in many cases where they had not been used with sufficient judgment. Their suitability for marine piers and other similar structures was alluded to, and examples quoted. Cylindrical foundations were noted, both of brick wells, of which the use in India is universal, not only largely in the present day for great railway bridges, but in ancient times by natives; and of iron cylinders, which, out of India, are the most favoured methods of construction for works of the kind. Several bridges in India, the new Tay bridge, double cylinders at the Cape and elsewhere, were alluded to in this connection, and the alternative of several small brick-wells or few larger ones was adverted to, as forming a subject of professional differences of opinion in India. After describing a curious operation witnessed by the author at Cawnpore, in destroying old well foundations to make room for new ones, the paper proceeded to the consideration of the pneumatic methods, both in cylinders and in caissons. The St. Louis, Brooklyn, Forth, and Harlem bridges, and one at Copenhagen, were briefly described as regards their substructure, as well as the Eiffel tower in Paris, and the Delaware Bay lighthouse, the latter, from its exposed position, being a work of unexampled difficulty, all these having been founded by means of the pneumatic process, but differing in detail; these, of course, being merely prominent instances of a system widely adopted, especially on the Continent of Europe and in the United States. Beyond the depth of about 100 ft. below water level, which is the limit of the scope of the pneumatic process, mechanical dredgers have to be used, and as the skin friction becomes in these cases so great that the weight of the cylinder itself, even if reinforced by all practicable temporary loading, is insufficient to sink it, the design must be made so that the caisson, or cylinder, must carry its own weight by loaded concrete partitions.

A paper *On Utilising Waste Underground Waters by Tunnelling in the Hills*, by Mr. T. Parker, C.E., of Adelaide, was next read. The author described the loss of water by evaporation, absorption, and percolation, and suggested tunnelling to catch the latter, especially in connection with the Adelaide water supply, the advantages being extra purity of water, economy, no reservoirs being required, and facility of extension. Professor Kernot remarked on the great waste of water, only 1 per cent. of the rainfall reaching the sea from the western rivers.

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents, nor can he take notice of anonymous communications. All letters must be accompanied by the name and address of the writer, not necessarily for publication, but as a guarantee of good faith.

THE SPARROW AGAIN.

Beginning at the end of the very positive letter of your correspondent, Mr. J. P. Nunn, I must inform him that I used the word "swallow" generically for the entire genus *Hirundo*. Their taking possession of a martin's nest is of such constant occurrence that I have known the latter birds to be positively driven away from a gentleman's mansion in Essex, in spite of all efforts for their protection. Their persecution of the true insectivorous birds is a sad reality. A correspondent of the *American Naturalist* describes the repeated raids which they made upon a wren's nest in his garden, and how he was obliged to protect the nest with a cover having a hole too small for the sparrow to enter. Now, as the wren is one of our most diligent insect-eating birds, this is a case in point. Further observations, alike in America and Europe, go to show that in proportion as the sparrow multiplies in any district other small birds become scarcer.

The suggestion that I "cannot know what kind of bird the American robin is," is very wide of the mark. I knew it forty years ago. But the comparative size of the birds is quite beside the question. If on opening the crops of two birds we find that of the one mainly filled with insects and that of the other with grain and fruits, we know at once that the former is a friend to the farmer and gardener, and the latter an enemy.

I am perfectly aware that the swallows do not feed on grubs and caterpillars. But I would invert Mr. Nunn's exclamation, and say, "If the flies and the moths are to be allowed to live and deposit their eggs that these may turn into food for sparrows, woe to all our fruits and flowers!" Sparrows, thinks Mr. Nunn, "congregate where they can obtain food." So do other birds. His examination of the nests of eighty-nine pairs of sparrows proves nothing, unless he can also show how many broods a pair of sparrows may have in a year (whilst many other species have one only), and how many nests there are, say, per square mile, and then make a comparative census of the small birds in the same manner. Until he has done this he has proved nothing.

The observations of S. A. Forbes are perfectly conclusive, at least for the district where they were made. Let Mr. Nunn shoot a few of his clients, and make an examination of the contents of their stomachs, and he will, I believe, find himself compelled to throw up his brief. ARUSPEX.

THE COCHINEAL INSECT.

The writer of the article on "Cochineal Insects" (SCIENTIFIC NEWS, p. 459) can scarcely be aware that the dye obtained from these insects, once so valuable, is rapidly falling into disuse, being to a great extent superseded by the azo-scarlets obtained from coal-tar. In consequence, many of the *Coccus* gardens are being turned to other uses.

The "green dye" obtained from caterpillars has been proved by Mr. Poulton and others to be identical with the chlorophyll or leaf-green of plants, and if required for use in the arts can be much more readily obtained from grass than from spinach. A TINCTORIAL CHEMIST.

DRAGON-FLIES.

Will you allow me to inform your numerous readers interested in entomology, that I shall be very pleased to assist any one desiring to commence the study of dragon-flies (*Odonata*). I shall also be glad to name and identify any specimens of these grand insects which may be sent to me.

Birmingham. W. HARCOURT BATH.

ANSWERS TO CORRESPONDENTS.

TEIGNMOUTH. — The subject of your communication was dealt with on page 193 of vol. i. of the SCIENTIFIC NEWS. We would direct your attention to the rules at the head of this column.

RECENT INVENTIONS.

The following list has been compiled especially for the SCIENTIFIC NEWS *by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents, of* 234, *High Holborn, London, W.C.; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester; and* 6, *Lord Street, Liverpool.*

PROPELLER FOR VESSELS.—Mr. R. Morris has patented a means for propelling vessels, torpedoes, etc., by compressed air. A cylinder is provided and fitted with a plunger, piston rod, and an air valve at each end. When the plunger is put in motion air is taken into the cylinder through the valve at one end and is forced out through the other valve into a pipe which passes through the exterior of the vessel to the water outside. The compressed air is thus forced against the water and sufficient force obtained to propel the vessel.

GALVANIC BATTERIES.—Mr. P. Skrivanow has patented a galvanic battery. This battery consists of an electrode of iron, and a plate of retort charcoal. Over the latter is spread a layer of peroxide of lead, and the whole is enveloped in a sheet of parchment paper retained by rubber bands. The two electrodes are placed in a solution of hydrate of potassium. A dry battery can be obtained by covering the positive electrode with several sheets of filtering paper soaked in the above solution, and applying above it the negative electrode.

MARINE ENGINES.—Mr. J. McGregor has patented a compound marine steam-engine so that the steam may be expanded through three successive stages with a satisfactory distribution of the various strains. To carry out the invention four cylinders are used in each instance, connected by pairs to two cranks on the same crank shaft. In a modification two high-pressure cylinders are geared to and work at the back of an intermediate and a low-pressure cylinder, the valves of the high pressure cylinders being actuated by an extension of the valve rods of the two larger cylinders.

ELECTRIC SHOCKS.—Messrs. J. Douglas and H. Abbott have patented an apparatus for producing and administering electric shocks. A case is provided containing a tray for carrying the battery, suspended by cords from a cross-bar fixed to two telescopic tubes which form handles outside the case. The pulling out of the tubes over their cores carries the cross-bar with them, and at the same time the tray and battery are lifted. The cross-bar carries a bracket to which the core of a magnet is fixed, so that as the handles are drawn out the current is increased. The weight of the tray and battery takes back the handles when released.

WATCH.—An improved watch or chronograph has been patented by Messrs. H. and C. Turler, of Bienne, Switzerland, the object of which is to enable the wearer to ascertain any space of time which has elapsed during a given period. In addition to the ordinary hands, the watch has three smaller supplementary dials, each provided with mechanism which is thrown into operation when desired, and on which are recorded the hours, minutes, and seconds respectively which have elapsed during the time it is desired to measure. When the special dials are not required, the mechanism is thrown out of action, and the watch is similar to an ordinary one.

ELECTRO MOTORS.—Mr. M. Immisch has patented an improvement in the construction of the cores of armatures of electro motors and dynamo machines. It consists in the employment of collars, keyed to an armature spindle. One of these collars is capable of longitudinal movement thereon, while both collars are formed with grooves the bottoms of which are inclined. These grooves receive keys having correspondingly inclined surfaces, so that the longitudinal movement of one of the collars will cause the keys to move outwards, and by acting upon the plates or wire of which the armature is built up, will firmly hold and tighten same, while exerting a yielding or elastic pressure thereon.

FIREARMS.—Mr. H. S. Maxim has patented means for pointing fire-arms. The object is to enable a gun to be elevated and sighted accurately without previously ascertaining the distance between the gun and the object aimed at. It is based upon the fact that the greater the distance of an object from a given point the less will be the angle at this point subtended by the object. It is carried into practice by providing a sight of two pieces arranged so as to be simultaneously adjusted toward or from each other, that is to say, assuming these adjustable pieces to be arranged in the back sight, the said pieces will be moved towards each other simultaneously with the raising of the sight and away from each other by the lowering thereof. The fore-sight is formed with a hole and two pins extending horizontally from opposite sides of the eye to its centre.

MARINER'S COMPASS.—Mr. J. C. Dobbie, of Glasgow, has patented improvements relating to the mariner's compass, comprising means for the suspension of the compass bowl and for the taking of azimuth bearings. The bowl of the compass is suspended by means of a link or chain from a metallic spring fastened vertically to the interior of the binnacle casing, or the springs may be horizontal and the gimbal ring provided with bearings which fit in or upon sockets formed on the before-mentioned springs. For taking azimuth bearings, a reflecting mirror is fixed on the case. This mirror is formed of two parts, hinged, or otherwise adjustable, so that one serves to reflect the object whose bearing is to be taken, and the other the reading of the compass-card. In use the mirrors are adjusted by hand to the requisite position, and the reading of the card is facilitated by the two mirrors.

GALVANOMETERS.—Messrs. W. E. Ayrton and J. Perry have patented a galvanometer. The invention relates to galvanometers of the siphon recorder type, whether used as measuring instruments or as telegraphic receivers. In order to prevent the sensibility of the instrument being altered by either a temporary or permanent variation of the strength of the magnetic field in which the movable coil is suspended, one or more small permanent magnets are attached to the movable coil with their magnetic axes parallel to the plane of the latter; the moment of the controlling couple and that of the deflecting couple then alter in the same ratio with any alteration in the strength of the field. When the zero is altered, for example, by bringing the instrument near a dynamo, the magnet or coils which produce the magnetic field are turned about an axis, passing through the axis of suspension of the movable coil into the proper position. The connections with the suspended coil may be made by means of mercury cups, or preferably by fine wire spirals.

ANNOUNCEMENTS.

CAMBRIDGE.—At St. John's College the following scholarships and open exhibitions are offered for competition to persons not yet in residence:—1. Foundation scholarships, two of the annual value of £80, two of £60, and two of £50, tenable for two years, and the tenure may be prolonged for two years more. 2. Minor scholarships, four of the annual value of £50 tenable for two years, or until the holder is elected to a foundation scholarship. 3. Exhibitions varying in number and value according to the merits of the candidates and the number of vacancies at the time of the election. Candidates for scholarships must be under nineteen years of age, but this restriction does not apply to candidates for exhibitions. Besides scholars and exhibitioners, a certain number of sizars may be elected according with the results of the examination. Candidates may present themselves for examination in classics, mathematics, natural sciences, Hebrew, and Sanskrit. The examination in classics and natural science will commence on Tuesday, December 11th; in mathematics and Hebrew on Thursday, December 13th. Candidates in Sanskrit must give a month's notice of their intention to present themselves for examination. The name of every candidate with certificate of birth and character should be sent not later than December 1st to the tutor under whom it is proposed to place him. Names will be received by any one of the tutors, Dr. Sandys, Rev. E. Hill, Mr. W. E. Heitland, and Rev. J. T. Ward.

LONDON INSTITUTION.—The following lectures will be delivered on Mondays and Thursdays, commencing Nov. 19th:—"Time and Tide—the Romance of Modern Science," Sir R. S. Ball, F.R.S.; "Electrical Transmission of Power," Prof. W. E. Ayrton, F.R.S.; "Time and Tide—the Romance of Modern Science," Sir R. S. Ball, F.R.S.; "Handel—Vocal, Instrumental, and Pictorial Illustrations," William H. Cummings, Esq.; "The Colours of Polarised Light," Prof. Thompson, D.Sc., B.A.; "Political Progress in the Seventeenth Century," Prof. Samuel Rawson Gardiner, LL.D.; "The Colours of Polarised Light—Part II.," Prof. Sylvanus Thompson, D.Sc., B.A.; "Life History of Some Plants," Prof. Charles Stewart; "The New Forces in India," Sir W. Wilson Hunter, K.C.S.I., C.I.E., LL.D.; "Life History of Some Animals," Prof. Charles Stewart; "The Story of a Tinder Box," with Experiments (Christmas Course for Juveniles), Dr. Meymott Tidy, F.C.S.; "Art and Artists," with illustrations, Harry Furniss, Esq.; "Pigmies," Prof. Flower, C.B., LL.D., F.R.S.; "Recent Babylonian Explorations," W. St. Chad Boscawen, Esq.; "The English Novel in the Seventeenth Century," Edmund Gosse, Esq., M.A.; "Astronomical Photography," A. A. Common, Esq., F.R.S.; "The Times of the Twelve Cæsars," Rev. Canon Benham, B.D.;" "Modern Wit," Armytage Bakewell, Esq.; "The Times of the Twelve Apostles," Rev. Canon Benham, B.D.; "Cædmon—Our First Poet in the Island of England," Rev. Stopford Brooke, M.A.; "Men, Women, and Artists," Harry Quilter, Esq., M.A.; "Some Curiosities of Magnetism," Shelford Bidewell, Esq.; "Darwin versus Lamarck," Prof. Ray Lankester, F.R.S.; "Ants," Rev. J. G. Wood; "The Legend of Beauty, or, Art as Representing the Passion of our Lives," Wyke Bayliss, Esq., F.S.A.; "Recent Studies of Some Forms of Minutest Life," Rev. Dr. Dallinger, F.R.S.; "Modern Composers of Classical Song—I. Franz Liszt, Johannes Brahms, and others," Carl Armbruster, Esq.: "Soap Bubbles, and what may be shown with them," C. V. Boys, Esq.; "Modern Composers of Classical Song—II. Robert Franz," Carl Armbruster, Esq.; "Marriage Laws—Ancient and Modern," E. B. Tylor, Esq., D.C.L., F.R.S.; "Algeria and Morocco," Henry Blackburn, Esq.; 'Our Early British Ancestors," Prof. W. Boyd Dawkins, F.R.S.; "The Phonograph," Col. Gouraud; "The Characters of the Great Composers, and the Characteristics of their Works," Prof. Ernst Pauer. The Christmas Course, by Dr. Meymott Tidy, is intended for juveniles, for whom seats will be specially reserved. Further particulars can be obtained on application to the Secretary of the London Institution, Finsbury Square, E.C.

NOTICES.

Binding Cases for Vol. I., price 2s. each.

Cases and Binding, Vol. I., including Title Page and Index, price 3s.

Vol. I., bound in cloth, with Title Page and Index, 9s. 6d. —by post 10s.

The Back Numbers of SCIENTIFIC NEWS can be obtained from all Booksellers and Newsagents, or direct from the Publisher, 138, Fleet-street, London, E.C. Price 3d. each, or by post 3½d.

SELECTED BOOKS.

Human Physiology (a Text-Book of). By Professor L. Landois, of Greifswald. Translated from the sixth German edition, with additions, by Professor Wm. Stirling, M.D., Sc.D., Owens College, Manchester. With 692 illustrations. Third edition. London: C. Griffin and Co. Price 34s.

Nature and Man. Essays, Scientific and Philosophical. By the late W. B. Carpenter, M.D., F.R.S. With an Introductory Memoir by J. Estlin Carpenter, and a Portrait. London: Kegan Paul, Trenoh and Co. Price 8s. 6d.

The Walks Abroad of Two Young Naturalists. From the French of Charles Beaugrand. By David Sharp, M.B., F.L.S., F.Z.S., President of the Entomological Society of London, etc. London: Sampson Low, Marston, Searle, and Rivington (Limited). Price 7s. 6d.

DIARY FOR NEXT WEEK.

Tuesday, Nov. 13.—Gresham College, Basinghall Street, E C., at 6 p.m.—*Music*, by Dr. Henry Wylde.
Institution of Civil Engineers, 25, Great George Street, Westminster, S.W., at 8 p.m.—*Friction-Brake Dynamometers*, by Mr. W. Worby Beaumont, M.Inst.C.E.
Anthropological Institute of Great Britain and Ireland, 3, Hanover Square, W., at 8.30 p.m.—*On a Method of Investigating the Development of Institutions; Applied to Laws of Marriage and Descent*, by Edwd. B. Tylor, Esq., D.C.L., F.R.S.

Wednesday, Nov. 14.—Gresham College, Basinghall Street, E.C., at 6 p.m.—*Music*, by Dr. Henry Wylde.

Thursday, Nov. 15.—Manchester Microscopical Society, 65, King Street, at 7 p.m. — Mounting Section. Demonstrators, Messrs. E. Ward and J. L. W. Miles.
Chemical Society, Burlington House, at 8 p.m.
Gresham College, Basinghall Street, E.C., at 6 p.m.—*Music*, by Dr. Henry Wylde.

Friday, Nov. 16.—Greenock Philosophical Society.—*Poetry: its Nature and Relations to Modern Life and Progress*, by William Jolly, Esq., H.M. Inspector of Schools.
Gresham College, Basinghall Street, E.C., at 6 p.m.—*Music*, by Dr. Henry Wylde.
Institution of Civil Engineers, 25, Great George Street, Westminster, at 7.30 p.m. Students' Meetings.—*Experiments on Beams*, by Mr. Ed. C. de Segundo, Stud.Inst.C.E.

METEOROLOGICAL RETURNS

for the ten weeks ending on Monday, Oct. 29th, 1888. Specially prepared for SCIENTIFIC NEWS from official reports.

	Mean Temperature.	Rainfall.	Duration of Sunshine.

FOR GENERAL READERS.

Vol. II. NOVEMBER 16, 1888. No. 20.

CONTENTS.

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

One of the common troubles to which laboratory workers, and more especially laboratory martyrs (*i.e.*, the hard-worked, ill-paid, and unglorified assistants), are subjected in the course of chemical work, is that of "*bumping*."

Certain liquids must be boiled, continuously boiled, in some cases to effect solution, in others for evaporation sake. Docile solutions submit quietly and amiably to such treatment; the bubbles of vapour are formed immediately the boiling point is reached, they are small and numerous, and detach themselves freely from the heated sides of the containing vessel. But certain other disagreeable liquids behave very differently. They rebel against the discipline of boiling, sullenly persist in remaining calmly in the liquid form even when their temperature is raised above their unquestionable boiling point, clinging with stubborn tenacity to the smooth sides of the heated vessel. Presently, however, their obstinate resistance is overcome by the expansive energy of additional heat.

The junior student who begins his work in qualitative analysis by heating his solutions in test tubes, frequently obtains a striking demonstration of the final result of this contest. Finding that his solution does not boil in accordance with his theoretical anticipations, he looks down the tube to see what is the matter, when suddenly a great bubble of vapour filling the lower part of the tube is explosively formed, and more or less of the liquid is projected to his face. As solutions of caustic potash and soda, and of sulphuric acid (oil of vitriol), are specially addicted to such proceeding, the demonstration may be unpleasant to the operator, who speedily learns to treat heated test tubes as old sportsmen treat gun barrels; he never presents their mouths towards himself or his friends.

In more advanced work, where beakers or flasks are used, this sudden formation of the big vapour bubble and its collapse jerks the vessel on its stand with a violent bump, from which the term "bumping" is derived. A flask may thus be broken, and the work of a whole day, or of several days, be thereby wrecked, or some drops of solution may be ejected from an open-mouthed beaker or evaporating dish, and thus a quantitative analysis be altogether spoiled. The smoother and cleaner the containing vessel the greater the liability—other conditions equal—to this bumping, and in chemical analysis the uttermost extreme of double-Dutch cleanliness must be observed.

If the vessel or liquid be decidedly dirty in the sense of holding particles of foreign matter, bumping rarely occurs, because the grasp of the liquid upon mere points is very weak. This may be shown by boiling water or any other liquid in a glass vessel which has one or more projecting points of roughness on its surface. By watching them during the heating it will be seen that, just as the liquid reaches its boiling point, streams of minute bubbles of vapour will pour from these points. The like occurs when any other gas is disengaged from a liquid, as, for example, the carbonic acid gas from champagne or other sparkling liquid. Ordinary drinking glasses commonly have such points on their surfaces, and from these may be seen such issuing streams of gas bubbles after the general effervescence has ceased.

To prevent bumping, chemists have imitated this by putting foreign solids into the liquid, solids that are insoluble and do not taint the liquid, such as pieces of charcoal, platinum wire, etc.

But there are some liquids that resist even these, or in which their action is uncertain and variable. A Russian chemist, W. Markownikoff, has lately struggled with this practical problem, and finds that coating the inside of the vessel with a thin deposit of silver is effective, but the silver film easily breaks off. His best results were obtained by using very thin capillary glass tubes, such as are easily obtained by heating an ordinary small glass tube in a gas or spirit lamp flame, and drawing it out when red hot. A hair-like thread is thus formed, which, however fine, remains tubular, as may be proved by breaking it asunder, placing the fine end under water, and blowing through the original undiminished tube. A small cloud or stream of minute air bubbles is thus blown into the water.

Markownikoff cuts up such hair-like tube into short pieces from $\frac{1}{8}$ to $\frac{3}{8}$ of an inch in length, seals up one end, which is easily done by holding it for a moment in a flame either before or after cutting it off. A few of these minute open-mouthed bottles, each containing a microscopic elongated air-bubble, are dropped into the liquid, which then boils gradually and without violence, the steam bubbles proceeding from these nuclei.

Tomlinson, who long ago studied the subject of nuclei, showed that minute air-bubbles are the most effective, not only in promoting ebbuliton, but also in the opposite action of initiating solidification. Thus, clean water that has been previously boiled, or water free from solid or gaseous particles, may be brought down considerably below the freezing point without freezing, if it stands undisturbed in a smooth vessel; but if a solid particle be dropped into it, and that particle has air adherent to it, or forces a little air down with it, crystals of ice are instantly formed. Supersated solutions of crystalline salts behave in the same manner; many of them very strikingly. This is notably the case with sulphate of soda.

The familiar experiment of stirring champagne with a piece of bread after ordinary effervescence has ceased, and thereby renewing it, is an example of this action of gaseous nuclei, the efficiency of the bread depending on its porosity and the air contained within its pores.

On one occasion I assisted at a Scandinavian midnight revel in the ancient capital of the Vikings. We emulated those Vikings by repeating their drinking ceremonies. When the bumpers were all adjusted, each man rose, thus with the others forming a circle round the table, each lifted his tall glass by the stem, raised it over head to full arm's length, then each reached forward, clashing all the glasses together in the centre of the circle and yelling out "skaal," in chorus to the clang. The liquor was champagne in the old-fashioned, tall, narrow glasses; much was spilled at the skaal, and the sparkling of what remained in the glass was much abated. Then the Norsemen performed a curious exploit. They rested their glasses on the table, upraised their outstretched hands, and brought down the palms with a heavy thump upon the mouth of the glass. This was immediately followed by a superficial re-effervescence that covered the surface of the wine with a head of white foam.

I repeated the performance and studied the phenomena, and found that, when thus struck and pressed, the flesh of the palm bulged downward into the glass, and sensibly rested upon an elastic cushion of compressed air. It had acted like the pressing of a piston into a closed cylinder, and evidently drove some of the air into the liquid at its surface, where the new effervescence occurred.

These and other facts that might be specified justify the conclusion that the action of Markownikoff's little tubes mainly depends upon the little measure of air they contain, though in the abstract I have read (Journal of the Chemical Society, November, 1888, page 1,155) no such explanation is suggested.

The abstractor, B. Brauner, adds that he has tried the device, "and found it invaluable, especially for the distillation of concentrated acids."

I should add that a short capillary tube with one end closed retains the air it contains with curious tenacity, and that it is probably condensed therein very considerably by its adhesion to the walls of the tube. A larger tube thus filled with air and immersed in a liquid with mouth upwards, is speedily filled with the liquid, the air bubbling into the water. Not so the short capillary tube. Strive as you may you cannot fill it with water if dry air has once taken up its quarters within it.

THE MARINE ZOOLOGICAL STATION AT ALGIERS.

DR. CAMILLE VIGUIER gives in *La Nature* an account of this institution, interesting as being the first of the kind established on the Southern or African shores of the Mediterranean. It occupies a small plot of ground on the peninsula of the Admiralty, and the building is shown in the accompanying illustration (fig. 1), for which we are indebted to the courtesy of the publishers of *La Nature*. It has the disadvantage of a close proximity to the coaling-station of the navy, so that there can be no windows upon this side up to the level of the first floor. This deprives the laboratories of the north light, well known to be the most favourable for microscopic work, and compels the tanks to be placed on the south side. It has, however, the advantage of proximity to the city, and of thus enjoying a regular supply of fresh water and of gas. The water is at a pressure sufficient to rise to the level of the terrace. The gas is distributed throughout as a source of heat, and, if needful, of light, and it furnishes besides the motive force necessary to pump sea-water and to drive the small dynamo which ordinarily supplies light to the whole establishment. Sea-water is taken, in ordinary weather, from the open sea, and a rotatory pump forces it into two reservoirs on the terrace. Thus salt water is distributed throughout the station at a pressure which in the tanks of the basement exceeds one atmosphere.

Though thus supplied from the open sea, the station is in the harbour, sheltered from the waves, and boats can always be used, except in extraordinary weather. The fishermen already begin to bring in curious animals which they find, and which are not marketable, and probably in this way interesting specimens will be secured.

The building contains cellars, stores, the machinery, and on the south side a long sink which can receive tanks of all shapes, fed at will either with fresh or salt water. This room is sufficiently illuminated by lights made obliquely in the masonry, in which are lodged the large tanks of the ground floor. The tanks on the ground floor are about a cubic metre in size, and are attended to from without by means of an iron gallery, reached by stairs. They are protected by means of glazed frames shaded by blinds. These tanks, fitted with rock-work, like the external tank, are so transparent that it has been possible to photograph a new *Alcyonaria*. All the tanks can be illuminated from without by means of an arc lamp, which serves for microscopic photography. The first floor is devoted to laboratories and a library.

As the establishment has not been created for the amusement of the public, and as the tanks are destined merely for the service of the station, it was considered that four large tanks would be sufficient for observing the animals in almost normal conditions, and that it would be better to reserve the remaining space for tanks glazed on all four sides, in which specimens which it was desirable to have always at hand could be kept.

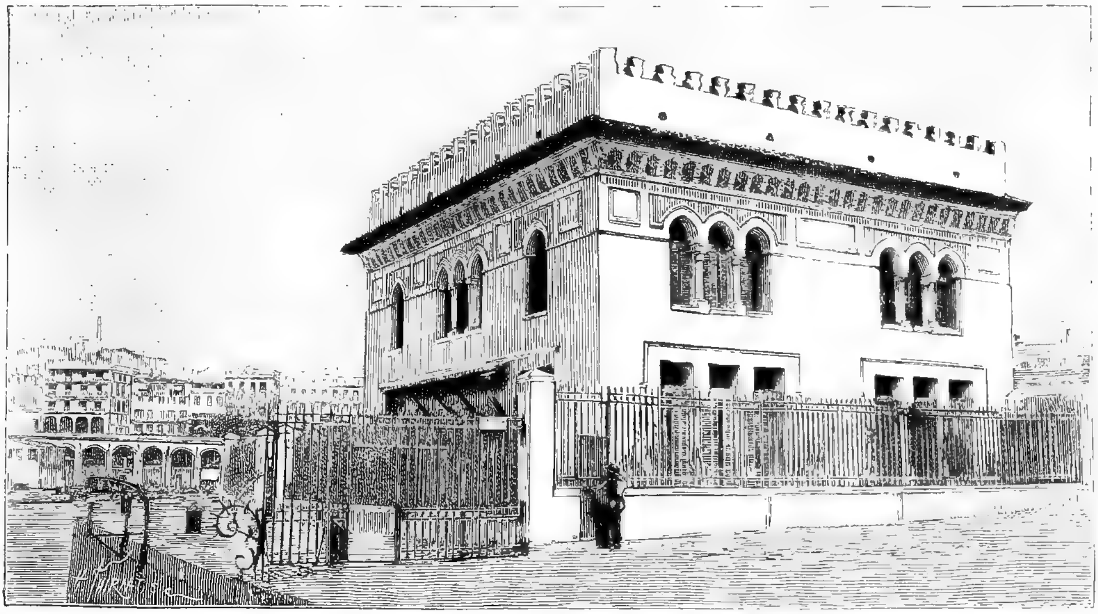

Fig 1.—Marine Zoological Station at Algiers.

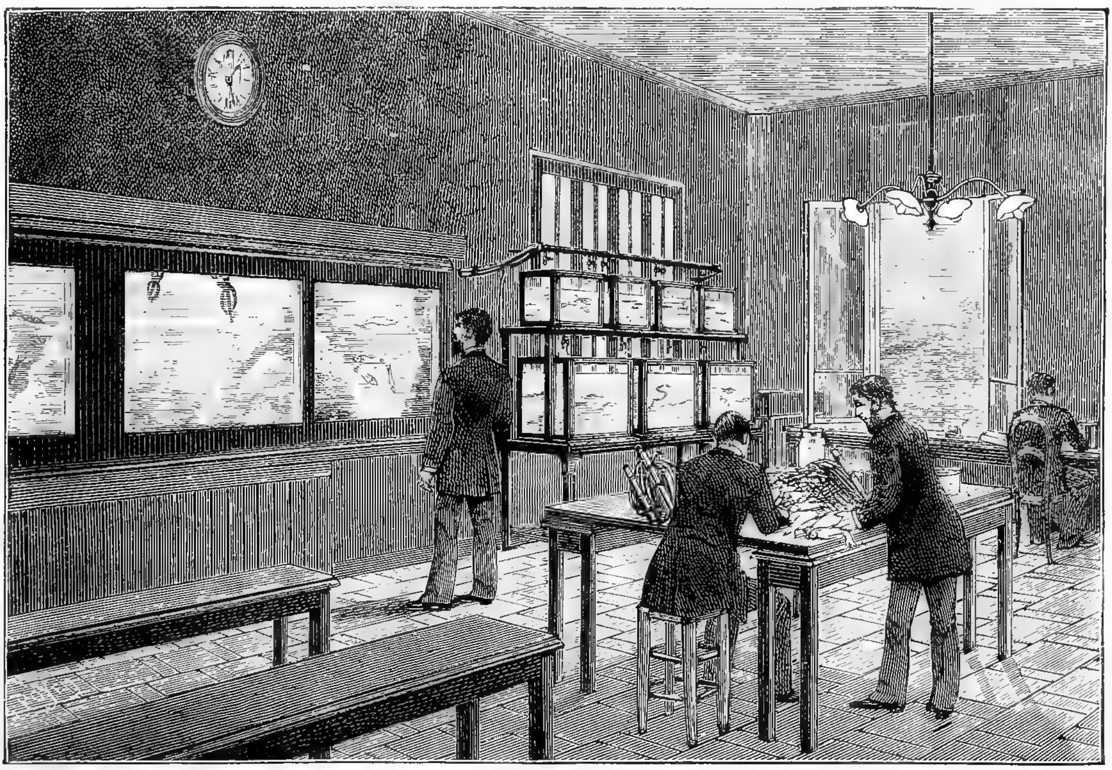

Fig 2.—Laboratory of the Marine Zoological Station at Algiers.

Fig. 2 shows the arrangement of these tanks, placed on iron frames in front of the large windows. The corners of the room, which are of course darker, are occupied by two stages of flat tanks. The large room on the ground floor, which serves also for a lecture-room and a laboratory, has a perfectly symmetrical arrangement. As the fresh-water fauna is still imperfectly known, each of the tanks on the west side may be fed either with fresh or salt water.

The outer tank of about eight cubic metres' capacity may serve, if needful, for animals of large size.

The reserves are entrusted to a small floating vivarium.

The laboratories of the first floor contain a long, flat sink, which are provided with two gas jets for heating a stove and a chafing-dish ; two cocks for fresh and salt water, both at sufficient pressure to work filter-pumps ; and two porcelain cocks for distilled water or alcohol. These sinks are fitted to receive small aquariums of from 60 to 80 litres, which a cart may take to the edge of the quay, and which may be lowered into the boat by means of a crane. The most delicate animals may thus be conveyed from the water's edge to the tanks in the station.

In each laboratory there is also a third gas jet for apparatus which may be needed on the work-table. Arrangements are being made to forward specimens and preparations to such naturalists as may require them for their studies.

ROMAN REMAINS AT LLANTWIT-MAJOR.

(Continued from p. 478.)

IN spite of the temptation to digress at this point, the plan of excavation was adhered to, and the trench was continued. A large fragment of a pillar was found, then

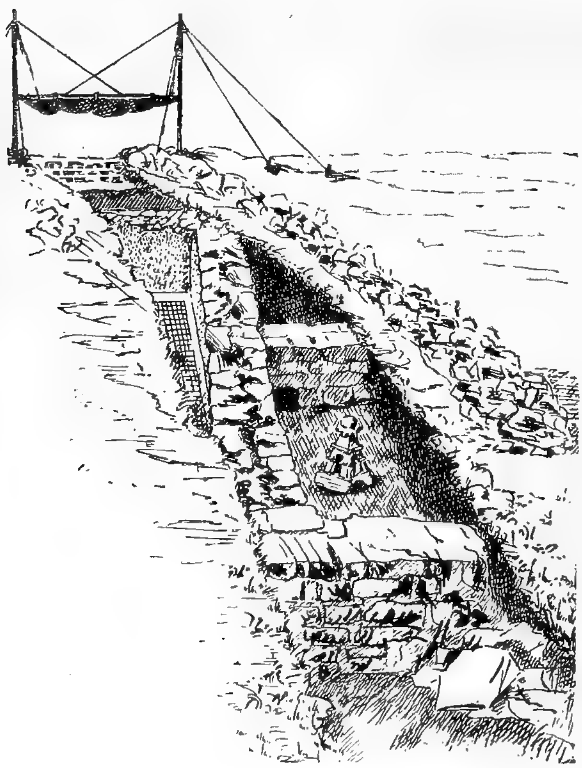

Fig. 2.—View of Trench.

the angle of the other side of the last wall, and a continuation of the longer wall from 27 to 44 feet, where another corner was observed, and in this, the third enclosed space, another fragment of a pillar, with ornamental base and many fragments of plaster, was encountered. In this way the trench work was continued, opening up two more enclosed spaces and passages, and yielding coins and a finial, among other articles and fragments of interest. At a distance of 54 feet from the third enclosed space a hypocaust was exposed for a length of 25 feet in the direction of the

Fig. 3.—Finial.

trench ; all the blocks of masonry and flues were very distinct, whilst at the entrance, on some steps, the skeleton of an old woman was found.

Our illustration (fig. 2) represents portion of the trench-work, showing the finial *in situ*, as discovered. Other points, such as the hypocaust at the end, the angles of walls, the bit of tesselated pavement, etc., will be readily distinguished.

The separate illustration (fig. 3) of the finial shows the ornamental character of this architectural fragment, and there can be very little doubt but that it formed part of an erection of considerable artistic pretensions.

The trench now extended some 300 feet, and in a period of a fortnight or so sufficient evidence had been brought to light to show that a Roman habitation of no mean degree lay hidden in that field at a depth of only a few feet; all the discoveries tended to support that view—the entrance-walls, the numerous rooms and passages, the tesselated pavement and the ornamental walls, the fragments of the pillar and finial, the extent of the hypocaust, etc.

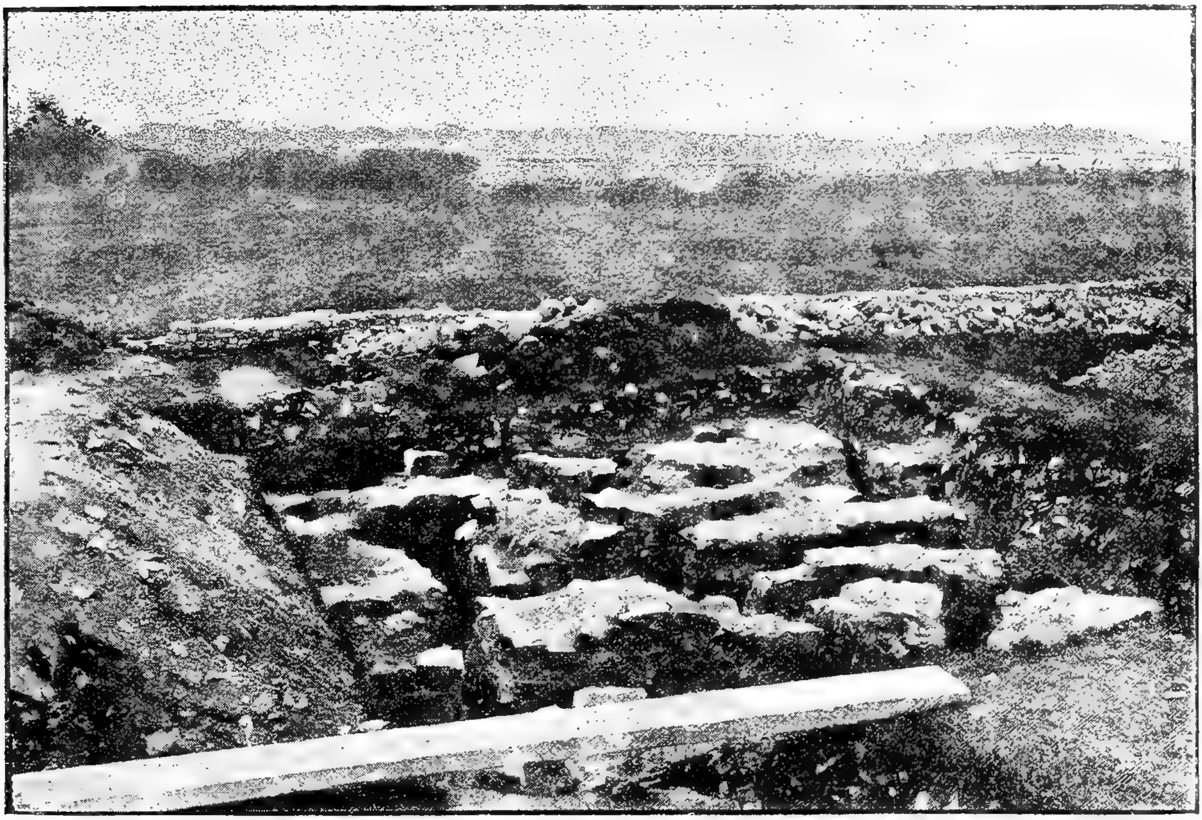

FIG. 4.—HYPOCAUST.

It will be a matter of no surprise that it was now determined to open up some of the treasures touched during the progress of the trench, and therefore excavations were continued in those places where enclosed spaces had been encountered. The bath, or hypocaust (shown in fig. 4), was found to be a chamber 22 ft. 9 ins. wide, and at least 25 ft. long, all the flues being in perfect condition, and in parts 2 ft. 6 ins. deep. The first enclosed space was found to measure 10 ft. by 16 ft., the second 27 ft. by 20 ft., with a large opening into another room, probably about 22 ft. square.

Long ere this stage had been attained the enthusiasm of many members of the Cardiff Naturalists' Society had been aroused, and some of the energetic members came to the assistance of Mr. Storrie in his interesting labours;

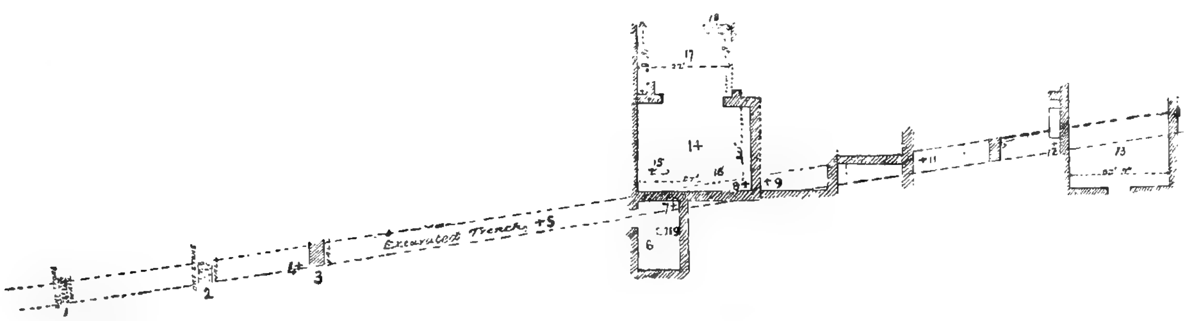

FIG. 5.—PLAN OF THE EXCAVATIONS. (Rough edges indicate sides of walls unexplored.)

among others, Mr. Progers and Mr. T. H. Thomas, the president of the Society, who had, *ex officio*, been a prime mover in the work, now came forward and excavated a good portion of the beautiful tesselated pavement, of which we give an illustration and description below, whilst Mr. J. Bell, C.E., drew the plans, and Mr. C. T. Vachell, M.D., looked after the business and legal matters. Owing to the joint exertions of these gentlemen on the occasion of our visit in September, things had assumed the stage of advance indicated in the following plan; the dotted lines show the course of the trench, whilst the various points of interest are numbered and duly indicated :—

1. First dry stone wall.
2. Second " "
3. Stone and mortar wall.
4. Urn of black pottery.
5. Part of bronze fibula.
6. First enclosure.
7. Part of quern.
8. Large portion of pillar.
9. Fragment of pillar with base.
10. Finial.
11. Coins.
12. Remains of old woman.
13. Hypocaust.
14. Second enclosure: room with tesselated floor.
15. Grave with human (female) remains.
16. Impression of horse's hoof.
17. Another room.
18. Graves with human remains.
19. Rectangular solid foundation.

(*To be continued.*)

THE PREVISION OF EARTHQUAKES.

UNDOUBTEDLY the attempts at foretelling destructive natural phenomena, such as tempests, floods, or earthquakes, meet with very general attention, but do not as a rule encounter either the confidence or the distrust which they merit. Hence it is required, in the interests of true science, that specialists—unpleasant as the task may prove—should undertake an examination of the data and the assumptions upon which such prophecies are founded. With especial reference to the last great earthquake in the Riviera, on February 23rd, 1887, Professor Hein takes occasion to undertake, in the *Naturforscher*, a thorough-going exposition of the notorious earthquake predictions of Falb.

At present geology distinguishes three kinds of earthquakes :—*Collapse earthquakes*, due to the subsidence of subterranean caverns, and felt over a very narrow space, are but of slight importance. *Volcanic earthquakes* are usually the forerunners of eruptions, and are, therefore, limited to volcanic territories. They never extend over wide regions, but the number of shocks is often very considerable. The *dislocatory* or *tectonic* earthquakes are the most common and the most important. Though without any direct connection with volcanoes, they agitate extended regions of the earth's surface, and take place along certain zones or lines of previously-existing displacements of the strata. Where such shocks are numerous, they occasion permanent displacements of the surface, which are even capable of measurement. As an example may serve, the triangular region Lägern—Rigi—Napf, in which the first-named point has moved nearer to the two latter by a metre (39 inches) in the course of the last thirty years.

Some time ago A. Perry, of Dijon, collected statistical evidence on earthquakes, and considered himself entitled to assert that these catastrophes occurred more frequently at new and full moon than at other times. This led him to the hypothesis of a tidal movement in the liquid interior of the globe, earthquakes being thus due to the action of a spring-tide. Though Perry himself subsequently ceased to advocate his hypothesis, it found a champion in Rudolf Falb, who considers all earthquakes as subterranean volcanic outbreaks occasioned by the attraction of the sun and the moon.

The only evidence advanced by Falb in support of his theory was of a statistical character, and this he does in a manner open to objections. Thus he ignores the great earthquake of Villach in 1348, which was unfavourable to his hypothesis. He also assumes that the earthquakes may occur from three to five days earlier or later, though the total interval between the times of their supposed maximum and minimum occurrence is only seven days. The same convenient liberty, we may remark, is claimed by those meteorologists who expect a change in the weather at the quarters of the lunation.

Further, since systematic observations of earthquakes have been collected, they have been found almost of daily occurrence. In the year 1880 fifty-nine shocks were experienced in Switzerland, and in the following year 166. From August 1st, 1870 to August 1st, 1873, there occurred in the Greek province Phokos 300 destructive shocks and 50,000 slight agitations. We may therefore assume, with a great probability, that in his earthquake statistics Falb has scarcely taken into consideration a thousandth part of the earthquakes which have occurred during the same time.

A discussion of the recent statistics of earthquakes shows in some groups no connection with the position of the moon. In other series there appears an excess of a few per cents. at full and new moon, as against the intermediate quarters. From the great frequency of earthquakes there can be found not merely slight but severe shocks, which agrees with Falb's supposition. But the same statistics show plainly that the moon is not the primary, nor even the secondary, cause of earthquakes. Its influence is restricted to facilitating by a small percentage the release of the tensions produced by other causes in the crust of the earth at the times of spring-tide.

Falb exaggerates the action of the tides of the earth's nucleus in another direction. The solid crust of the earth, he admits, is plastic enough to yield to a tidal wave of, at the outside, a foot in height, and to accommodate its form accordingly. This is evident, as the solid matter passes downwards into the liquid state, not abruptly, but by intermediate stages of a plastic character. Further, on Falb's hypothesis, the subterranean earthquakes must be the most common, and the shocks must proceed from a central point—both of which points are very rarely experienced. Lastly, the prediction of further shocks in a district which has been visited by destructive agitations is no particular proof of acuteness. It has long been known that every somewhat severe earthquake is heralded by some faint, often scarcely perceptible, shocks. Then comes the main convulsion as a group of shocks in rapid succession, followed for months or years by great agitation, until the disturbed strata have come to an equilibrium, and the threatening tensions in the regions concerned have entirely or chiefly disappeared. And these tensions in the earth's crust depend not on a tendency to subterranean outbreaks, but upon the subsidence of the crust upon a contracting nucleus.

THE MIRAGE AGAIN.—According to *Cosmos*, a most remarkable case of mirage was seen at St. Maurice (Valais) on October 11th last. There was seen—evidently in the night, though the exact hour is not given—the image of a splendid cathedral as if projected on a white cloud. Buttresses, bell-turrets, and the tower, with its lofty steeple, were all seen by several spectators during at least half an hour. Supposing that there is no exaggeration in the description, we have here a problem no less difficult than interesting.

General Notes.

University College, Liverpool.—Mr. Henry Tate has presented the sum of £16,000 to the council of this college for the erection of the library block of the college buildings.

The Value of Higher Education.—The following significant advertisement is quoted from the *Birmingham Daily Post*:—"2d. per hour. French, German, natural history, mathematics. Privately. University man. B.Sc."

Apiculture Abroad.—In Austria apicultural societies and publications receive subventions from Government to the yearly amount of 20,000 florins. In France similar aid is extended to the very modest figure of 43¼ francs!

Dr. W. Spottiswoode's Mathematical Works.—The mathematical papers of the late President of the Royal Society (Dr. W. Spottiswoode) are to be brought out in a volume. The task of collecting and editing has been deputed by Mrs. Spottiswoode to Mr. R. Tucker, the editor of Clifford's *Mathematical Papers*.

Contamination of Water.—Professor E. H. S. Bailey remarked at the last meeting of the American Association (quoted in *Popular Science Monthly*), that ammonia may be sometimes a natural constituent of waters and not indicative of any animal pollution.

Utilisation of Atmospheric Nitrogen.—Dr. Charles Marcel, of Ouchy, has offered the trifling prize of 1,000 francs for the best investigation of the use of atmospheric nitrogen in food. He who devises a practical means of fixing atmospheric nitrogen will gain millions, always supposing that he is not robbed of his invention.

An Indicator of Electric Currents.—A simple contrivance for showing whether or no a wire is traversed by an electric current is due to Mr. P. B. Delany. The instrument is a ring which can be worn on the finger and which contains, instead of a stone, a small compass. On approaching this ring to a conductor the needle indicates the passage of a current.

The Flying Machine.—Professor Joseph Le Conte thus summarises the prospects of these devices:—"A pure flying machine is impossible. All that we can expect—all that true scientists do expect—is a skilful combination of the balloon-principle with the true flying principle to make aerial navigation possible in moderately favourable weather."

Absence of Oxygen in the Sun.—From spectroscopic observations lately made at the Grand Mulets, on the ridge of Mont Blanc, M. Janssen, of the Academy of Sciences, concludes that oxygen does not exist in the sun's atmosphere in a state capable of producing the spectral manifestations which it gives in the earth's atmosphere. The spectral lines and bands of oxygen disappear the higher we ascend.

The Intermittent Lake of Carniola.—Herr Putik (*Popular Science Monthly*) has lately re-examined this lake in order to ascertain the cause of its periodical emptying and filling. An enormous cave, known as Karlovka, situate at the north-western angle of the lake, serves for the outlet of the overflow. It lies at the foot of a range of perpendicular rocks and leads to a chain of underground lakes, five of which Herr Putik has explored.

Origin of Human Fear of Darkness.—Dr. F. Oswald (*Popular Science Monthly*) points out the timidity of our "poor relations" after nightfall. "In the daytime the restless vigilance of the tree-man enables him to hold his own against his wiliest foes. But after sunset the owl-eyes of the prowling Felidæ give them a fatal advantage, and the instinct of *night-fear* may thus deeply and perhaps indelibly have impressed itself upon the mental organism of our forefathers."

Royal Institution of Great Britain.—At the general monthly meeting held on Nov. 5th, Sir James Crichton Browne, M.D., F.R.S., vice-president, in the chair, Mr. Amand Routh, M.D., was elected a member. Seven candidates for membership were proposed for election. The special thanks of the members were returned for the following donation to the fund for the promotion of experimental research:—Mr. Lachlan Mackintosh Rate, £50.

The Heat of the Sun.—According to recent observations the heat of the sun at any given place is not constant, but is liable to considerable variations. In 1883, from the beginning of July to the middle of August there was an increase of heat of 6 per cent.; from then to the middle of September a decrease of 8 per cent.; from the middle of September to the middle of October there was little change. At the beginning of June, in September, and in October, the sun was covered with a great number of spots. In August there were much fewer spots. The solar heat seems to vary inversely as the number of spots.—*Astronomie.*

The Distance of the Sun.—The results of the American observations of the last transit of Venus, in 1882, have been tabulated and summarised by Professor Harkness. Ten stations of observation had been established in the United States, and 1,472 photographs of the transit had been taken. The mean of the results gives the parallax as 8·847 min.; that is, the mean distance of the earth from the sun is about 92,385,000 statute miles. Professor Newcomb had, 20 years ago, estimated the parallax at 8·848 min.; and the American astronomers estimate the possible error at not more than 130,000 English miles.

The Late Mr. Richard A. Proctor.—A petition, which has already been extensively signed by some of the most distinguished men in science and literature, is being drawn up to the First Lord of the Treasury in favour of the claims of the widow and children of the late Mr. Richard A. Proctor to a pension under the Civil List in consideration of Mr. Proctor's services to science and to the popularising of science. Mr. Proctor left a family of six children by his first wife and two by his second. The total resources of his widow are stated to be not more than £150, and one of his sons suffers from an incurable hip disease.

Mirages.—On July 15th last, about 11 a.m., at Hudikwall, on the Baltic, a great number of spectators saw in the fields a singular effect of mirage. They perceived a ship capsizing in a sea which was fearfully agitated, and a large boat just leaving her. The apparition was visible for about five minutes. In the beginning of August, according to the Austrian papers, there was observed at Vidorec, near Warasdin, an extraordinary mirage in the vast plains surrounding this locality. There were distinctly seen numerous divisions of infantry going through evolutions at the command of a leader of lofty stature. This phenomenon lasted several hours during three successive days. Inquiries were made if any divisions of infantry had been manœuvring at a distance, and if these evolutions had been rendered visible at Vidorec by a mirage, but nothing of the kind could be ascertained.

The Municipal Laboratory in Paris.—In this useful institution there have been examined and condemned in 1887, as unfit for human food, 165,410 kilos (the kilo = 2 lbs. 3 ozs.) meat and fish; 446,900 kilos of vegetables and fruit; 14,500 kilos preserved fruits and fruit-juices; 123,325 kilos mushrooms and tomatoes. Whilst in July, 1886, of 100 samples of beer examined, 55 were found sophisticated with salicylic acid, and in December of the same year 7 per cent., last year the proportion of adulterated samples had fallen to 3 per cent. In milk there is also an improvement. In 1886, 23 per cent. of the samples were found to have been watered, but last year only 21 per cent. The case is worst with wines. Of the 7,295 samples tested, only 3,071 were found pure. The residue—more than one half—had been either watered, "plastered," or mixed with salicylic acid, colouring matters, etc.

Refining Silver by Electricity.—According to the *Chronique Industrielle*, the method of Moebius for refining silver by electricity is being brought into extensive use. It is especially suitable for the treatment of auriferous silver containing about 11 per cent. of gold. The expense is about $1\frac{2}{8}$ franc per kilo. Moebius employs in an ordinary electrolytic bath anodes of argentiferous matter, and a thin plate of pure silver as cathode. The bath is a weak solution of nitric acid at 1 per cent. The anodes, which are about 12 millimètres in thickness, are placed in muslin bags, which retain the gold, platinum, peroxide of lead, and other foreign bodies contained in the matter. The current employed is of 150 ampères, with a difference of potential between the plates of one volt. During the whole operation brushes pass and repass over the surface of the cathode, and cause the silver deposited to fall to the bottom. If the matter contains copper, it dissolves in the nitric acid, but it is not deposited upon the cathodes.

Great Ocean Depths.—Her Majesty's surveying ship *Egeria*, under the command of Captain P. Aldrich, R.N., has, during a recent sounding cruise and search for reported banks to the south of the Friendly Islands, obtained two very deep soundings of 4,295 fathoms and 4,430 fathoms, equal to five English miles, respectively, the latter in latitude 24° 37′ S., longitude 175° 8′ W. the other about twelve miles to the southward. These depths are more than 1,000 fathoms greater than any before obtained in the Southern Hemisphere, and are only surpassed, as far as is yet known, in three spots in the world—one of 4,655 fathoms off the north-east coast of Japan, found by the United States steamship *Tuscarora;* one of 4,475 fathoms south of the Ladrone Islands, by the *Challenger;* and one of 4,561 fathoms north of Porto Rico, by the United States ship *Blake*. Captain Aldrich's soundings were obtained with a Lucas sounding machine and galvanised wire. The deeper one occupied three hours, and was obtained in a considerably confused sea, a specimen of the bottom being successfully recovered. Temperature of the bottom, 33·7 deg. Fahr.

Secular Depression of Land in France.—A long series of observations has been carried out all over France since the year 1884 for the purpose of detecting any variations of level of the land. These observations have been conducted by men belonging to the Génie corps under specially selected officers. The result of this series of observations is most important. It would appear that a secular depression from south to north is in progress. While on the coast of the Gulf of Lyons no alteration of level has been noted, on the line between Marseilles and Lille, a stretch of 820 kilomètres, the ground is sinking towards the north at the very serious rate of three centimètres yearly. It is noteworthy that the direction of the sinking is complicated; it is about three times greater towards the north-east than in the direct line from south to north. The rate along the line of the meridian is about one millimètre yearly on every 27 kilomètres; whereas it is one millimètre on every ten kilomètres in a north-easterly direction. Should this rate of depression continue, north-eastern France would in the course of a few centuries encounter a calamity similar to that which, at the end of the 13th century, befell the Netherlands.

The Public Health.—The Registrar-General's return for the week ending November 3rd shows that the deaths registered during that period in twenty-eight great towns of England and Wales corresponded to an annual rate of 19·6 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The six healthiest places were Brighton, Birkenhead, Derby, Nottingham, Portsmouth, and Halifax. In London 2,373 births and 1,613 deaths were registered. Allowance made for increase of population, the births were 534, and the deaths 27, below the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had increased in the six preceding weeks from 15·8 to 21·2, declined again last week to 19·7. During the first five weeks of the current quarter the death-rate averaged 19·2, and was 0·1 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,613 deaths included 1 from small-pox, 88 from measles, 24 from scarlet fever, 32 from diphtheria, 19 from whooping-cough, 22 from enteric fever, 34 from diarrhœa and dysentery, and not one from typhus, ill-defined forms of fever, or cholera; thus, 220 deaths were referred to these diseases, being 19 above the corrected average weekly number. In Greater London 3,124 births and 2,025 deaths were registered, corresponding to annual rates of 29·5 and 19·1 per 1,000 of the estimated population. In the outer ring 11 deaths from measles, 10 from diphtheria, and 10 from diarrhœa were registered. Measles caused 5 deaths in West Ham and 2 in Leyton sub-districts; and 2 deaths from diphtheria were returned in Croydon, in Kingston, and in Tottenham sub-districts.

ON VERNATION AND THE METHODS OF DEVELOPMENT OF FOLIAGE, AS PROTECTIVE AGAINST RADIATION.

A Paper read by the Rev. George Henslow, M.A., F.L.S., F.G.S., before the Linnean Society, and Reprinted from the Journal by permission of the Society.

In his work on "The Movements of Plants," Mr. Darwin says:—"The fact that the leaves of many plants place themselves at night in widely different positions from what they hold during the day, but with the one point in common, that their upper surfaces avoid facing the zenith, often with the additional fact that they come into close contact with opposite leaves or leaflets, clearly indicates, as it seems to us, that the object gained is the protection of the upper surfaces from being chilled at night by radiation."*

He furthers adds† :—"We exposed on two occasions during the summer to a clear sky several pinned-open leaflets of *Trifolium pratense*, which naturally rise at night, and of *Oxalis purpurea*, which naturally sink at night (the plants growing out of doors), and looked at them early on several successive mornings after they had assumed their diurnal positions. The difference in the amount of dew on the pinned-open leaflets and on those which had gone to sleep was generally conspicuous; the latter were sometimes absolutely dry, whilst the leaflets which had been horizontal were coated with large beads of dew. This shows how much cooler the leaflets freely exposed to the zenith must have become than those which stood almost vertically, either upwards or downwards, during the night.

"From the several cases above given there can be no doubt that the position of the leaves at night affects their temperature, through radiation, to such a degree that when exposed to a clear sky during a frost it is a question of life and death."

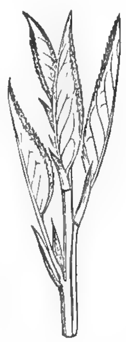

Fig. 1.—Portugal Laurel.

It is the object of the present communication to show that many, perhaps the majority of, leaves as they develop on the expansion of buds in spring assume the same positions as leaves of those particular plants which are remarkable for sleeping at night, and appear to exhibit a similar care, but in a more perfect way, in protecting the upper surfaces; and the inference to be drawn from all the phenomena presented by young growing leaves, as it seems to me, is the same, namely, to shield their upper surfaces especially from injury caused by radiation—viz., chill and desiccation. Moreover, it is not an unusual thing for the young leaves only to be subject to hypnotism, the older ones ceasing to rise and fall by day and night: thus Mr. Darwin mentions *Melilotus* as an instance; and I find it is the same with the French Bean. Lastly, experiments made to test this theory are decidedly corroborative.

Vernation, as explained and illustrated in text-books on botany, and on page 33 of this volume of Scientific News, is solely concerned with the various methods by which the rudimentary leaves are folded up in the buds of different plants; and the internal wooliness, as well as external resinous matters, etc., are usually regarded as being safeguards against injury to the buds within from the severity of winter weather. Beyond that surmise I am not aware that any attempt has ever been made to offer any *rationale* of the processes of vernation; nor has any one noticed the special behaviour of developing leaves and stipules, as well as of the axes and petioles which support them. If, however, we keep in view the two assumed objects—first, the securing an erect or dependent position of the blades so as to place their surfaces in a plane at right angles to the surface of the earth; and secondly, the protection of the upper surfaces,—it will be seen how various are the efforts of nature to secure these two ends during the period of development, and while the young leaves and shoots are succulent and delicate, such being only too readily, and often severely, injured by the cool nights, sharp frosts, and cutting winds of spring, at the very time when the buds are expanding. The various methods of protection are more perfect than in sleeping plants, inasmuch as the young leaves are more delicate than when adult. Testing the effects of desiccation by the heat of the sun, I found that when young clover-leaves, naturally conduplicate, were forcibly spread out with the upper surfaces exposed to the sun for twenty minutes, the edges soon curled inwards, and they lost 37·2 per cent. of weight. Those spread out with their under surfaces exposed remained flat, but lost 43·2 per cent. of weight in the same time, *i.e.*, rather more than the preceding. In all experiments with clover-leaves exposed at night, I found the differences were not so pronounced as in many other plants.

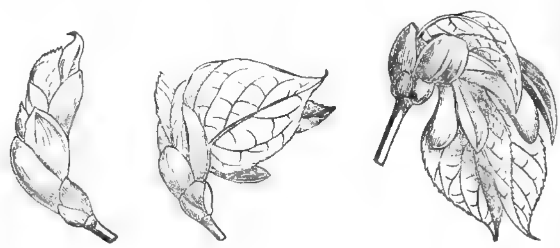

Fig. 2. Fig. 3. Fig. 4.
The Lime in Different Stages of Development.

In observing the effects of frost upon delicate leaves one sees that they are especially injured along the margins; and, moreover, where so affected, they are more or less dried up. The first fact gives a significance to the revolute and involute kinds of vernation, in which the margins are rolled outwards and inwards respectively. This led me to suspect that whenever leaves suffered from radiation not only was there a reduction of temperature, but a loss of moisture would seem to accompany the loss of heat. A similar loss of moisture would occur by desiccation, in consequence of cool dry winds, and must be equally guarded against. If this were so, then the balance would indicate the loss. With this object in view, I weighed a number of undeveloped leaves together of several plants, and made two groups of each, selecting leaves as nearly like as possible for each group of the same plant. I, then, following Mr. Darwin's method, fixed all of one group with their upper surfaces exposed upwards with card-clips, such as are use by entomologists for spreading out the wings of butterflies; the other group of leaves were laid on cork,

* P. 284.
† Pp. 293, 294.

with their leaflets naturally conduplicate or otherwise protected as in nature. In the morning I weighed each group again, and reduced their losses to percentages of the original weights of each group respectively. I found that there was in every case a generally much greater loss in the case of the leaves artificially exposed than with the others, as will be seen from the following examples :—

		Loss p. c.		Loss p. c.
Laurustinus,	exposed naturally	8·7.	Spread out,	18·7
Portugal Laurel	,, ,,	8·4	,, ,,	12·6
Lime	,, ,,	4·5	,, ,,	21·4
Laburnum	,, ,,	14·8	,, ,,	33·0
Ash	,, ,,	2·3	,, ,,	11·8
Rose	,, ,,	10·6	,, ,,	17·6
Periwinkle	,, ,,	5·0	,, ,,	12·05
Clover	,, ,,	24·4	,, ,,	29·3
Walnut	,, ,,	18·7	,, ,,	24·6

Very few nights of the month (May, 1885) were frosty, so that several attempts to carry out experiments were unsatisfactory, as so many nights were cloudy, windy, and stormy, and ill-suited for radiation ; yet on one occasion, when about three degrees of frost occurred, the Walnut, Lime, and Laburnum leaves when spread out showed to the eye unmistakable injury; whereas these three kinds of leaves, placed as they occur on the trees, did not appear to be hurt. Other leaves treated in the same way and subjected to the same slight frost did not *appear* to have suffered ; but I had not at that time thought of weighing them.

I will now add a selected series to illustrate the various methods adopted whereby the young and developing leaves are protected from injury by radiation.

I. Simple Leaves. (1) Opposite : (i) *erect.*—This position is assumed in all cases of opposite leaves which I have had an opportunity of examining. The leaves face one another with their upper surfaces more or less in close contact, concealing the bud between them. In shrubby Veronicas and Hypericums and Periwinkle the leaves are almost, as it were, glued together, so firmly do they cohere all round the margins. In others, such as *Aucuba* and *Laurustinus*, they are more slightly adjusted. The only exceptions that I have met with were Snowberry, *Weigela*, Honeysuckle, and the leaflets of the Elder, all being of the same family, Caprifoliaceæ.* The pairs of leaves had their edges involute, and one of each pair slightly embraced the opposite leaf, and so wrapped up the bud within it.

(ii.) *pendulous.* I have not met with any instance of opposite leaves being pendulous in the young state.

(2) Alternate : (i.) *erect.*—Good examples may be seen in the Common and Portugal Laurels (fig. 1). As the upper surfaces of different leaves cannot be in contact, issuing from separate nodes and at different elevations, each leaf is conduplicate, *i.e*, the two halves of the blade are folded together and thereby press their upper surfaces of the halves against one another; indeed, so tightly is this done, that it is not at all easy, in many instances, to separate them. It may be noted here that the conduplicate vernation is an extremely common one both for simple and compound leaves, and the significance of it will be now very apparent. It is sometimes further complicated by having the surfaces plicate, as in the Vine, Beech, Maple, Currant, Raspberry, etc., conditions which are probably additional safeguards against radiation.

* I first discovered this difference in *Weigela*, and that led me to examine the others, which revealed the fact that this peculiar form of vernation is an ordinal character.

As other instances of the erect position may be mentioned Rhododendron, the leaves of which, as of the Dock and Primrose, are revolute ; but those of the Violet, Pear, and Michaelmas Daisy are also erect but involute, while the Cherry has them convolute. In all these the undeveloped leaf is cylindrical or an elongated cone, erect, and offers no extent of surface, while the margins, the most sensitive parts, are specially protected.

(ii.) *pendulous.* The Lime, Hazel, and *Ampelopsis Veitchii* are good examples. In the case of the Lime, as soon as the bud expands and escapes from the winter (stipular) scales, the inner stipules develop considerably : those on the upper side are concave and ovoid and cover the upturned edges of the conduplicate leaves, which at once take a position in a vertical plane ; the stipules at the sides elongate much more than the former, furnishing some lateral protection to the whole bud, which now curves strongly downwards, and somewhat resembles a mussel in shape (fig. 2). As the bud continues to develop, the branch becomes more and more strongly curved downwards, so that the leaves are held vertically (figs. 3 and 4) ; and as the lower and older ones increase in size, they assume a horizontal position and undertake to protect the younger ones, which are concealed beneath them. Thus the protecting care is handed on to each leaf as it arrives at maturity, until the whole series are developed and the branch and leaves become horizontal.

(To be continued.)

WATER AS A CONSTITUENT OF ORGANIC SUBSTANCES.

WATER, says Dr. Whitelaw, forms three-fourths of the weight of living animals and plants, and covers about three-fourths of the earth's surface. Professor Chaussier dried the body of a man in an oven, like a brick in a kiln, and after desiccation the body weighed only twelve pounds. Rather more than a pound of water is exhaled daily by the breath, about $1\frac{3}{4}$ lbs. by the skin, and $2\frac{3}{4}$ lbs. by the kidneys, making the daily emissions of water by the body about $5\frac{1}{2}$ lbs., or not quite three quarts. The following is the percentage of water in some well-known articles :—

Wheat	15	Mangel wurzel	85
Barley	15	Cabbage (leaves)	92
Oats	16	Cabbage (stem)	84
Rye...	12	Mushroom ...	96
Rice	13	Fungi	86 to 95
Beans (field)	15	Potato	75
Beans (kidney)	23	Water melon	94
Peas...	14	Cucumber ...	96
Turnips	88	Vinegar plant	95
Carrots	83	Wheat flour	13 to 16
Rye flour	14	Cocoa	5
Barley flour	14	Manna	10
Indian corn flour	14	Figs...	21
Oatmeal	14	Plums	75
Wheat bread	44 to 48	Apples	80
Rye bread ...	44 to 49	Gooseberries	80
Cane sugar ...	5	Peaches	75
Linseed cake	10	Egg (entire)	74
Flesh	77	Milk	87
Skin	58	Blood	79 to 83
Bones (variable)	7 to 20	Gastric juice	97
Beef	74	Trout	80
Veal	75	Pigeon	79
Mutton	71	Cheese	40
Haddock	82	Brandy	56
Sole...	79	Whisky	47
Tea ...	5	Rum	30
Coffee	12	Beer	90

Natural History.

OFFICINAL RHUBARB AND GARDEN RHUBARB
(Rheum Officinale and Rheum Hybridum).

In adapting from our esteemed contemporary *Cosmos* an account of these two plants, we shall be compelled to rectify a few errors as far as garden rhubarb is concerned.

The medicinal or so-called Turkey rhubarb has been cultivated in Europe for some time, but long previously its root had been used as a tonic and purgative. All that was known about it in former days was that it was imported from Asia, and especially from China, in the form of irregular woody fragments. The Russian Government acquired a monopoly of this drug. Their commissioners, established at Kiachta, on the Chinese frontier, bought all the roots, and selected the finest for transmission to Europe, where they were sold under official supervision. Hence the Russian rhubarb is still highly esteemed in the drug trade. Since 1863, however, this monopoly has come to an end. The rhubarb is generally

met with in rounded fragments of a rather pure yellow. It broken, the fracture is marked with red and white veins. Its odour is powerful, and its taste bitter. It crackles under the teeth, and colours the saliva yellow. The lumps are pierced with holes, in which small fragments of gut-cord are often found. When the crop is gathered the lumps are strung on a cord, like a chaplet of beads, and are dried in the sun. In certain villages.

they are suspended between the horns of goats. Two other species of rhubarb are known in commerce—those of China and Persia. But there are upwards of a dozen species of *Rheum* which might yield the medicinal product, and it is remarkable that up to the last century no one knew exactly which species was preferable.

Boerhaave made some important experiments on this subject. He procured the seeds of various species of *Rheum*, and sought out the one whose roots resembled most nearly the kind employed in medicine. It is now established that this kind is the *Rheum officinale*, a native of Eastern Thibet and Western China. It is a herbaceous plant, with strong branching roots and large, broad, palmated leaves, green above and whitish below. The flowers are produced in terminal pannicles of a yellowish white. The aërial stems, and not the roots, of the plant yield the true Chinese rhubard.

According to Dr. Thorel, the genuine rhubarb is found chiefly among the high mountains of Thibet. The plant grows vigorously only on the borders of the snow-line, at altitudes of about 12,000 to 13,000 ft. The Lamas, perceiving the considerable profit to be derived from the trade in this plant, endeavour to seize possession of it. They declare that the root has a sacred character. The harvest is conducted with very peculiar ceremonies, and it concludes with terrible imprecations against all who trespass on the sacred ground until the next harvest. But it appears that, in spite of these solemn prohibitions, both Thibetans and Chinese plunder the forests, caring little for the imprecations of the Grand Lama.

In 1867 the Paris Société d'Acclimatation received from Thibet a chest containing roots of the precious plant. It has since been cultivated, and has been the subject of interesting observations, but its medicinal properties are enfeebled in our climates.

It might be an interesting experiment to try the cultivation of the medicinal rhubarb in the higher regions of the Alps or the Pyrenees.

The *Rheum hybridum* is largely cultivated as an article of food in Britain and in the United States, bearing in the latter country the name of "pie-plant." *Cosmos* asserts that the early leaves, mixed with a little sorrel to heighten the flavour, are used as a vegetable, and are considered equal to spinach.

We have only heard of one instance of rhubarb-leaves being eaten in England. A family had been beguiled by an indiscreet newspaper paragraph into trying this spring vegetable. The results were serious, as the leaves of rhubarb contain oxalic acid!

The writer goes on to say that the leaves are utilised in this manner during the months of April and May, whilst after May they are used as a material for tarts. He also ventures to assert that such tarts have a finer flavour than that of the green gooseberries so much admired in Northern France, Belgium, and England.

Every one knows that the flavour of rhubarb is coarser than that of green gooseberries, and that it quickly disappears from the markets and shops after the latter have come into season.

The leaves of rhubarb, which are not eaten, may, it is said, be boiled with potatoes and bran and given to pigs.

We may add here a brief notice of the other uses to which the rhubarb plant may be turned. In the manufacturing districts of the North, where rhubarb is cultivated on a larger scale than in any other part of England, the leaves are sometimes used in setting indigo vats for woollen dyeing, as an aid to fermentation. For this purpose the leaves are collected together, pressed, and used under the name of woad. It must be remembered that in modern days the true woad is not used on account of the trifling amount of indigotine which it develops, but merely as an aid to fermentation. Many experienced and successful blue dyers would not know whether they were employing woad or rhubarb-leaves.

A less legitimate use for these leaves is said to take place in the manufacture of tobacco.

Had it not been for the triumphant introduction of the coal-tar colours, the root of rhubarb would have been extensively used in the manufacture of dyes. By treatment with nitric acid it may be made to yield fine rose, crimson, purple, and brown shades. But as these dyes were unable to compete with the coal-tar colours, either in beauty or in price, they have fallen into complete forgetfulness.

The Influence of Sunlight on Trees.—In the latest report of the head of the Forestry Department of the United States reference is made to the effect of light on the growth of various trees. It is well known, says Professor Fernow, that light is necessary for the development of chlorophyll, and, therefore, for the life of all green plants, and especially for that of trees. The heat alone which accompanies the light is not sufficient, although the relative influence of the light and the heat on the growth is still an open question, as well as the relative requirements in light of different species of trees. In the case of forest weeds, which in forestry serve as an indication of the amount of shade which the trees exert, and with that their capacity of impeding evaporation, some require full sunlight for their development, others are averse to a high degree of light. To this must be due the change in the plants of a district when its forests are removed. Then the amount of light or shade needed is modified by site. Where the sunlight is strong, in higher altitudes, drier climates, or where the growing season is longer, or there are more sunny days, some species will endure more shade. The flora of high altitudes in general requires light. Trees nearly always develop best, in other words make most wood, in the full enjoyment of light, but their capacity of developing under shade varies greatly. The yew will thrive in the densest shade, while a few years overtopping kills the larch; the beech will grow with considerable energy under partial shade, where the oak would only just keep alive and the birch would die. When planted in moist places, all species are less sensitive to the withdrawal of light. In the open, maples, elms, sycamores, and others grow well and make good shade trees, in a dense forest they thin out and have but scanty foliage. Conifers, such as spruces and firs, which preserve the foliage of several years, have perhaps the greatest capacity of growing under shade, and preserving their foliage in spite of the withdrawal of light. In America sufficient *data* to group the forest trees according to the amount of light required by them have not yet been collected, but rules based on experience have long been formed in Germany, where the behaviour of trees under different conditions of light has been carefully studied. It has been found, for instance, that on the same branch those leaves which are developed under the full influence of sunlight are not only larger and often tougher in texture, and thicker, but that they have a larger number of stomata or breathing pores than those less exposed to light. The whole subject is one of the utmost importance in forestry, and observations and experiments are to be carried out in regard to it in the United States.

THE SAND GROUSE.—In *Humboldt* we find it stated that hitherto not a single case of this immigrant bird having produced young in Germany has come to light. Some alleged instances proved on examination to be merely partridges, or—more frequently—corn-crakes. The fact that these birds have throughout the season been seen in flocks is a proof that they have not paired.

DOCILITY OF THE FIELD-MOUSE.—According to a friend, the field-mouse is much more easily domesticated than the house-mouse. The latter seems to have an inborn, hereditary shyness which can only be eliminated by prolonged care and kindness. The field mouse on the contrary, becomes tame in a few days, and can soon be liberated for a temporary run in the garden, after which it readily returns to its owner.

SUICIDE OF SCORPIONS.—M. Serge Noirkoff, of Constantinople, writes to *La Nature* as follows:—"Having heard that the scorpion puts an end to its life if it finds itself in danger without the prospect of escape, I caught half-a-dozen of these creatures and tried the experiment. I arranged upon the ground glowing charcoal so as to form a circle to which there was no outlet. The scorpion was placed in the centre of the circle, which was so wide that it would not be incommoded by the heat. Finding itself surrounded by fire, the animal began by searching for a road to escape. Its movements, slow at first, became finally a frantic race along the circumference of the circle. It then retired to the centre, and put an end to its life by plunging its sting into its back, and in a few seconds expired with convulsive movements. The five other scorpions were then tried successively, each time with the same result."

COMPARATIVE PSYCHOLOGY.—Dr. F. L. Oswald (*Popular Science Monthly*), in a very able article, disfigured, however, by the Cuvierian title, "Four-handed Sinners," remarks that "every step in the progress of comparative anatomy has more plainly demonstrated the fact that the alleged contrasts in the construction and the functional characteristics of human and (lower) animal bodies are mere differences of degree, and a similar conclusion must force itself upon the unprejudiced observer of animal soul functions."

ANIMAL NOTIONS OF TIME.—Dr. A. S. Hudson, writing to the *Popular Science Monthly*, refutes the contention that, *e.g.*, dogs distinguish the recurrence of Sunday not by counting the days, but by perceiving certain peculiarities in the movements about the house, etc. Dr. Hudson mentions a herd of five cows to which salt was always given every Sunday. On that day, accordingly, they always collected at the gate, waiting for the customary dole. Now, the field where they grazed was remote from the house, isolated from the outer world, and away from any thoroughfare. From week to week, and from month to month, they saw no person except the man who milked them, and had no conceivable means of distinguishing Sunday—to them salt-day—save by the lapse of days.

THE PROBOSCIS OF THE ELEPHANT.

WE need not dwell upon the mingled strength and flexibility of the elephant's trunk, which are sufficiently illustrated by anecdotes familiar to every child. The internal structure of this marvellous organ is less generally known, and the very few who have had an opportunity of dissecting it are by no means agreed as to the meaning and use of some of its arrangements. A cross-section of the trunk is triangular near the base, elsewhere rounded. The side next to the mouth is flattened. Towards the middle of the section, but a little nearer the front than the back surface, are seen the cut ends of two tubes side by side. These are the nostrils, which are lined by a thick yellow layer, upon which is spread a thin, moist, and sensitive mucous membrane Many small muscles radiate outwards from the nostrils connecting them with the skin, while transverse muscular fibres pass across from side to side, between and behind the nostrils. Lastly, a great number of longitudinal or semi-spiral muscles enclose the others, passing to the skin at various points. Thus there are muscles to shorten and thicken the trunk, muscles to narrow and lengthen it, and muscles to bend it to any side. Moreover, the great number and independence of these muscles allow of one portion being bent to the right while another is bent to the left, and so on. It is said that there are 30,000 to 40,000 separate muscles in the whole organ. The tip of the trunk has a prehensile and muscular finger.

The trunk of the elephant plainly represents the nose united to the upper lip. In some other quadrupeds, *e.g.*, the elephant-shrew of Africa, the nose is drawn out in almost the same proportion as in the elephant, but here it is the cartilages of the nose which are prolonged, while in the elephant the cartilages have no very unusual development, but an immense addition of muscular and membranous tissues is made to the extremity of the proper nose. The snout of the tapir has somewhat of the same structure as that of the elephant, though it is but slightly developed in comparison. The muscular and membranous elements in particular are greatly foreshortened.

The primary function of the proboscis in the elephant is obviously to bring food to the mouth. The short neck does not allow the mouth to reach the ground while the animal stands erect. Why should the neck be so short? Because it is loaded with heavy tusks and grinders. The tusks alone have been known to weigh 300 lbs. If we try to imagine a long-necked elephant, we are compelled to clothe its neck with an absurdly copious mass of muscle and ligament. The great bulk of the animal magnifies out of all direct proportion the mechanical difficulty of supporting the head. (See an article on "Some Effects of Difference of Size," SCIENTIFIC NEWS, vol. i., p. 202.) The true sequence seems to be—(1) heavy teeth and tusks in an animal of gigantic bulk; (2) short neck; (3) proboscis, long enough to reach the ground.

The attachment of the muscular roots of the proboscis requires an unusual extent of cranial surface, and the forehead of the elephant is of necessity immensely wide and high. But the brain is by no means large in proportion. A rough estimate shows that the elephant's brain weighs only about 1-1,000th of the total weight of the body, whereas in a harvest mouse the proportion is 1-20th. So rapidly do the strength and weight of the driving machinery increase with increased bulk! Although the elephant's skull must be unusually extensive externally, its internal cavity is only of moderate size, far below the proportion obtaining in small quadrupeds. This disparity between the external and internal surfaces of the skull is reconciled in an interesting way. Were the intermediate space to be filled with ordinary bone, the elephant's skull, which (exclusive of the tusks and teeth) already weighs something like 200 lbs., would become, at a guess, nearly as heavy again. In place of solid bone, a number of large air-cells, separated by slender walls of bone, occupy the interval between the inner and outer tables of the skull. It is interesting to notice in a divided skull how the direction of the thin partitions is varied, so as to offer the most effective resistance to pressure at every point, without an atom of needless substance.

A number of observers with good opportunities, and presumably competent, such as Sir Emerson Tennent, Gordon Cumming, and others, have described the power which the elephant possesses of ejecting large quantities of water from the trunk. Sir E. Tennant represents that this is accomplished by placing the proboscis in the mouth, and thence withdrawing gallons of water. Where the water comes from, and how it is regurgitated, are questions upon which anatomy throws hardly any light. The cardiac end of the stomach, it is true, exhibits a number of transverse folds, which have been supposed to act as valves, shutting off a special water-chamber, and the late Dr. Harrison, of Dublin, many years ago described a special muscular apparatus, which he thought might aid the stomach in regurgitating a portion of its contents into the æsophagus. But more recent observers, such as Professor Morrison Watson (*Journal of Anatomy*, 1871), and Miall and Greenwood ("Anatomy of Indian Elephant"), find nothing which can be called a cardiac water-chamber, nor yet any special muscles for emptying it. There is, indeed, at the back of the mouth, a pouch capable of holding a small quantity of water, perhaps a quart or two. All the rest must (it would seem) be sucked up directly from the stomach into the trunk, which is probably sufficiently capacious, when distended, to lodge several gallons of fluid. It is much to be desired that naturalists who have access to elephants living under tolerably natural conditions would clear up the difficulties of this curious subject. Can it be ascertained how much water the trunk alone is capable of lodging? Is certain proof to be had that water is returned from the stomach? There are still unsolved questions of great interest connected with the physiology and habits of the elephants, and there is room for fear that these visibly declining species may become extinct before science has completely satisfied her curiosity respecting them.

POISONS IN THE WORKSHOP.

(*Concluded from p.* 110.)

An exceedingly deadly substance largely employed by electro-platers, and used also to a considerable extent in photography, is the cyanide of potassium. This substance is a solid body of a white or whitish colour, very easily soluble in water, and giving off a powerful and very peculiar odour, which is decidedly poisonous, and produces headaches and other disturbances of the nervous system. Hence all workrooms where it is used or stored in quantity should be well ventilated. In the state of solution it gives off its noxious vapours more freely. Those who have to deal with such solutions should allow them to come in contact with the hands as little as possible, especially if there is any cut or abrasion of the skin. Solutions of cyanide on exposure to the air quickly turn of a brownish colour. We have it on good authority that a workman in an electro-plating establishment at Sheffield had on the table before him two jugs, one containing a solution of cyanide of potassium and the other partly full of beer. Feeling thirsty he took up the wrong jug and swallowed a hearty draught of the deadly fluid before he found out his mistake. In spite of the almost instant attention of three medical men, he was dead in less than twenty minutes. This case emphasizes the rule that no article of food or drink should ever be kept or consumed in any room where poisons are manufactured or used.

Such instantaneously fatal cases are of course rare. But the health of workmen who continually inhale the fumes of this cyanide is always more or less affected.

We must now turn to the coal-tar colours and inquire whether these dyes are found to produce effects upon their producers and users similar to those which are sometimes found to result from wearing garments dyed with such colours? Our own experience, by no means trifling, gives a decidedly negative reply. We have never seen a case of illness which could, with even the remotest probability, be suspected as being due to the manufacture, the dissolving, mixing, etc., or to dyeing and printing with them. We are happy, however, to reinforce our observations with the much wider observations of Dr. Grandhomme. This gentleman has for some years acted as inspecting physician of the celebrated coal-tar colour manufactory belonging to Messrs. Meister, Lucius, and Brüning, at Hoechst. This establishment presents opportuities for studying the subject not, perhaps, to be met with elsewhere. There are a thousand workmen employed in addition to forty foremen and managers, twenty-five chemists, one engineer, and thirty clerks. Each class of colours is prepared in a distinct workroom, and a stringent rule provides that no man shall enter any department save his own. Hence the risk of error in assigning any illness to a wrong cause is practically eliminated. The ventilation is admirable, and every apparatus giving off hurtful gases is placed in connection with the chimney. Rooms containing combustible or explosive substance are illuminated solely by the electric light.

A capital point is the exclusion of arsenic. The magenta employed is made on the Coupier process, and consequently both this colour and all that are further prepared from it are absolutely non-arsenical. Thus their physiological action, whatever it might prove, could not be complicated by the effects of arsenic.

Some of the primary materials from which colours are prepared are undoubtedly poisonous. Benzol has repeatedly proved fatal to all lower animals to which it has been given. If the vapour is inhaled by man, it gives rise to irritation of the brain, dizziness, ringing in the ears, nausea, and drowsiness. Only one serious case is on record, which, however, did not terminate fatally. It is, however, very probable that the constant or frequent breathing of this vapour must have a debilitating effect.

Nitro-benzol, the intermediate step between benzol and aniline, is more formidable. It produces difficulty of breathing, dizziness, drowsiness, and convulsions, death often occurring from general paralysis. Remarkably enough, these symptoms sometimes do not set in until twenty-four hours have elapsed. Forty-four cases of acute poisoning in human subjects, due to contact with this substance, have been observed, of which fourteen proved fatal.

Aniline itself is also a well-recognised poison, whether in its pure state or as the "aniline oil" of commerce. According to circumstances, it may produce either acute or chronic poisoning.

We shall, perhaps, call forth the scepticism of our readers if we say that the *pure* salts of rosaniline, *e.g.*, magenta if only free from arsenic, as well as the derivatives of rosaniline, such as aniline blue, violet, and green, are harmless! Such, however, is indisputably the case. The men employed in the magenta-house have good health, and on frequent and careful examination they have been found free from those affections which magenta was suspected to bring on. It has also been administered to animals, and medical men have experimented on themselves, but without result. Dr. Grandhomme considers that the irritation of the skin occasioned by wearing stockings dyed with magenta has been due to the presence of arsenic.

The manufacture of the lovely colours, eosine and erythrosine, seems injurious. Though these colours, when administered to animals, produce no symptoms of disease, yet the health of the workmen in the eosine-house was not satisfactory. Of the seventeen persons employed in this department, sixteen were annually on the sick-list for a longer or shorter time. A curious effect produced is violent perspiration of the hands, sweat rolling down in drops from the tips of the fingers.

Upon the whole, however, it may be considered that the manufacture and use of the coal-tar colours are not specially dangerous employments. But from all this it does not follow that such colours, even non-arsenical, can be safely worn in immediate contact with the skin. Certainly many stories of "blood-poisoning" (!) from the use of garments dyed with aniline colours are merely *canards*. Sometimes, on rigid scrutiny, both the alleged victim and his or her medical adviser are found to be non-existent. Sometimes the cause of the mischief is said to be some colour which is not in the market at all. Still we should recommend our readers, as far as may be possible, to eschew the present rage for dyed under-clothing.

We have thus briefly surveyed the manufactures most dangerous to public health. There are not a few others, less important, which space does not allow us to take into consideration.

ITALIAN EXHIBITION.—This exhibition closed on Wednesday, Oct. 31st. The exhibition has proved so attractive that it is in contemplation to present a further display of the arts and industries of Italy next year.

Reviews.

Papers and Proceedings of the Royal Society of Tasmania, for 1887. Hobart: Mercury Office.

Among the more noteworthy papers in this volume is one by R. M. Johnston, F.L.S., raising the question "How far can the general death-rate for all ages be relied on as a comparative index of the health or the sanitary condition of any community?" He concluded that while the total death-rate for all ages may be used locally as a fairly trustworthy index of the health and the sanitary condition of any given place from year to year, it is a most fallacious index as regards the comparative health and sanitary condition of different localities.

Mr. W. Saville Kent, F.L.S., discusses the acclimatization in Tasmanian waters of the true salmon (*Salmo salar*), and an epidemic said to have occurred at the fish-breeding institution at Plenty. The disease in question is one too well known in England and Scotland, and is due to the parasitic fungus, *Saprolegnia ferox*. For this disease, temporary immersion in sea-water is recommended. Hard waters, caustic alkalies, and other chemical agents seem to favour the spread of the disease. Perhaps it would be well if waters which have been used in washing sheep were kept out of the rivers.

There are a fair number of botanical and zoological papers, but as these consist for the most part of the description of species, they are not well suited for notice in our columns. We may here except certain papers by Colonel W. V. Legge, F.Z.S., namely, "A First List of the Birds of Maria Island," the "Highlands of Lake St. Clair," and the "Breeding of some Sea-birds on the Actaeon and Adjacent Islands."

Primary Methods in Zoology Teaching, for Teachers in Common Schools. By W. P. Manton, M.D. Boston: Lee and Shepard.

The reader who is sanguine enough to hope that this "jumble of comparative anatomy and physiology," to use the author's candid phrase, will qualify him to teach the subject, is doomed to disappointment. A book so slight and hasty is insufficient even to guide the first steps of the learner—it is a mere extempore effusion of amateurish notions. The excellent manuals of Huxley, Parker, and Morse show a better way to that knowledge which must be possessed by every teacher of zoology who would not be a humbug. We are sorry to say that we can find no merit or usefulness in Dr. Manton's little book. The illustrations, which are "purposely crude," are also ill-selected and ill-drawn.

Star Atlas, containing Maps of all the Stars from 1 *to* 6·5 *Magnitude between the North Pole and* 34° *South Declination, and of all Nebulæ and Star Clusters in the same region which are visible in telescopes of moderate power.* With explanatory text by Dr. Hermann J. Klein. Translated and adapted for English readers by Edmund McClure, M.A., M.R.I.A. London: Society for Promoting Christian Knowledge. Price 7s. 6d.

This atlas contains eighteen maps, printed by E. A. Funke, of Leipsic. The first twelve are beautifully clear and exquisitely engraved star charts. The remaining six maps contain a reproduction of the Brothers Henry's photograph of the star cluster of the Pleiades, and various other nebulæ and star clusters, all marvels of typography. There is also a well-written introduction containing some useful tables, and a description of the more interesting fixed stars, etc., contained in the maps. We can strongly recommend this atlas to those of our readers who are interested in astronomy.

RECOGNITION OF HUMAN BLOOD.

THE diagnosis of human blood, as distinguished from that of the lower animals, is often an important point of criminal jurisprudence, when blood-stains on garments or weapons are laid before the courts as evidence.

This difficult question has lately been discussed in the *Journal of Comparative Medicine*, by Dr. H. Formad.

For deciding the general question whether a certain stain is due to blood or to some vegetable juice or artificial dye the spectroscope and various chemical reagents come into play. But to prove that a given specimen of blood is human or otherwise the microscope alone is of any value, and the sole method in which it is applicable is to measure the blood-cells. The distinction of the blood of any mammalian animal from that of the lower classes of animals is easy, from the fact that in mammalia only the cell is round and non-nucleated. The distinction between the blood of man and that of the lower mammalia turns entirely upon the micrometric measurement of the cells.

The following animals only have blood corpuscles larger than man, *i.e.*, exceeding $\frac{1}{3200}$ of an inch: the elephant, the great ant-eater, walrus, sloth, platypus, whale, capibara, and (according to Wormley) the opossum. Animals whose blood corpuscles are slightly below those of man in size, they having corpuscles from $\frac{1}{3500}$ to $\frac{1}{3000}$ of an inch in size, are the seal, beaver, musk-rat, porcupine, monkey, kangaroo, wolf, and guinea-pig. None of these are domestic animals. All other animals, including all domestic species, have blood corpuscles of a mean diameter less than $\frac{3}{3500}$ of an inch, and, in fact, those animals to which blood-stains found on the clothing of criminals are commonly ascribed, such as the ox, pig, horse, sheep, and goat, have corpuscles with a mean diameter less than $\frac{1}{4000}$ of an inch.

The question may, however, be raised whether the blood corpuscules of *all* mammalian species have been examined with sufficient care. It is very possible that the animals here lumped together under the name "monkey" may have blood-corpuscles not alike in size. Especially is this the case with the anthropoid apes.

Dr. Formad summarises the facts as at present known, as follows:—

1. The blood-corpuscles of birds, reptiles, and fishes, being oval and nucleated, can never be mistaken for human blood.

2. Fresh human blood cannot be mistaken, under the microscope, for the blood of any animal whose corpuscles have a mean diameter of less than $\frac{1}{4000}$, or even $\frac{1}{3600}$ of an inch.

3. (*a*) If the average diameter of the corpuscles in fresh blood be less than $\frac{1}{4000}$, then it cannot possibly be human blood; (*b*) if the diameter be above $\frac{1}{3500}$ inch, then it *may* be human blood; (*c*) if the blood corpuscules, after exhaustive measurement, give a mean diameter exceeding $\frac{1}{3300}$ of an inch, then it *is* human blood, provided it is not the blood of any of the wild beasts mentioned.

These conclusions apply especially to fresh blood. Dried blood, it is asserted, can be distinguished with equal accuracy, provided it has been dried rapidly. If it has dried slowly it will have undergone decomposition, and its structure cannot be made out. A good liquid for moistening dried blood is Virchow's solution, consisting of thirty parts caustic potash and seventy parts water. At least five hundred measurements should be made in order to arrive at certainty as to the average diameter of the cells.

If the corpuscles have become spheroidal from the absorption of moisture, or crenated from drying, they may still be distinguished, because such changes are the same in the corpuscules of all animals, and have their proportionate and corresponding ratio of alteration in form and decrease in size, the range or scale of decrease being always alike in the same animal.

The red blood corpuscules which have become spherical by imbibing liquid have, according to Dr. Formad's observations, the following mean diameters in different species: man, $\frac{1}{4300}$ inch; guinea pig, $\frac{1}{4500}$ inch; wolf, $\frac{1}{4600}$ inch; dog, $\frac{1}{4800}$ inch; rabbit, $\frac{1}{4900}$ inch; ox, $\frac{1}{5600}$ inch; sheep, $\frac{1}{6700}$ inch; goat, $\frac{1}{8100}$ inch.

These figures prove that the diameter of the corpuscles in each animal, when rendered artificially spherical is about one-third less than that of the normal biconcave or disc-like corpuscles of the same animal.

Dr. Formad believes that human blood can thus be positively distinguished from that of any other animal. Other eminent microscopists do not feel equally satisfied.

MICROSCOPIC MANIPULATION.

THE remarks which follow are intended for workers who have had some practice in the simplest modes of preparing and mounting microscopic objects. They form a sequel to the article "How to Work with the Microscope," already published in the SCIENTIFIC NEWS, (vol. i., N.S., p. 82).

Let us suppose that some animal tissue is to be prepared for microscopic examination. It is a good plan to procure a small mammal, and remove from the fresh-killed body a number of different tissues, say, stomach, small intestine, a large nerve, such as the sciatic, and a piece of spinal cord. These should be placed immediately in the hardening fluid. Only small pieces which can be rapidly penetrated by the fluid should be taken. No part of the object should be more than $\frac{1}{8}$ in. from the surface. The fluid should be greatly in excess of what is required to cover the tissues; thus four or five small bits may be placed in about four ounces of fluid. Trim the tissues to such shapes that by merely looking at them you can see how they lay in the body and how they must be cut. For instance, the long axis of the piece may correspond to the long axis of the organ, the narrow end of the piece to the narrow end of the organ, and so on.

Procure from the chemist 6 oz. of 10 per cent. solution of chromic acid, and keep it by you in a stock bottle. Dilute some of this to $\frac{1}{3}$ per cent. for ordinary use as a hardening fluid. Various other solutions possess special advantages of their own, but it is of the first importance not to be bewildered by a multiplicity of reagents, and the beginner will do well to have only one process in his mind, until he has thoroughly mastered it. The solution should be changed after 24 hours, and then allowed to act for several days (2 to 14, according to the size of the tissues).

Avoid as far as possible all fingering or pulling of the parts. Epithelium, in particular, must never be rubbed, however lightly. Wide-mouthed stoppered bottles are used in all the operations with fluid; those which have contained chromic acid must be scrupulously washed with strong mineral acid and water before they are used for any other purpose.

The next step is to remove all free chromic acid, and gradually to dehydrate the tissues. Different strengths of alcohol are employed. Buy a gallon of methylated alcohol of good strength, and a few ounces of absolute alcohol. The methylated alcohol should contain 80 per cent. of spirit. Mix it with water so as to get a 40 per cent., and also a 60 per cent. solution. Then remove the tissues from the chromic acid, add to them a small quantity of 40 per cent. alcohol, pour this away, and add a relatively large quantity of the same. After 24 hours change to 60 per cent., and renew the fluid once or more, according to the size of the tissues and the amount of colouration of the alcohol. Then change to methylated alcohol of full strength. If the tissues are not immediately wanted, keep them in methylated alcohol. Too long soaking in absolute alcohol renders them brittle and over-contracted. The gradual saturation with strong alcohol should occupy about a fortnight. Note that waste alcohol should be kept for redistillation.

All is now ready for staining. Here, again, it is best to practise one method only until proficiency has been gained. Begin with alcoholic borax-carmine, and stain the tissues whole before cutting. The staining fluid is made in this way: Take a 4 per cent. solution in water of borax. Saturate with carmine (2 to 3 per cent.), leaving the mixture to stand for a day or two, and stirring now and then. Add an equal bulk of methylated alcohol. Let the solution stand for a week, and then filter.

Place the tissues in perfectly clean bottles, with enough of the staining fluid to cover them. Leave them for two or three days, then pour off the fluid, and add methylated alcohol, slightly acidulated (two drops of hydrochloric acid to the ounce). The crimson stain is thereby fixed, and brightened in colour. Transfer once more to ordinary methylated alcohol, and just before cutting to absolute alcohol for twenty-four hours.

Most tissues require imbedding to give sufficient firmness. For cutting by hand nothing is better than cacao butter. Make a small rectangular paper tray, about 1 in. long, $\frac{1}{2}$ in. wide, and $\frac{1}{2}$ in. deep. Fill this with the melted cacao butter, dry the tissue superficially, and place in the tray. Take care that it is completely immersed in the butter, and don't heat the butter more than is absolutely necessary. When the preparation is cold remove the paper, and pare down the block with a sharp knife. It is undesirable to have to cut through much of the imbedding substance with the razor, and equally undesirable to weaken the block too much. The top of the block must therefore be trimmed so as to slope away on all sides, and the operation must be repeated frequently as cutting proceeds. To prevent melting in the hand hold the block in a piece of paper. Use the sharpest razor you can obtain, wet the blade and also the tissue with methylated alcohol, pick up the sections as cut with a small camel-hair brush, and transfer to a watch-glass of methylated alcohol. When a sufficient number have been obtained pick away and remove the chips of imbedding substance with a needle and brush, replace the methylated alcohol by absolute, and this again by oil of cloves. Finally pick out the sections one by one with a section-lifter, and mount in balsam.

Where a mechanical microtome is required Fearnley's may be recommended. It is good and cheap, and admits of imbedding either in a waxy medium or in celluloidin. Special instructions are required for this or any other mechanical microtome. Caldwell's rocking microtome is indispensable where many consecutive sections are required, but it is not well adapted to the wants of the beginner. It is somewhat costly, and the necessary appliances, to say nothing of the continuous time required by the different operations, presuppose serious devotion to biological work. Hand-cutting will do a great deal, and no microtome can altogether replace it. The novice will therefore do well to give his principal or sole attention to hand-cutting for at least the first few months of his initiation.

THE ACTION OF MICROBIA UPON COLOURING MATTERS.

THE following memoir has been submitted to the Paris Academy of Sciences by its author, M. J. Raulin:—

If we colour wort in alcoholic fermentation with magenta, Nicholson blue, imperial violet, saffranine or Poirrier orange No. 2, a part of the colouring matter is seized upon by the yeast and dyes it strongly, whilst cochineal, logwood, orchil, and extract of indigo do not dye it. In the former case we have a true tinctorial action analogous to that which the same colouring matters exert upon animal fibres.

The spores of *Aspergillus niger* have been sown in artificial liquids suitable for cultivation, one containing nitrate of ammonia; a second, a salt of aniline; a third, a salt of rosaniline; a fourth, extract of indigo; the fifth being entirely free from nitrogen. The mould flourished well in the first liquid, but gave merely an insignificant yield in the four others. It will be remembered that M. Pasteur has found moulds able to assimilate the nitrogen of ethylamine, and that M. G. Ville has observed large plants assimilating the nitrogen of ethylamine and methylamine. Are these differences of action connected with the differences of constitution of compounds belonging respectively to the aromatic and to the fatty series?

Yeast-water, beer-wort, or an artificial sugary liquid, slightly acidified if tinted with extract of indigo, are slowly and progressively decolourised in a few days in the absence of any organism, but in presence of air. This is an oxidation, since carbonic acid gas hinders the decolouration. Certain ærobic organisms, such as *Aspergillus niger*, *Mycoderma vini*, *Mycoderma aceti*, hinder or retard this decolouration by opposing the access of oxygen. Active beer-yeast produces the same effect; still, after some weeks, beer-wort in active fermentation by means of ordinary brewers' yeast, if tinted with extract of indigo, is decolourised in the absence of atmospheric oxygen, but this is a reduction by hydrogenation, for the colour reappears on the contact of air, and this reduction coincides with the development of microbia, similar to the lactic ferment.

To render this decolouration of extract of indigo by reduction as certain and as rapid as possible, the yeast-water is left to itself for some days at a temperature of about 75° Fahr. It is then full of bacteria, and gives off a putrid odour. The bacteria increase rapidly if they be sown in fresh yeast-water.

If such yeast-water be coloured with extract of indigo, this is decoloured more or less rapidly. A quarter of an hour suffices in the most favourable cases. In a few hours we may thus reduce 500 milligrams of dry extract of indigo in 1 litre of liquid. This decolouration is so much the more rapid as the microbia are more numerous. On the other hand, heat and antiseptics such as phenol (which kills the organisms) oppose the decolouration. Filtration renders the filtrate inactive, whilst the liquid remaining upon the filter retains its activity. The decolouration, therefore, is not the result of the action of a substance previously generated by the microbia, which would accumulate in the liquid, unless we suppose that heat, antiseptics, and atmospheric oxygen introduced by filtration destroy this substance—an inadmissible hypothesis, since on saturating the unfiltered liquid with oxygen we do not destroy the faculty of decolouration. This power of the microbia is therefore an actual action, direct or indirect, inherent in their life. It is a reductive action, since the indigo resumes its colour on exposure to the air, and the bacteria themselves are anærobic.

We must not confound this phenomenon with the decolouration of extract of indigo in an alkaline solution of glucose, for in the latter case the microbia are not necessary, and in the former the decolouration still takes place in a neutral or slightly acid medium. It is not due to hydrogen set at liberty, for its quantity is quite insufficient to explain the result.

This phenomenon is doubtless connected with the special mode of respiration of these organisms.

M. Duclaux has observed the decolouration by reduction of extract of indigo in milk, making its appearance at the same time as the first organisms, and M. Dubois has observed the spontaneous decolouration of litmus in closed vessels, as due to a kind of micrococcus.

It is not alone upon extract of indigo that these microbia exert their activity by hydrogeneration. Logwood, orchil, saffranine are decolourised rapidly, though less so than extract of indigo, and resume their colour on exposure to air. Certain azo-colours, such as the ponceau 3R of Meister, Lucius and Brüning, the orange No. 2 of Poirrier and Bordeaux red, are decolourised rapidly, but do not recover their colour in the air. Nicholson blue and imperial violet are decolourised in a few days, but magenta, cochineal, and the colouring-matter of wine resist for some weeks. Hence the microbia in question may prove useful reagents for foreign colouring-matters added to wine.

Abstracts of Papers, Lectures, etc.

SOCIETY OF ENGINEERS.

At a meeting of the Society of Engineers, held at Westminster Town Hall on the 5th November, Mr. A. T. Walmisley, President, in the chair, a paper was read on "The Practice of Foundry Work," by Mr. H. Ross-Hooper.

The paper first briefly compared the particular qualities and properties of pig iron, with the view of determining the varieties which are best adapted to the requirements of the different kinds of castings made; and showing how the nature of cast-iron depended not only upon the amount of carbon that it contained, but upon the conditions under which that carbon existed. The author then proceeded to illustrate how the failing of portions of a cast-iron structure may be traced to a want of knowledge in the way the lines of crystallisation flow on the cooling of the metal, and mentioned the weak points to be guarded against in the designing of cast-iron work. Moulding or the production of a hollow mould to receive the metal was next considered; for to mould melted iron into any required shape or form two things are necessary—(1) a pattern of the article to be produced, (2) a substance which will retain the impressions of the pattern made upon it and resist the violence of the metal when poured therein. To make a pattern a man requires to be thoroughly conversant with the principles of moulding, to so construct it that it may give a minimum of trouble to the moulder; the materials used for pattern making and the general essential points of this branch being touched upon. The differences between green and dry sand moulding, the requisites of a good foundry sand, and the mode of preparing a mould for a small girder bed-plate were entered into in detail, noticing those particulars which should be observed in the construction of sand moulding, and showing the uses of cores and the method employed in their formation both large and small.

The author next proceeded to describe the features of loam moulding, illustrating (by means of a working model) the process of constructing a mould for a drum capable of holding 200 feet of one-inch wire rope used in the erection of the Sukkur Bridge, India.

After explaining the operations of chill casting, malleable cast-iron, and the system of moulding known as "Jobson's Blocks," whereby sand moulds of thin delicate patterns can be made by ordinary labourers, the author mentioned the different modes adapted for casting according to the forms and requirements of the various articles to be produced, and how sound results can only be obtained by a careful attention paid to the feeding of the metal to supply the shrinkage and drawing away which must inevitably occur on the cooling of the metal. The cupola, its construction, and advantages over other types of furnaces, and the manner of charging it, together with the appliances necessary to a foundry in the shape of drying stoves, laddles, cranes, etc., and a "fettling shop" for the ultimate cleaning and dressing of castings were duly considered.

The author then treated of the examination of cast-iron work and the care that should be observed in all inspection of the same, and finally discussed the tests usually applied and the general strength of cast-iron.

LEEDS GEOLOGICAL ASSOCIATION.

At the meeting on Oct. 25th, Mr. J. E. Bedford, F.G.S., the President, delivered an address on "The Oil Fields of the United States and Russia." There are now, he said, two large centres from which petroleum products are derived—the State of Pennsylvania, in the United States of America, and the district of Baku, in Southern Russia. To the Americans is due the credit of having developed an enormous trade and of benefiting the world at large. Paraffin is the most generally known product of the petroleum industry. It is obtained by distillation of the crude petroleum in large retorts or stills. When the heat rises to the boiling point the distillation commences, and the lighter spirit or gasoline, generally called benzoline, is the first product. When this is all gone, the heat of the still is increased, and paraffin distils over, and is collected separately. The distillation is then continued at a higher temperature, when other oils of a higher specific gravity are produced. These oils are too heavy for burning in lamps; the temperature at which they vaporise being very high, they will not burn on a lamp wick. This oil has good properties, which have been utilised in another direction. As a lubricating material for steam cylinders it has no equal. Having no action on metals, and being stable at a high steam heat, it is very much superior to tallow or vegetable oil for this special purpose. Another bye-product in the paraffin industry which has recently come into extensive use is vaseline—a semi-solid paste, which, when purified, has a fine amber colour, and is used for dressing wounds, and for the bases of ointments and pomades. As it is one of the paraffin series it never becomes rancid, as all animal and vegetable fats do, by the separation of the fatty acid from the glycerine. No doubt all petroleum districts will show evidence of the presence of the oil by exudation on the surface or by the oil being brought up by springs of water. In order to obtain the oil in large quantities, bore-holes are made and carried deep enough to reach the oil-bearing strata. This is generally sufficient for a fairly constant flow of crude oil. There is often pressure sufficient for the oil to be spouted into tanks without pumping. It is then conveyed to the refineries either by special railway tanks or by lines of iron pipe. Many of the latter are several miles in length. Petroleum is now being largely used for fuel in place of coal. The Standard Oil Company of Cleveland, Ohio, have constructed a pipe line 207 miles long, stretching from Lima to South Chicago. The pipe is 8 inches in diameter. There is a powerful pumping engine at Lima, and this forces the oil all the way to Chicago, where a steady stream issues, amounting to 5,000 barrels a day. The company have reservoirs into which the oil is run, and they supply great quantities to the ironworks of the district. There is great difference in the geological age of the strata in which oil and gas are found. In Ohio, Kentucky, Virginia, and Tennessee the oil has its origin in sandstones or shales of Devonian age, or in the Trenton limestone of the Lower Silurian. In describing the Wyoming oil region, Mr. Bedford quoted from Professors Aughey and Ricketts, who state that the cretaceous rocks are the best developed, and the most important of the whole series. They are from 5,000 feet to 6,000 feet thick, and are divided into four groups—the Dakota, Colorado, Fox Hills, and Laramie. They consist mainly of a coarse conglomerate, firmly cemented; porous sandstones and sandy shales, but no limestone. Every one of those groups has oil springs, or contains strata whose outcrops are saturated with oil. With one single exception, no petroleum occurs (in this district) in any other than cretaceous rocks. The exception is the Schoshone oil, which is found at a lower horizon, namely—at or near the bottom of the Triassic or the top of the carboniferous formation. Thus in the Eastern States the oil is found in Silurian and Devonian strata, and in the Western States it lies in the cretaceous rocks. The names of these beds are local, and sound somewhat strange to English geologists; they, however, are similar in their fossil remains to a great extent, and will correspond with those of our wealden, upper and lower greensand, and chalk. Passing now to the Russian oil-fields, it may be said that the method of production by boring is the same as in America, but the yield is still greater. The petroleum has been worked commercially since the Russians annexed the district in 1801. Formerly a monopoly existed in this trade, but upon its abolition several companies were established, and an enormous production has resulted. There are between 400 and 500 wells drilled in the Baku district, about 100 of which yield a supply, only some twenty of these being flowing wells. These are all comparatively close together, and occupy a space of land not more than 3½ miles square. One of these wells spouts a jet of oil into the air amounting to a million gallons in twenty-four hours. Petroleum is largely obtained in other parts of the Caspian district. Mr. Bedford gave a very interesting account of the boring operations necessary to reach the oil, which have to be taken to a depth of from 300 ft. to 600 ft. As soon as indications appear of oil, which is generally preceded by a rush of gas, a cap is fixed on the top, with valves to control and regulate the flow; for in some cases the oil has come up with such force that it has destroyed everything around. The yield is enormous; the Droojba well sent up two million gallons a day for some time. Messrs. Noble Bros. had one well which spouted thirty million gallons in four weeks. The copious supply at Baku will be understood when it is stated that the single well just described equals in its flow of oil all the 25,000 wells of America put together, and there is yet no sign of any diminution of quantity. The position of Baku is rather unfavourable for the transmission of the oil to the European and Indian markets. It is now sent to Batoum on the Black Sea in railway tanks, and this journey generally takes a week or ten days. It is intended to lay a pipe line to convey it, which will be some 600 miles in length. There are several theories which attempt to account for the formation of petroleum in the rocks. Some great chemists think that it has originated by the union of inorganic elements, that the carbon existing in the strata combined in some way with hydrogen and oxygen. The more generally received opinion is that the oil is the result of the decomposition of animal and vegetable remains, which lived at the time when the rocks were laid down. The evidence seems to point to animal remains as the most likely to yield hydrocarbons. If the oil had been derived from plant life, one would expect to find the fossil plant remains in fair quantity, but this is not so. Coal strata would be expected to furnish oil; but little, if any, is ever found in them. Animal remains are always found in strata yielding oil. The Trenton limestone contains orthoceratites in great quantities, and the cavities often contain several ounces of oil. Hoefer says that all slates which give hydro-carbon oils on distillation are rich in animal remains, while they show few of vegetable origin; and that the rocks which contain large quantities of vegetable remains are not bituminous as a rule, but become so when animal remains are also present. The fact of salt water being so often present with petroleum also points to a marine fauna. Supposing that these fossil remains have been subjected to heat and pressure for a great length of time, as they no doubt have, then great chemical changes would occur; decomposition would begin with the nitrogenous portions of the animal (the gelatine, albumen, etc.). The fats not being so easily changed, would remain to a later period and be absorbed by the rocks. These fats are different in chemical constitution from the paraffin series of oils, and further decomposition would be necessary to produce paraffin. The latter are not so complex in the construction of the molecules as organic fats are, being less organised, one might say, and approaching more nearly to carbon compounds of mineral origin. This points to the assumption that the process of dissociation, and the reforming of other compounds, had proceeded until a substance had been formed which refused further chemical changes, and this has resulted in the whole series of paraffins known to chemists.

Australasian Association for the Advancement of Science.—At a meeting of the Council of the Australasian Association for the Advancement of Science, the President, Mr. H. C. Russell, being in the chair, the following motions were carried :—

"That the delegates appointed for the Sydney meeting of the Association be requested to form local committees in their respective colonies. upon the same lines as the local committees of the British Association."

"That the authors of papers be informed that if the papers contributed by them are not published by the Association in full, they are at liberty either to contribute the papers to local societies, publish them in any journal, or dispose of them in any way they may desire."

"That a formal application be made to the Government for a refund on behalf of those members of the Association who paid full fare to travel over the railway lines to Sydney."

The financial statement, which was submitted, showed a credit balance of £230.

Notices were received of the appointment of the following gentlemen to the general council :—Mr. F. G. A. Barnard (Field Naturalists' Club, Victoria); Professor H. M. Andrew, M.A. (Melbourne University Science Club); Mr. A. Purchase, C.E. (Institute of Architects, Victoria); Mr. A. O. Sachse, C.E., F.R.G.S. (Victorian branch of the RoyalGeographical Society of Australasia).

London Mathematical Society.—At the meeting held on November 8th (Sir J. Cockle, F.R.S., President, in the chair), the President, in a few well-chosen and touching sentences informed the members present of the loss the Council and the Society had sustained during the recess by the decease of Mr. Arthur Buchheim. After the election of the Council, the new President (Mr. J. J. Walker, F.R.S.) took the chair, and called upon the retiring President to read his address on "The Confluences and Bifurcations of Certain Theories." The following further communications were made :—"On Cyclotomic Functions §1 Groups of Totitives of n; §2 Periods of nth Roots of Unity," Prof. Lloyd Tanner; "On a Theory of Rational Symmetric Functions," Capt. P. A. MacMahon, R.A.; "The Factors and Summation of $1^r + 2^r + \ldots + n^r$," Rev. J. J. Milne; "Raabe's Bernoullians," Mr. J. D. H. Dickson; "Certain Algebraical Results Deduced from the Geometry of the Quadrangle and Tetrahedron," Dr. Wolstenholme; "On a Certain Atomic Hypothesis," Prof. K. Pearson; "On Deep-Water Waves Resulting from a Limited Original Disturbance," Prof. W. Burnside.

Liverpool Geological Association.—At the monthly meeting of this Association held on November 5th, Mr. Percy F. Kendall, of Owens College, Manchester, delivered a lecture on "The Geology of Mull," in the course of which he said: To a geologist the history of Mull was the history of a volcano. In no other part of the British Isles were the results of long-continued volcanic action so clearly visible as in this outlying region of Western Scotland. There, what had once been a volcano, rivalling Etna or Teneriffe in magnitude, had been acted upon by denuding forces until it was laid open to its very core. The granitic rocks and representative acid larvas and tuffs of the earlier stages of volcanic activity were seen to be penetrated and overlain by the basic larvas of a later stage; while the fragmental rocks formed during the clearing of the volcanic chimney, and the intricate system of dykes and intrusive sheets incidental to the building up of a great volcanic cone, were clearly exposed to view. The work done during each stage of volcanic activity was then ably sketched by Mr. Kendall, who indicated what conclusions might be drawn from the distribution of products, and the arrangements of the dykes. The energy of the underground forces seems to have culminated in the Miocene period, when floods of basaltic lava were poured out of the vent, deluging the country for miles round. It was owing to a happy accident in this period that the inundation of a certain valley by a mass of lava resulted in the preservation of the Mull leafbeds, the mud in which the leaves were imbedded having been preserved to our own day, thanks to its hard capping of igneous rocks.

St. John's Natural Science Society, Upper Holloway.—On November 2nd this rising Society held a very successful conversazione in the gymnasium attached to St. John's Institute.

Amsterdam Royal Academy of Sciences.—At the ordinary meeting of the Physical Science section on Saturday, 27th October, M. Behrens read a paper which treated of the manner in which the volcanic lakes in the Eifel mountains originated, and demonstrated that they could not owe their origin to the crumbling down of extinct volcanoes. From experiments made by the author, he rather concluded that the Eifel Lakes must be regarded as incomplete volcanoes, formed by the softening and continuous blasting of the sedimentary rocks, only a little lava being brought to the surface.

THE FOUNDATION-STONES OF THE EARTH'S CRUST.

An Evening Discourse delivered by T. G. Bonney, D.Sc., LL.D., F.R.S., F.G.S., etc., before the British Association, on September 10th, 1888.

(Continued from p. 464.)

On the other side what evidence can be offered? In the first place, any number of vague or rash assertions. So many of these have already come to an untimely end, and I have spent so much time and money in attending their executions, that I do not mean to trouble about any more till its advocates express themselves willing to let the question stand or fall on that issue. Next, the statement of some of the ablest men among the founders of our science, that foliation is more nearly connected with cleavage than with structures suggestive of stratification. In regard to this I have already admitted, in the case of the more coarsely crystalline rocks, what is practically identical with their claim, for they also assert that when the banding was produced, very free movement of the constituents was possible; and in regard to the rest I must ask whether they were speaking of cleavage-foliation or stratification-foliation, which had not then been distinguished, and I know in some instances what the answer will be. The third objection is of a general nature. To prevent the possibility of misstatement I will give it as a quotation: "To a geologist (especially one belonging to the school of Lyell) it is equally difficult to conceive that there should be a broad distinction between the metamorphic rocks of Archæan and post-Archæan age respectively, as that the pre-Tertiary volcanic rocks should be altogether different in character from those of Tertiary and recent times." Of course in this statement much depends on the sense attached to the epithet "broad." As an abstract proposition I should admit, as a matter of course, that from similar causes similar consequences would always follow. But in the latter part of the quotation lurks a *petitio priucipii.* During the periods mentioned volcanic rocks appear, as we should expect, to have been ejected from beneath the earth's crust similar in composition and condition, and to have solidified with identical environment. Hence the results, allowing for secondary changes, should still be similar. But to assume that the environment of a rock in Early Archæan times was identical with that of similar material at a much later period is to beg the whole question. My creed also is the uniformitarian, but this does not bind me to follow a formula into a position which is untenable. Other studies with which I have some familiarity have warned me that a blind orthodoxy is one of the best guides to heresy. "The weakness and the logical defect of uniformitarianism"—these are Professor Huxley's words—"is a refusal, or at least a reluctance, to look beyond the 'present order of things,' and the being content for all time to regard the oldest fossiliferous rocks as the *ultima Thule* of our science." Now, speaking for myself, I see no evidence since the time of these rocks, as at present known, of any very material difference in the condition of things on the earth's surface. The relations of sea and land, the climate of regions, have been altered, but because I decline to revel in extemporised catastrophes, and because I believe that in nature order has prevailed and law has ruled, am I therefore to stop my inquiries where life is no longer found, and we seem approaching the firstfruits of the creative power? Because palæontology is perforce silent; because the geologist can only say "I know no more," must I close my ear to those who would turn the light of other sciences upon the dark places of our own, and meet their reasoning with the exclamation, "This is not written in the book of uniformity"? To do this would be to imitate the silversmiths of old, and silence the teacher by the cry, "Great is Diana of the Ephesians."

What, then, does the physicist tell us was the initial condition of this globe? I will not go into the vexed question of geological time, though as a geologist I must say that we have reason to complain of Sir W. Thomson. Years ago he reduced our credit at the bank of time to a hundred millions of years. We grumbled, but submitted and endeavoured to diminish our drafts. Now he has suddenly put up the shutters and declared a dividend of less than four shillings in the pound. I trust some aggrieved shareholder will prosecute the manager. However, as a *cause célèbre* is too long a business for the end of an evening, I will merely say that while personally I see little hope of arriving at a chronological scale for the age of this earth, I do not believe in its eternity. What, then, does the physicist tell us must have been in the beginning? I pass by those earliest ages, when, as "Ilion, like a mist, rose into towers," so from the glowing cloud the great globe was formed. I pass on to a condition more readily apprehended by our faculties—the time—the *consistentior status* of Leibnitz—when the molten globe had crusted over, and its present history began. Rigid uniformitarian though you may be, you cannot deny that when the very surface of the ground was at a temperature of at least 1,000 degs. F., there was no rain, save of glowing ashes—no river, save of molten fire. Now is ending a long history with which the uniformitarian must not reckon—of a time when many compounds now existing were not dissolved but dissociated, for combination under that environment was impossible. Yet there was still law and still order—nay, the present law and order may be said even then to have had a potential existence—nevertheless to the uniformitarian gnome, had such there been, every new combination of elements would have been a new shock to his faith, a new miracle in the earth's history. But at the times mentioned above, though oxygen and hydrogen could combine, water could not yet rest upon the ruddy crust of the globe. What does that mean? This, that assuming the water of the ocean equivalent to a spherical shell of the earth's radius and two miles thick, the very lava stream would consolidate under a pressure of about 310 atmospheres, equivalent to nearly 4,000 feet of average rock.* But on the practical bearing of this consideration I will not dwell. Let us pass on to a time, which, according to Sir W. Thomson, would rather quickly arrive, when the surface of the crust had cooled by radiation to its present temperature. Let us, merely for illustration, take a surface temperature of 50° F. (nearly that of London), and assume that the present rise of crust temperature is 1° F. for every 50 feet of descent, which is rather too rapid. If so, 212° F. is reached at 8,100 feet, and 250° F. at 10,000 feet. Though the latter temperature is far from high, yet we should expect that under such a pressure, chemical changes would occur with much more facilty than at the surface. But many Palæozoic or even later rock masses can now be examined which at a former period of their history have been buried beneath at least 10,000 feet of sediment; yet the alteration of their constituents has been small; only the more unstable minerals have been somewhat modified, the more refactory are unaffected. But for a limited period after the *consistentior status*, the increase of crust temperature in descending would be far more rapid; when one twenty-fifth of the whole period from that epoch to the present had elapsed, and this is no inconsiderable fraction, the rate of increase would be 1° for every ten feet of descent. Suppose, for the sake of comparison, the surface temperature as before, the boiling-point of water would be reached at 1,620 feet, and at 10,000 feet, instead of a temperature of 250° F., we should have one of 1,050° F. But at the latter temperature many rock masses would not be perfectly solid.† According to Sorby the steam cavities in the Ponza trachyte must have formed, and thus the rock have been still plastic at so low a temperature as 680° F. At this period then, the end of the fourth year of the geological century, whatever be its units, structural changes in igneous and chemical changes in sedimentary rocks must have occurred more readily than in any much later period

* If we take the S.G. of water as unity, and that of mean rock as 2·7, the pressure would be = 3,911·1 feet of rock.

† The lowest temperature, which, so far as I know, has been observed in lava (basic) while still plastic, is 1,228° F.

in the world's history. A temperature of 2,000° F., sufficient to melt silver—more than sufficient to melt many lavas—would have been reached at a depth of about four miles. It would now be necessary to descend for at least twenty miles, in order to arrive at this zone. It, during the ninety-six years of the century, has been changing its position in the earth's crust, more slowly as time went on, from the one level to the other.

There is another consideration, too complicated for full discussion, too uncertain perhaps in its numerical results to be more than mentioned at present, which, however, seems to me important. It is this, that, in very early times, as shown by Professor Darwin and Mr. Davison, the zone in the earth's crust, at which lateral thrust ceases and tension begins, must have been situated much nearer to the surface than at present. If now, at the end of the century, it is at the depth of five miles, it was, at the end of the fourth year, at a depth of only one mile. Then, a mass of rock, 10,000 feet below the surface, would be nearly a mile deep in the zone of tension. Possibly this may explain the mineral banding of much of our older granitoid rock, already mentioned, and the coincidence of foliation with what appears to be stratification in the later Archæan schists, as well as the certainly common coincidence of microfoliation with bedding in the oldest indubitable sediments.

Pressure no doubt has always been a most important factor in the metamorphism of rocks; but there is, I think, at present some danger in over-estimating this, and representing a partial statement of truth as the whole truth. Geology, like many human beings, suffered from convulsions in its infancy; now, in its later years, I apprehend an attack of pressure on the brain.

The first deposits on the solidified crust of the earth would obviously be igneous. As water condensed, denudation would begin, and stratified deposits, mechanical and chemical, become possible, in addition to detrital volcanic material. But at that time the crust itself, and even stratified deposits, would often be kept for a considerable period at a temperature similar to that afterwards produced by the invasion of an intrusive mass. Thus not only rocks of igneous origin (including volcanic ashes) would predominate in the lowest foundation-stones, but also secondary changes would occur more readily, and even the sediments or precipitates should be greatly metamorphosed. Strains set up by a falling temperature would produce, in masses still plastic, banded structures, which, under the peculiar circumstances, might occur in rocks now coarsely crystalline. As time went on, true sediments would predominate over extravasated materials, and these would be less and less affected by chemical changes, and would more and more retain their original character. Thus we should expect that as we retraced the earth's course through "the corridor of time," we should arrive at rocks which, though crystalline in structure, were evidently in great part sedimentary in origin, and should beyond them find rocks of more coarsely crystalline texture and more dubious character, which, however, probably were in part of a like origin; and should at last reach coarsely crystalline rocks, in which, while occasional sediments would be possible, the majority were originally igneous, though modified at a very early period of their history. This corresponds with what we find in nature, when we apply, cautiously and tentatively, the principles of interpretation which guide us in stratigraphical geology.

I have stated as briefly as possible what I believe to be facts. I have endeavoured to treat these in accordance with the principles of inductive reasoning. I have deliberately abstained from invoking the aid of "deluges of water, floods of fire, boiling oceans, caustic rains, or acid-laden atmospheres," not because I hold it impossible that these can have occurred, but because I think this epoch in the earth's history so remote and so unlike those which followed, that it is wiser to pass it by for the present. But unless we deny that any rocks formed anterior to or coeval with the first beginning of life on the globe can be preserved to the present time, or, at least, be capable of identification—an assumption which seems to me gratuitous and unphilosophical—then I do not see how we can avoid the conclusion to which we are led by a study of the foundation-stones of the earth's crust, namely, that these were formed under conditions and modified by environments which, during later geological epochs, must have been of very exceptional occurrence. If, then, this conclusion accords with the results at which students of chemistry and students of physics have independently arrived, I do not think that we are justified in refusing to accept them, because they lack the attractive brilliancy of this or that hypothesis, or do not accord with the words, in which a principle, sound in its essence, has been formulated. It is true in science, as in a yet more sacred thing, that "the letter killeth, the spirit giveth life."

CORRESPONDENCE.

THE MARTIAN CANALS.

Your recent articles on this subject summarise the observational results in a thorough manner; but the final and theoretical chapter much disappoints me. It may, possibly, have been written a month or two back; if so, the entire omission is explained of what is, in my opinion, the best hypothesis yet advanced—one due to Dr. Eugène Penard, of Geneva.

This first appeared, I believe, in *L'Astronomie* for October, and supposes the canals to be due to inundation of fissures, in the probably thick crust of the planet, produced by its secular contraction. We observe such clefts on a reduced scale in the moon, as well as in the Western States, the Deccan, and the South of France. In the case of the larger canals, we have probably a sinking *en masse* of the slice between two parallel fissures, such as occurs terrestrially in the Rhine Valley. Fractures here, as Daubrée found with glass, etc., would only stop at the edges, or on meeting with other cracks.

To extend this:—In the case of doubles, it is evident that a general sinking between the two clefts would occur but to a lesser extent, and therefore, after flooding, paler in tint. This explains why in August last the Lick telescope showed no duplicate canals, but simply shady bands of the width of the mapped twins.

Why, too, does your contributor dismiss the late Mr. Proctor's diffraction theory with the single argument that rivers do not cross continents from sea to sea? This is not even a terrestrial fact; for the Rhine and the Rhone form an almost continuous waterway across Europe, the Vosges and Jura Mountains preventing a straight course. Other examples might be given. The real and fatal objection is, that eyepieces of different powers have not been found to give distances varying out of proportion to them, as they would in the case of diffraction images.

In *L'Astronomie* for November, the indefatigable editor (M. Camille Flammarion), who furnishes fully half the "copy," gives utterance, in his usual enthusiastic style, to a somewhat lengthy "Last Word on the Planet Mars." In this he carefully reviews all Schiaparelli's recent observations, and finally comes to the conclusion that "the essential features of the Martian geographical configuration do not change." Whilst admitting our knowledge to be as yet insufficient to enable us to theorize, he regards the inundations as due to solar tides, and adheres to the hypothesis that the canals are really rivers, whose straight course is due to the absence of mountains (worn down, possibly, by past denudation), and the rapid precipitation of water in an atmosphere whose pressure is probably much less than ours.

Where seas are, there rivers must certainly be, and, as he points out, the canals always open into gulfs of estuarine appearance, and do not actually pass straight across continents, but end usually in lakes, whence other canals emerge, often at an angle. W. S.

South Kensington, Nov. 10th.

RECENT INVENTIONS.

The following list has been compiled especially for the SCIENTIFIC NEWS *by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents, of* 234, *High Holborn, London, W.C ; Newcastle Chambers, Angel Row, Nottingham ; Ducie Buildings, Bank Street, Manchester ; and* 6, *Lord Street, Liverpool.*

THERMOSTAT.—Messrs. C. R. Kinnell and G. Rothnie have patented a thermostat for automatically regulating the supply of gas or liquid fuel employed in heating buildings. The apparatus is in the form of an ordinary thermometer, having the upper portion of the tube divided into parts through which the gas passes. While the temperature remains below a certain degree the tube is open. If the heat exceeds this degree, then the quicksilver in the thermometer rises and enters this tube, thus diminishing or shutting off the gas supply. The temperature having fallen, the quicksilver falls, and the passage for the supply of fuel is again open.

GOLD ORES.—Mr. P. J. Ogle has patented an arrangement of the amalgamated plates used in the treatment of gold ores. The invention consists in employing a series of short amalgamated copper plates, mounted on a series of steps furnished with grooves, in which each plate slides, allowing the water carrying the crushed ore to fall from one to the other, thus bringing the float, or fine gold, into actual contact with the amalgamated plates. This arrangement causes the wash water to be broken up, and the plates being adjustable, a fresh surface of mercury can be presented to the wash water as soon as the working surface is inactive through saturation.

GASES IN MINES.—Mr. F. Bosshardt has patented an apparatus for detecting and announcing the presence of explosive gases in mines, on behalf of J. Molas. The apparatus consists in the combination of a diaphragm furnished with silver strips inside a chamber with a suitable number of terminals, in such a manner that on undue accumulation of gases entering the chamber the diaphragm is lifted and forms a contact between the silver strips and the terminals, thus causing a simultaneous and automatic ringing of alarm bells, and the lighting of an incandescent lamp through suitable electric connections.

ELECTRIC BATTERIES.—Mr. D. Urquhart has patented a process for the manufacture of elements for electric batteries. The plates or elements are made of peroxide of lead brought into intimate contact by means of an aqueous solution of ammonia, which produces a slow chemical change in the peroxide, causing it to become a permanently coherent mass. These plates are then treated with a solution of oxide of lead in caustic alkali. Means for making contact between the elements and the conductors are provided, which consist of an elastic fitting piece pressing platinum foil in contact with the interior of the element, the said platinum foil being connected to the conductors.

ALUMINIUM.—Mr. A. B. Cunningham has patented a process for producing aluminium and aluminium alloys. A bath of molten lead alloyed with metallic sodium is provided. The aluminium-containing substance is immersed in this bath, and volatilisation takes place, the fumes as they rise being caught and reduced before they can escape. The metal thus obtained having a very low specific gravity and no affinity to lead, rises to the surface, whence it may be skimmed off, and afterwards separated from any adhering lead. The process is continuous, as after the removal of the aluminium the bath is replenished with the amount of lead skimmed off, and recharged with sodium.

ELECTRO-DYNAMIC GENERATORS.—Mr. R. Tathan has patented improvements in electro-dynamic generators and motors. The armature, or equivalent, of such machines is provided with a commutator which rotates in contact with brushes, and the object of the invention is to increase the durability and efficiency of the armature. To carry this out, a to-and-fro motion is given to the brushes, in the direction of the longitudinal axis of the armature. Carriers are provided, and connections whereby the desired motion is imparted to the brushes, and apparatus is provided capable of being thrown into and out of contact with the commutator, for the purpose of truing, polishing, and maintaining the commutator circular in cross section.

CHROMIUM.—Messrs. T. and E. Rouff have patented a process for the manufacture of chromium, based on the simultaneous employment of alkaline or alkaline earthy chromates, and silica. A neutral chromate is mixed with flint and charcoal, placed in a reducing apparatus and heated to a red heat. At this temperature a silicate and free chromic acid are formed, and the latter is reduced to metallic chromium by the carbon. This spongy chromium is washed to eliminate the silicate, and a chromium is obtained containing the impurities of the materials employed. If to the mixture of the neutral chromate, etc., oxides of copper be added, alloys of copper and chromium are obtained in a single operation.

POWER HAMMERS.—Mr. A. Davy has patented a power hammer which is self-acting and operated by steam. According to this invention the piston is fitted in a cylinder whose lower end is always open to steam pressure, and in which the steam is exhausted from the lower to the upper side of the piston, and thence to the atmosphere, the arrangement of the exhaust ports and the length of the piston being such that one of the ports is always closed by the piston. The length of the piston is about equal to the stroke, and the areas of the upper and lower faces of the piston are so proportioned that the steam, after having passed from the under to the upper end of the cylinder, will, owing to the larger area of the upper surface of the piston, overcome the pressure of the steam on its under side.

DIARY FOR NEXT WEEK.

Tuesday, Nov. 20.—Institution of Civil Engineers, 25, Great George Street, Westminster, S.W., at 8 p.m.—*Friction-Brake Dynamometers*, by Mr. W. Worby Beaumont, M.Inst.C.E.

Zoological Society of London, 3, Hanover Square, W., at 8.30 p.m.—*Contributions to the Skeletal Anatomy of the Mesosuchia, based on fossil remains from the clays near Peterborough, in the collection of A. Leids, Esq.*, by Mr. J. W. Hulke, F.R.S., F.Z.S.—*On the Small Mammals of Duval County, South Texas*, by Mr. Oldfield Thomas, F.Z.S.—*On the Mammals obtained by Mr. C. M. Woodford during his second expedition to the Solomon Islands*, by Mr. Oldfield Thomas, F.Z.S.—*Liste Supplementaire des Oiseaux recueillis en Corea par M. Jean Kalinowski*, by M. L. Taczanowski, C.M.Z.S.

Wednesday, Nov. 21.—Royal Meteorological Society, 25, Great George Street, Westminster, S.W., at 7 p.m.—*Results of an Investigation of the Phenomena of English Thunderstorms during the years* 1857-59, by Mr. G. J. Symons, F.R.S.—*Notes on the Meeting of the International Meteorological Committee at Zurich in September*, 1888, by Mr. Robert H. Scott, M.A., F.R.S. Models of Hail-stones—spheres about 2½ inches in diameter—forwarded by Mr. A. C. Stratten, will be exhibited.

Thursday, Nov. 22.—Society of Telegraph Engineers and Electricians, 25, Great George Street, Westminster, at 8 p.m.

Saturday, Nov. 24.—Physical Society, Normal School of Science, South Kensington, at 3 p.m.—*On the Measurement of the Luminosity of Coloured Surfaces*, by Captain Abney, R.E., F.R.S.—*On the Suppressed Dimensions of Physical Quantities*, by Professor Rücker, F.R.S.

SELECTED BOOKS.

The Metallurgy of Gold. A practical Treatise on the Metallurgical Treatment of Gold-bearing Ores, including the processes of Concentration and Chlorination, and the Assaying and Refining of Gold. By M. Eissler, formerly Assistant Assayer of the U.S. Mint, San Francisco. With ninety illustrations. London: Crosby Lockwood and Son. Price 7s. 6d.

The Principles of Agricultural Practice as an Instructional Subject. By J. Wrightson, M.R.A.C., F.C.S., etc., Professor of Agriculture in the Normal School of Science and Royal School of Mines, etc. With Geological Map. London: Chapman and Hall, Limited. Price 5s.

SALES.

EXCHANGES.

METEOROLOGICAL RETURNS

for the ten weeks ending on Monday, Nov. 5th, 1888. Specially prepared for SCIENTIFIC NEWS from official reports.

SCIENTIFIC TABLE TALK.

BY W. MATTIEU WILLIAMS, F.R.A.S., F.C.S.

THE readers of SCIENTIFIC NEWS have had before them, in Nos. 17, 18, 19, a description of the curious observations that have been rec ntly made on "the mysteries of Mars," and of some of the efforts to explain them.

Twenty years ago I wrote an essay on "The Meteorology of Mars" which constitutes the sixteenth chapter of "The Fuel of the Sun," and have quietly watched the observations that have been made at each subsequent opposition. These observations not only confirm my original views of the atmospheric conditions prevailing on this planet, but as regards the "canals" they present phenomena which I partially anticipated, and which follow as natural consequences of the conditions I then theoretically described.

The reader may ask, What has the meteorology of Mars to do with the fuel of the sun? A short explanation will answer this. In the first chapters of the book I discuss the limits of our atmosphere, and show reasons for concluding that it and our aqueous envelope are merely portions of the universal medium pervading all space, and that their quantity attached to each orb is proportionate to its gravitating energy. This was a heresy twenty years ago, but is now widely accepted.

Knowing the gravitating energy of the earth and the quantity of its atmosphere, we are supplied with units affording data for calculating the density of the atmosphere of other orbs, provided we know respectively these two elements and their dimensions. Solar phenomena follow of necessity in all cases where there are solar dimensions.

As an *experimentum crucis* I calculated thus the theoretical atmospheres of the moon and all our planets, and compared the results with observed phenomena. All came right excepting Mars, which had hitherto been described as a planet with a dense atmosphere, while my calculation gave it a total supply of atmospheric matter equal to about $\frac{1}{20}$ of our own, or, allowing for the smaller base upon which it is resting, it becomes an atmosphere having a pressure of $2\frac{3}{4}$ lbs. on each square inch of the planet's surface, against 15 lbs. on ours. Therefore, the mercurial barometer should there stand at a mean of $5\frac{1}{2}$ inches, and water should boil at 138 degs. Fah., be as volatile as bromine, and much more so than alcohol down here.

But what were the grounds upon which the accepted estimate of the planet's dense atmosphere was based? I found on examination that there were none beyond a fanciful assumed provision for maintaining a temperature suitable for supposed human inhabitants. No measure of refraction by occultation had been made, and when fairly interpreted, all the telescopic phenomena flatly contradicted it.

If such an atmosphere prevailed with the assumed protecting vapours, Mars should have dense clouds. Mars has no such dense clouds. But there is something that occasionally obscures the planet, especially towards its outer visible boundaries, during opposition, when we best see it.

With such an atmosphere as my calculation demands, with such volatile water, on a planet with the intensity of solar heat at its surface less than half of that on the earth (0·431 to unity), there could exist "nothing denser than a thin veil of stratus, or cirro-stratus, cloud, formed of ice crystals, the kind of cloud or mist which in our upper atmosphere makes halos round the moon. The mid-day region and a certain distance around it would but rarely be subject to this small degree of obscuration, as the sun's heat there should, under ordinary circumstances, hold in transparent solution all the vapours it had raised." Outside of this circle, north, south, east, and west, "a deposition of hoar frost must be continually taking place all round the disc of the planet, and this will commence at a certain angular distance from the meridian centre of the disc, and increase gradually towards the circumference. The rotation of the planet will, however, produce a considerable difference in the results of this deposition. All that falls on the east and west sides oı the planet will be thawed and evaporated by the next day's sunshine, so that the maximum accumulation in these directions can be but one night's deposition; but on the north and south there will be a continuous accumulation which will only be thawed up to a certain latitude by the annual summer presentation of either hemisphere to the sun." ("Fuel of the Sun," page 169.)

Now let the reader turn to page 433 of this magazine, and he will see by Schiaparelli's diagram that what I described theoretically twenty years ago was observed by him in May and June of this year. The letters *bbbbb* surrounding each picture indicate "white spaces," besides the well-known polar patches.

With apology for inevitable egotism, I will quote my own essay again. "At the poles and for some distance around them, the annual amount of deposition must exceed the annual amount of thawing and evaporation, and therefore a gigantic glacial mountain must there accumulate, with a continual growth and tendency to assume the conical form. As the deposition of ice crystals would commence before actual sunset, and would probably reach its maximum, or even be finished, before reaching the boundary line of day and night (in consequence of the thinness of the atmosphere and the resulting rapidity of radiation), the building up of this polar mountain would be very irregular. In mid-winter the lower slopes would receive the greatest accessions. With the advancing line of daylight the elevation of the zone of maximum deposition would increase until it reached the summit. This coincidence of maximum deposition with the summit would occur twice a year, before and after mid-summer. During the summer the only regions receiving any deposition at all would be the summit and its immediate vicinity; while at the same time the sides would be rapidly thawing by the powerful action of the continuous sunshine of the one long arctic summer day. *At this season, the slopes of the arctic mountain would be riven by gigantic ice-floods and water-floods, avalanches, glaciers, and torrents.*"

The "canals" are, I believe, these "water-floods" or "torrents." Their theoretical magnitude will be understood by considering the dimensions of the polar ice mountain, which, according to Professor Phillips, reaches in winter to latitude 50, that is, nearly half way from the pole to the equator of the planet; the polar snow circle as seen by the telescope has a diameter of 2,000 miles in winter, on a world having but half the diameter of ours. Its reduced summer diameter is about 500 miles; thus a ring of ice measuring 6,283 miles in outer circumference, and 750 miles broad, is thawed away in half a Martian year. Its thickness, according to my original estimate, is measurable in miles. The consequent floods must be enormous, vastly beyond anything within the reach of our terrestrial experience, although on a globe so much smaller, only one-fourth of our area.

Over what kind of ground would these great torrents flow? As I have shown in the above quoted essay, the seas of the tropical and temperate zones of Mars cannot be of liquid water; they must be oceans of ice, the mere surfaces of which are daily thawed and refrozen. Thus the apparent paradox of these rivers crossing the seas as well as the land, is explained.

Besides this, there should be, as I have argued, a great moraine heap surrounding the regions of polar snows; this ring moraine "consisting of the materials which the advancing polar glacier has scooped out and driven before it. This perpetual out-thrust of the great polar glacier—this continual erosion of the circumpolar regions of the planet, ever at work since the date of its primeval consolidation, must have produced a sensible alteration of the shape of the planet—must have flattened it in the immediate neighbourhood of its poles, and bulged it in the moraine regions beyond."

We thus obtain theoretically a great ring-shaped circumpolar lake, walled up by a surrounding ring-shaped ridge of moraine matter of mountainous dimensions.

Between the time of the writing and publishing of these speculations, Mr. Browning published his stereograms of Mars and some charts. On these are shown a ring of water completely surrounding the limits of the North Polar ice, to which Mr. Proctor gave the name of Schröter Sea, and beyond this a circular ridge which he calls "Laplace Land." Similar features are repeated around the South Pole, where the circular erosion valley is named "Phillips Sea," and the ring moraine is, on its polar boundary, so symmetrical that it nearly represents a parallel of latitude, but on its equatorial side has some remarkable promontories bearing the names of "Cassini Land" and "Lockyer Land."

If my theoretical views are sound, the waters of these circumpolar seas must in the Martian summer time rise to the upper limits of the great moraine barrier and overflow or break through it, then flow onward in a course determined by the general slope, which should be pretty regular, owing to the regularity of the piling-up action.

In reference to this it should be remembered that the Martian summer is nearly double the length of ours, the tilting of its axis a little greater, and the eccentricity of its orbit much greater, all increasing the variations of climate. Therefore the winters of the polar regions must be intensely cold and the summers hot, and their heat most effective, on account of the continuous sunshine. The amount of thawing would therefore be enormous, and floods pouring over or through the barrier proportionate.

If it should happen that two notches or outlets of the great moraine ridge occur near together, a great river would flow from each. With similar conditions of slope, their courses should be nearly parallel; hence the "germination" or twinning of the "canals." I must not be tempted into further details, having already overrun my space.

CAUSE OF THE ABSENCE OF TREES IN THE AMERICAN PRAIRIES.

FOR a considerable time the grass-fires which in former days recurred almost periodically have been regarded as the chief cause of the absence of trees in the wide prairie districts of North America, since they must infallibly destroy any young growth. Still, they cannot have been the original cause, for the prairies existed before human beings and fires could have occurred. Another hypothesis has sprung from recent investigations on loess and laterite; the "ground-water" in the prairie regions lies at such a depth as to be out of the reach of the roots of the young trees. Hence seedlings perish in the first prolonged drought, and trees can in consequence maintain themselves only on the margin of rivers. One striking phenomenon, however, could not be thus explained—the occurrence of isolated woods, not in hollows, but, on the contrary, on sandy eminences where they might have least been expected. The most extensive case of this kind is the forest belt known as the Cross Timbers.

Professor Thomas Meehan has recently given a very satisfactory explanation of this phenomenon in a paper read before the Philadelphia Academy of Sciences. He has observed in the neighbourhood of Roan Mountain, in North Carolina, small tracts of grass land lying isolated in the forest. These tracts have evidently maintained their boundaries very accurately for a long time, and are surrounded by very ancient trees. They have been formed by *Danthonia compressa*. The seeds of trees which fell upon the grass were unable to reach the soil, and thus withered away; but as soon as cattle were turned upon these meadows, and the grass was eaten down, young trees sprang up everywhere; and though most of them were browsed down by the cattle, some escaped, shot up, and finally overspread the entire meadow. Meehan applies this observation to the great prairies. He considers that the grasses took possession of these regions soon after their elevation above the sea level, and certainly before the seeds of trees could be brought thither and could be developed. The trees advancing laterally found themselves checked by the grass, which hindered their seeds from vegetating, and only permitted them to advance very slowly by suckers from the roots. Since the advent of man they have been further retarded by the prairie-fires. The sandy tracts formed an exception, as upon them the grass grew less luxuriantly, and the seeds of the trees were able to vegetate. Thus in the prairie region we meet the striking phenomenon that the sandy tracts are wooded, whilst richer soils remain covered with grass.

NEW HEATING APPLIANCES.

MESSRS. FLETCHER AND CO., of Warrington, have just added two more heating apparatus to the already large variety introduced by them. Fig. 1 represents an instantaneous water heater which is at once simple and efficient. It can be made only 14 ins. long by 6 ins. high, and can be fixed to a wall as illustrated; a heater

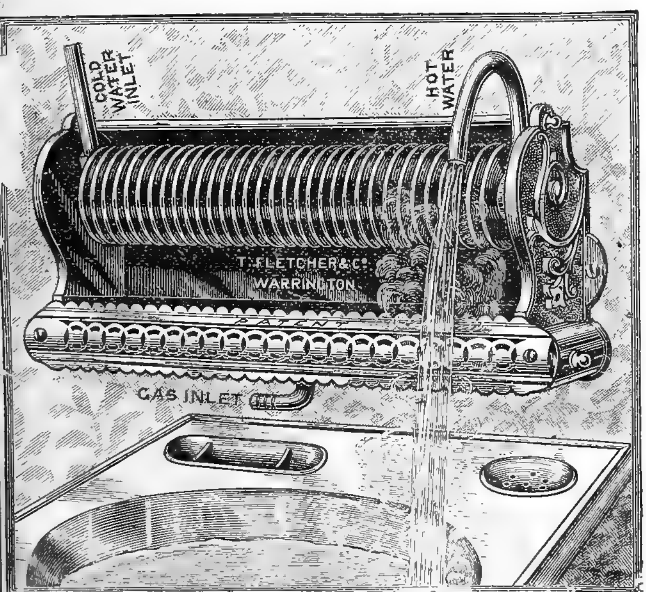

Fig. 1.

of this size will yield one quart of water per minute, heated from 60 degs. to 125 degs. F. It will be seen that a large number of circular flanges are attached to the cylindrical body of the heater, and as these flanges are made of copper, and as jets of gas are burnt under them, they offer a large heating surface and conduct heat rapidly to the water. The heater is strongly made, and is not easily injured even if the gas is lighted and the water forgotten. The inlet and outlet tubes at each end of the heater are interchangeable so that they can be fixed on whichever end is most convenient.

Another useful little apparatus is shown in Fig. 2. This consists of an atmospheric burner, above which there is a movable cylinder, and on this a stand for

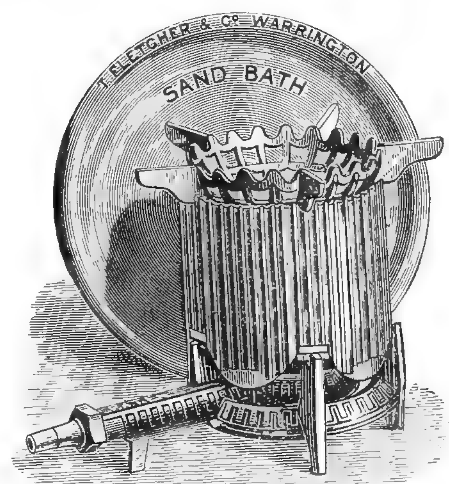

Fig. 2.

glass flasks, porcelain dishes, flat-bottomed vessels, or a sand bath. By lowering or raising the cylinder the vessel to be heated can be placed at different heights, and by this simple contrivance and by turning on the gas more or less the temperature can be closely regulated. These burners are made in four different sizes.

THE GREENLAND EXPEDITION.

THE *Times*, in a letter from a Danish correspondent, gives the following account of Dr. Frithiof Nansen's adventures in his attempt to cross Greenland on snow-shoes:—

In May Dr. Nansen and party left in the *Thyra* for Iceland, *viâ* Granton, and on June 4th they embarked in the Norwegian whaler, the *Jason*, Captain Jacobsen, who had promised to take them to the eastern Greenland coast in Denmark Sound. Circumstances did not prove as favourable as had been expected, and the *Jason* had to try several places without being able to come near enough to the shore. At last a convenient point was found outside the Srmilik Fjord at about 65 deg. 30 min. N. lat., and on July 17th, at 7 p.m., the doctor and his five men, with their well-packed baggage, were landed on the ice rim. From Isafjord, in Iceland, they had brought a little pony, whose assistance they had reckoned upon for drawing their heavy sledges over the first ice and for then supplying them with some fresh meat, but fodder got short on board and the pony had to be killed before leaving. The party had a light boat to help them over open spaces in the water, and their first advance, as seen from the vessel, appeared quite satisfactory. The last that was seen of them was some hours later, when, from a huge ice-block, they waved their adieu and disappeared in the fog. Since then until now nothing has been known of the party, fear and hope struggling for the upper hand. We now learn that not less than twelve days were spent on the ice before they reached *terra firma*, and it will most likely turn out that this part of the expedition was the most trying and the most dangerous. The landing was effected some 300 miles more to the south than originally intended, and this proves that strong southernly currents must have carried the ice floes along the shore and away from it. How they managed to climb the steep glaciers in order to get upon the real inland ice we are not as yet told, but the actual journey across, beginning on August 15th, took forty-six days. The distance being about 400 miles, this gives a daily average of less than ten miles, but it appears that when the party had reached an altitude of some 7,500 feet a northern snow-storm compelled them to deviate from their intended course, whereby the actual distance traversed has evidently been much increased. The highest altitude registered was over 10,000 ft., and here they found a temperature of from –40 deg. to –50 deg. C. At the end of September the descent, the last but not least dangerous portion of the trip, was made, not at the colony of Christianshaab, as first intended, but in a small bay not far from Godthaab. Dr. Nansen and Mr. Sverdrup here built a kind of boat or floating raft with their sleeping-bags and some drift timber, and leaving behind the four others, managed to reach Godthaab. Here they found that the last vessel for this season had left, but they heard that there might be some chance of there still being a steamer ready for starting at Ivigtut, the Cryolith shipping-place, and so they hired two kajak-men to bring letters to Ivigtut. The *Fox* had then gone, but some mishap to the engine had compelled the steamer to return for repairs, and it was only half an hour before its second starting that the kajak-men, paddling with all speed from the north, were observed. Dr. Nansen's letter to the captain of the steamer pleaded hard for himself and his followers to be waited for some days—he ventured even to say only for four days—and expressed in touching terms his and their longings for home after so many dangers and fatigues. It seems to all a great pity that the captain did not feel competent to meet this fervent wish, even if it should have taken a longer time, but peremptory orders from home, where this incident had not been foreseen, bound his hands, and the advanced season did, in fact, expose his steamer, already crowded with passengers, to the danger of being frozen in if he had tarried longer, and he felt sure that the whole party could not have reached him in less than a month. So Dr. Nansen and his followers will be compelled to stay over the winter at Godthaab, but as this colony is, relatively speaking, quite a big place, they will have every comfort that civilisation and human company can afford until next spring brings them home to receive the reward of praise and admiration to which their courage, pluck, and endurance so fully entitle them. It is hoped that the letter from Dr. Nansen which the *Fox* is announced to bring for Mr. Gamel will contain some continuous and succinct report of the various stages of the expedition. If that proves so I shall forward you a translation of it.

In a subsequent issue of the *Times* the following appeared :

The short letter from Dr. Nansen to Mr. Augustin Gamel, in Copenhagen, the defrayer of the expenses of the expedition, is as follows :—

Godthaab, Oct. 4th.

I have at last the great joy to report to you that Greenland has been successfully crossed from east to west. I regret that the very short time left to me before despatching my messengers will not permit any detailed account. I can just jot down a few words to be forwarded by the kajak-men I am sending southwards in the hope of stopping the *Fox* at Ivigtut, and getting her to wait for us and take us home this autumn. But in case the kajak messenger should catch the steamer without inducing her to wait for us, I write these few lines just to inform you that we are all alive and well.

As you will know, we left the *Jason*, the Norwegian sealer, on July 17th, and expected to reach the shore the next day. But in this we were sadly disappointed. Screwing ice, maelstroms, impassable ice, where it was alike impossible to row or to drag the two boats, stopped us. One of the boats was stove in, but we got it repaired again. We drifted seawards at a speed of 30 sea miles in the 24 hours. Drifted in the ice for 12 days. Strove hard to get to the shore, were three times on the point of succeeding, but were as often carried out to sea again by a current stronger than our power of rowing. Were once, for a whole day and night, very near perishing in tremendous breakers of the sea against the ice-rim. After 12 days drifting about, we managed at last to get ashore near Andretok, north of Cape Farewell, at 61 degrees and some minutes of northern latitude. We rowed again northwards, reaching Uminik, from which point the crossing of the inland ice began on August 15th.*

We directed our course for Christianshaab on the western coast. Encountered severe snowstorms and had heavy ground. Estimating that it would be too late to reach Christianshaab in time for this autumn's vessel, we altered our course and steered for Godthaab, the ice-fields in that direction having, besides, been hitherto trodden by no one. After altering course reached height of 10,000 ft., with temperature of 40 degs. to 50 degs. C. below zero. For several weeks we remained at an altitude of over 9,000 ft. Tremendous storms, loose, new-fallen snow, enormously difficult passage. Towards end of September we reached at last the western side above Godthaab. Had a perilous descent on ugly and very uneven ice, but got safely down to Ameralik Fjord. Managed to build a kind of boat from floor of tent, bags, bamboo reeds, and willow branches. In that frail craft Sverdrup and I rowed away, and arrived here on October 3rd. The four men are left at Ameralsk, living there on short rations fare, but will be sent for as soon as possible.

There you have in short outline our Saga. We are all perfectly well, and everything has been in the best order. I hope that we may catch this steamer, and that instead of this letter you may see our sunburnt faces.—With many greetings, yours ever devotedly, FRITHIOF NANSEN.

P.S.—Just now the kajak-men must leave, profiting by the favourable weather. They have 300 miles to make before getting to Ivigtut.

At the same time is published a letter from Mr. Sverdrup to his father, and as this gives certain supplementary details, I give a translation also of that :—

Godthaab, Oct. 4th, 1888.

We arrived safely here yesterday after forty-six days' wandering from east to west. It did not prove so easy to get on shore from the *Jason* as we had expected. We got into formidable ice-screwings, and the current took us southwards and out from the shore, so that we had twelve days' very hard work before getting to land, and that 300 miles more to the south than we had intended. We began at once to work back along the coast, and this took us another twelve days, so that we did not begin our crossing of the ice before August 15th. The ascent was very fortunate, as we chanced to find comparatively easy ice to climb up. We shaped our course for Christianshaab, but after getting up to 7,500 ft. we were attacked by a northern snowstorm. We resolved, therefore, to set our course for Godthaab, the distance being shorter, and there being a better chance of favourable winds. I may

* It appears that after getting into the shore the party found a line of open water between the land and the ice rim. It must have taken them even more than twelve days to regain the ground they had lost by drifting to the south, since the crossing did not begin before August 15th.

truly say that we had a hard time of it. The snow and ice were very heavy, and the weather was trying. For nearly three weeks we were up at nearly 10,000 ft., and had a temperature of —40 degs. to —50 degs. C. Only for four days were we snowbound. After all, we have to be thankful it was not worse. After getting down from the inland ice on the western coast, we had before us some ninety miles of barren country, of which the half lay along a fjord. We tried to cross here, but found it too hard work; so we managed to construct a kind of boat from the bottom of the tent and some bags, and in that, after four days' rowing, Dr. Nansen and I reached here, where we had the most cordial reception from all the inhabitants of the colony. Two boats have now been sent to the bottom of the fjord to fetch our comrades. The regular vessel has long since left, but some 250 or 300 miles further south there is supposed to be, at Ivigtut, a steamer loading for Copenhagen, and we are now sending a kajak-message in order to stop that steamer if possible. We have but little hope of that, however, and are preparing to pass the winter here. That may be very comfortable after all, but, of course, we would prefer getting home. I must hurry up, as we are now going to dine with the parson, and, in fact, we have not had time for anything, as since arriving here we have gone from one social party to another. You may see from that how well we are off. I was the only one of our whole party who got over all the tremendous fatigues without the smallest ailment. I am, and have been all the time, as fresh and sound as a fish.—With the kindest regards, etc.

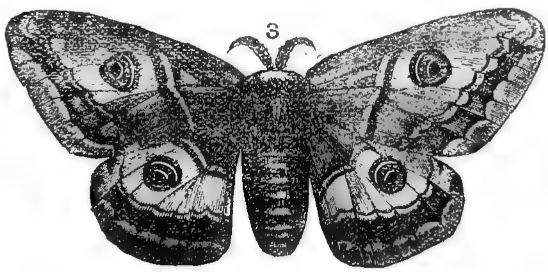
THE NEGLECTED SENSE.

If in ordinary modern life any one of our senses may be pronounced useless, it is that of smell. Yet it has capabilities which are quite overlooked, and which, if systematically cultivated, might enable it to play a part in the study of the natural sciences second to that of sight alone. Hearing, however important it is as a means of communication with our fellow-men, is almost out of court in the exploration of natural phenomena.

Of course the acuteness of smell in man is much less highly developed than it is in certain of the lower animals. Everyone is familiar with cases proving the wonderful olfactory power of the dog, especially of the bloodhound. But the faculty of scent in certain insects is inconceivably more acute and delicate. This is especially the case with moths. If a virgin female of certain species, *e.g.*, *Saturnia carpini* or *Sphinx convolvuli*, is shut up in a box, males of the same species will come flying, even though the nearest locality where they could have been concealed is at the distance of nearly a mile, and though woods, eminences, and houses may intervene. The emanations from the female moth, of whatever nature they may be, are evidently diffused through space and diluted with an excessive quantity of air, which may be scentless or may be saturated with other odours. Yet this infinitesimal trace is sufficient to guide the male towards her with unfailing accuracy. This is as if a human being were able to detect the presence of an individual of his own species at the distance, according to the lowest computation, of from four to five miles. Did hounds possess such a sense they would not search and snuff about for the track of the fox, but would go at once in a straight line to the spot where he might be lurking.

Such feats we cannot hope to rival. We do not possess the highly-developed olfactory nerve of the dog, or the plume-like antennae of *Saturnia carpini*. But even among mankind the sense of smell reaches a degree of delicacy which is to other persons scarcely credible. The aborigines of Peru, Chili, and other parts of South America can, in the darkest night and in the thickest woods, distinguish respectively a white man, a negro, and one of their own kindred by the smell. They have in their own language words to express the differences —words which, of course, cannot be rendered into any European tongue. But our defective power of smell, as compared with that of such semi-savages, is due not to any natural deficiency on our part, but to our manner of living. The writer feels justified in making this assertion from an instance which came under his own observation. A lady who had suffered long and severely from neuralgia was at last advised to renounce tea and coffee, all hot liquids, all spices, condiments, and everything else of an irritating or stimulating nature. She carried out this advice, and her power of smell became quite a wonder to all her acquaintances. Her judgment on the purity of a water supply became more than analytical in its accuracy and delicacy.

Here, then, lies the secret. She lived as far as foods and drinks are concerned, like the native Peruvians, and if she did not quite equal them in the nicety of her sense of smell, it was because in her earlier life she had been in the habit of using mustard, pepper, hot tea, and the like. It is, therefore, very probable that a similar style of living would in all persons very much improve this



Saturnia Carpini.

neglected sense. Even at present, according to a paragraph from *Liebig's Annallen* quoted in our number for July, 1887, our smell is more delicate than our eye-sight. No little admiration has, for instance, been excited by the delicacy of the spectroscope. We all know how, by means of this instrument, extremely minute portions of various chemicals—far too small to respond to any other test—may be made clearly evident to our sight. Of these spectroscopic indications the most delicate of all is the yellow band which appears when a trace of the metal sodium is burnt in a gas-flame or in an electric spark (see articles on the spectrum in our numbers for June, July, and August, 1887). But without the aid of any instrument, and without any previous training, the human nose is capable of detecting quantities of certain substances thirty times smaller. It is possible to recognise by smell $\frac{1}{4000000000}$ of a milligramme of mercaptan, and as a milligramme is only the 0·0154th of an English troy grain we have here a degree of delicacy of which it is hard to form any definite idea!

There is another circumstance which gives additional value to scent-indications. Although we have no names for different smells and can merely describe them by comparisons, they fix themselves in the mind far more permanently than the impressions of the other senses. If we have once met with any particular odour, we recognise it years after, even though we may never have come across it in the interim.

Of this we have a remarkable instance in our personal experience. When the writer was at the age of ten, a lady who had lived many years in South Africa, returned to England, bringing with her a large quantity of buchu-leaves. All her clothes were saturated with the scent of this drug, and as she paid a visit to our family we were struck with the smell, though we did not even know the name of the plant. Some thirty years afterwards happening to call upon a medical friend, we recognised this smell in his house, and found that he was experimenting on the best method of obtaining the virtues of the plant in a concentrated form.

It will be admitted that to the biologist the sense of smell may be of great service in recognising animal and vegetable species. The chemist, in like manner, uses it in distinguishing volatile bodies, and may often by its aid obtain a valuable hint as to the reactions which are going on. What is wanted is, firstly, a nomenclature for smells, just as we have for colours and for sounds, so that we may put on record and make known the impressions which we receive.

Secondly, we want means for training this sense. Few persons, perhaps, would be willing to renounce spices, condiments, spirits, hot liquids, tobacco, etc., but it may be useful to know that a draught of cold water, held in the mouth but not swallowed, gives a temporarily increased delicacy to the smell.

It may also be asked how far we can obtain in our researches the assistance of insects? Bees have already served to detect the difference between true cane-sugar and its hated rival beet-sugar—a distinction which our scientific instruments have hitherto been unable to show.

ARTIFICIAL CAVERNS.

IN various parts of the earth there are found cavities evidently of artificial origin, and as evidently not connected with mining or with any other industrial operations. Such excavations, in the form of underground passages, are particularly abundant in Bavaria and Austria, and have for some time attracted the attention of archæologists. The following account of these so-called "earth-stalls" is chiefly derived from the *Beitragen zur Anthropologie und Urgeschichte Bayerns*, the *Mittheilungen der Anthropol Gesellschaft in Wien*, and the *Naturforscher*.

The number of these evidently very ancient cavities is exceedingly great, and is being often increased by fresh discoveries. Many local traditions point with certainty to the existence in various places of underground passages which have not yet been brought to light.

These "earth-stalls," or goblin holes, have been particularly studied during the last nine years by the Rev. Lambert Karner. He has visited and explored nearly 200 such caverns in Lower Austria and Moravia, accompanied in many instances by his friend the artist Spoettl, who sketched the most remarkable features on the spot.

The "earth-stalls" form complete systems of passages and chambers. Their main feature is the labyrinthine ramification of the passages, which can be traversed only by one person at a time, and that generally in a bent or even creeping attitude. There are perpendicular passages or shafts, with holes into which the feet may be introduced in ascending or descending, some of them being seven yards in height. There are also at regular intervals small niches about the size of a fist, in which burning lamps have been placed, as appears from the traces left. The chambers have often an elegant form, and are fitted with seats or benches and large, handsome niches, with pointed or rounded arches. The size of these chambers, hundreds of which have been measured by Karner, is almost always alike—nearly 2 yards in height, and 1½ to 2 yards in length and breadth. Another curious fact is the uniform position of these chambers, and, indeed, of the whole structure, with reference to the points of the compass, as the angles of the chambers are turned towards the four cardinal points. Some of them have large niches, symmetrically arranged, with bell-shaped or dome-shaped tops.

At the summit there is often an air-hole, and a niche for holding a light is generally opposite the end of every passage. In many cases the access to the final chamber is very difficult, and this is excavated with especial elegance, and seems to have been a kind of sanctuary.

As an example we may take the caverns at Oberndorf. The passage leading to the last chamber from the last but one is only 20 ins. in width and 22 in height. It leads first due south, and then forms an angle and turns to the north-east. The chamber which is ultimately reached is distinguished by its size and shape from all others. It is 4 yards long, rather more than 1½ in width and height, with an arched top. In each of the sides there are two elegantly formed niches.

It must further be added that the plan often takes the form of a cross, and that the excavations are connected with wells locally regarded as holy. Both the passages and chambers have been provided with doors.

What can have been the purpose of these excavations? The oldest documents in which they are mentioned date from the beginning of the 13th century, but they are indisputably much more ancient. After considering the great extent of territory over which they occur—Bavaria, Upper and Lower Austria, along the Bohemian frontier, in Movaria, in Hungary, and Styria—and everywhere with the same characteristic peculiarities, and remembering that this region coincides with the great kingdom of the Quadi, Karner comes to the conclusion that the earth-stalls must date back to the time of the Quadi.

His conjecture is supported by the fact that artificial caverns have been found within the lines of the great Quadian fortress at Stillfried. Karner does not believe that these caves served exclusively as dwellings, since no fireplaces have been found in them. It is probable that the excavations were visited only at times, and that for a fixed purpose, probably for worship. Whether rites were here performed in honour of the dead is for the present doubtful, for in the hundreds of chambers which Karner has explored nothing decisive has been found, although he was told of skeletons lying there. In Moravia traditions are current of old men who dwelt in these excavations, and who on being touched crumbled away into ashes. According to a statement quoted by Harkmann, two urns were found in 1886 in an artificial cave in Upper Austria, the first discovery of the kind made in any of these excavations. But no details concerning these alleged urns have been made public.

If the conjecture be well founded that these caves are the work of the Quadi, they must date back to the first centuries of our era, for the very name of the Quadi, a race allied to the Marcomanni, who occupied the regions mentioned from the first to the fourth century, disappears from history entirely in the fifth century.

General Notes.

An Application of the Phonograph to Medical Studies.—According to *Cosmos*, it is proposed to supplement pathological treatises by a collection of typical phonographs representing the normal sounds of the heart and lungs.

Chemical Interaction of Solids.—Mr. W. Hallock (*Science*) has read a paper controverting the views of the Belgian chemist Spring. Hallock maintains that the chemical action detected by Spring is due to the vapour given off by one of the bodies.

Sanitary Neglect in Florida.—Sanitary investigations in Florida undertaken in reference to the epidemic of yellow fever show in some of the towns a most deplorable condition. In Maclenny, a small town of perhaps 600 inhabitants, the only water supply is obtained from wells of 15 to 20 feet deep, and inevitably polluted.

Royal Society.—We learn that the Copley medal has this year been awarded to Professor Huxley, in recognition of his investigations into the morphology and histology of vertebrate and invertebrate animals, and for his services to biological science in general during many past years. The Rumford medal is to be given to Professor Tacchini, renowned for his researches in solar physics, and the Davy medal to Mr. Crookes for his researches on the electric discharge in high vacua. The Queen has approved the award of the Royal medals to Baron Ferdinand von Mueller, the Australian botanist, and to Professor Osborne Reynolds, of Owens College, for his researches in mathematical and experimental physics. The medals will, as usual, be presented at the anniversary meeting of the Society on St. Andrew's Day.

Comparative Statistics of the Sexes.—Every census taken in Germany shows a decrease in the number of men and an increase of women. The last census shows a million women more than men, or 104·3 women to 100 men. There are still more boys than girls, which proves that a higher death-rate is the cause of the numerical inferiority of males, joined also to emigration. In Berlin women predominate to such an extent that there are more than 108 women to 100 men. Between the ages of 60 and 70 there are 150 women to 100 men, and between 70 and 80 no fewer than 196 women to 100 men. This shows that men expend more vital energy than women, and therefore succumb more readily to any destructive influence which they may encounter.

Adulteration of Wines.—The sophistication of wines and liqueurs in France is exciting not merely popular but official alarm, and at a recent Cabinet Council special legislative action was resolved on. Dr. Laborde, in a memoir laid before the Academy of Medicine, states that he has found in one litre of "liqueur de noyau" from five to six grammes of nitro-benzol, a highly poisonous product of coal-tar. The same liqueur is sometimes got up instead, with the aldehyde of benzo-nitril. The same authority shows that absinthe occasions tetanic convulsions. It is remarkable that none of our moral reformers call attention to the necessity of absolutely prohibiting the importation of this deadly liquid into Britain, and its manufacture and sale here.

The Edinburgh Exhibition.—Last Friday a meeting of the Edinburgh International Exhibition Association was held in Dowell's Rooms, Sir Thomas Clark presiding. The report of the joint committee, appointed by the association and the executive, as to the disposal of the exhibition surplus, recommended that the sum of £2,000 be paid to Sir James Gowans for services rendered to the exhibition, and that the surplus be thereafter divided as follows:—£1,500 to the Edinburgh Public Library, £1,000 to the Scottish Meteorological Society in aid of the Ben Nevis Observatory, £850 to the Edinburgh Exhibition Trust for the purpose of carrying on or assisting future exhibitions in Edinburgh or elsewhere, including artisan and amateur exhibitions, £100 to the Edinburgh Choral Union, £100 to the Royal Scottish Geographical Society, and £50 to the exhibition of decorative handiwork at present being held in Edinburgh.

Royal Geographical Society.—At the opening meeting of this session of the Royal Geographical Society, Mr. H. H. Johnston, the well-known traveller, and Her Britannic Majesty's Consul in West Africa, read a paper on the Niger Delta and the Oil Rivers. The theatre of the University of London, in which the meeting was held, was quite filled, the audience including several distinguished persons. Mr. Johnston's account of the Niger and its neighbours, their scenery, their luxuriant and varied vegetation, the native villages and towns on their banks, with their inhabitants, the results of European contact with the natives, and his own remarkable adventures, was of an unusually attractive character. Moreover, Mr. Johnston exhibited on the screen throughout his lecture a continued succession of pictures from the lantern, some of them from photographs, but most of them from his own beautiful sketches; while a large number of his original sketches were inspected by the interested audience after the lecture. The large map constructed under Mr. Johnston's care, which was exhibited, records the results of his own observations, and is a valuable addition to the cartography of West Africa.

A Spring over 3,000 feet Deep.—In carrying out the works for utilising the waters of the Seltzer Spring, Saratoga, for the purpose of liberating and storing in liquid form the carbonic acid gas with which the spring abounds, Mr. Oscar Brunler, who is superintending the arrangements, has made a remarkable discovery. The Seltzer Spring was discovered about three years ago by Dr. Haskins, who put down the drill to the depth of 500ft. At this depth an abundant supply of water was found flowing from a crevice in the rock bottom. Recently, in order to ascertain the depth of the spring, Mr. Brunler sounded it with a line and plummet; but, instead of resting at 500ft., the weight sank the whole length of the line, 900ft. Other soundings have since been made, the weight used being a piece of 1in. gas-pipe, filled with lead, and weighing 34lbs., until a depth of 3,300ft. has been reached, and yet without touching bottom or any obstacle. It will be impossible to take further soundings until instruments expressly designed for the purpose have been made. Mr. Brunler admits that the line may have been carried away by some powerful current, but he holds to his belief in the existence of a subterranean sea of greater or less extent, and of there being some connection between it and the Atlantic Ocean. In other words, Saratoga is over a vast water-filled cavern, the roof of which is about 500ft. thick. He also thinks it probable that at a given depth and temperature carbonic acid gas may be found in a liquid state. Should the existence of a subterranean sea be established, it would dispose of many theories and scientific speculations as to the source and course of the mineral springs at Saratoga.

The Equatorial Boundary of the Occurrence of Snow.—H. Fischer (*Berlin Gesellschaft für Erdkunde*) distinguishes between the mean altitude at which snow occurs every winter and the extreme boundary which it reaches in exceptional seasons. The immediate coasts of the Mediterranean, save to the north of the Adriatic and the Ægean, experience a fall of snow only exceptionally. From the Cilician Taurus the mean limit of snow extends over Mosul to Bagdat and Schiras, rises then to Teheran, and runs over Herat, Candahar, and Kelat in Beloochistan, on the mountains west of the Indus, to 28 N.L. On the southern slope of the Himalayas the boundary runs at about 5,500 feet above the sea level. In the interior of China the limit is not certainly determined. It cuts the Chinese coast to the north of Shanghai, touches the southern parts of Kiuschin and Schikoku (Japan), and meets the west coast of America in 47½° N.L. Passing through the Rocky Mountains and the Sierra Nevada, it turns downwards, almost to the tropic of Cancer. In Texas it bends to the north again, crossing the Mississippi in 31½° N.L., leaves America a little to the south of Cape Hatteras, and meets the French coast to the south of Bordeaux. In the southern hemisphere it follows in general the parallel of 40° S.L. Neither the coast regions of Tasmania nor the western and northern parts of the southern island of New Zealand suffer from snow every year. Along the Andes the line rises to 8° S.L. Snow falls occasionally in Mesopotamia, Lahore, Canton, in Mexico, but never at the southern point of California. In the southern hemisphere snow occasionally falls along the Blue Mountains of Australia to 27° S.L. In New Zealand only the extreme northern point enjoys an immunity from snow. Snow has been known to fall in Rio de Janeiro, and even in 20° S.L., a little farther inland.

The Annual Ring in Trees.—In the course of his last report, the chief of the forestry section of the Agricultural Department of the United States, referring to the annual rings in trees, asserts that these exist as such in all timber grown in the temperate zone. Their structure is so different in different groups of timber that from their appearance alone the quality of the timber may be judged to some extent. For this purpose the absolute width of the rings, the regularity in width from year to year, and the proportion of spring wood to autumn wood must be taken into account. Spring wood is characterised by less substantial elements, the vessels of thin-walled cells being in greater abundance, while autumn wood is formed of cells with thicker walls which appear darker in colour. In conifers and deciduous trees the annual rings are very distinct, while in trees like the birch, linden, and maple the distinction is not so marked, because the vessels are more evenly distributed. Sometimes the gradual change in appearance of the annual ring from spring to autumn wood, which is due to the difference in its component elements, is interrupted in such a manner that a more or less pronounced layer of autumn wood can apparently be recognised, which again gradually changes to spring or summer wood, and then finishes with the regular autumn wood. This irregularity may occur even more than once in the same ring, and this has led to the notion that the annual rings are not a true indication of age; but the double or counterfeit rings can be distinguished by a practised eye with the aid of a magnifying glass. These irregularities are due to some interruptions of the functions of the tree caused by defoliation, extreme climatic condition, or sudden changes of temperature. The breadth of the ring depends on the length of the period of vegetation; also when the soil is deep and rich, and light has much influence on the tree, the rings will be broader. The amount of light and the consequent development of foliage is perhaps the most powerful factor in wood formations, and it is upon the proper use of this that the forester depends for his means of regulating the development and quantity of his crop.

The Public Health.—According to the Registrar-General's return for the week ending Saturday, November 10th, the deaths registered in 28 great towns of England and Wales corresponded to an annual rate of 19·0 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The six healthiest towns were Bradford, Brighton, Hull, Leicester, Halifax, and Wolverhampton. The highest annual death-rates, measured by last week's mortality, were—for measles, 1·8 in Blackburn, 2·2 in Portsmouth, 3·0 in Leeds, and 3·8 in Cardiff; from scarlet fever, 1·0 in Manchester, 1·2 in Salford, and 2·2 in Blackburn; from whooping-cough, 1·0 in Birkenhead; from "fever," 1·1 in Oldham, 1·3 in Newcastle-upon-Tyne, and 1·6 in Salford; and from diarrhœa, 1·4 in Bolton and in Cardiff, and 1·6 in Derby. The 45 deaths from diphtheria in the 28 towns included 34 in London, 2 in Liverpool, and 6 in Salford. Small-pox caused 1 death in Preston, and 1 in Hull, but not one in London or in any of the 25 other great towns. In London 2,770 births and 1,520 deaths were registered. Allowing for increase of population, the births were 70 and the deaths 167 below the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had been 21·2 and 19·7 in the two preceding weeks, further declined last week to 18·5. During the first six weeks of the current quarter the death-rate averaged 19·1, and was 0·4 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,520 deaths included 109 from measles, 18 from scarlet fever, 34 from diphtheria, 15 from whooping-cough, 14 from enteric fever, 18 from diarrhœa and dysentery, and not one from typhus, ill-defined forms of fever or cholera; thus 208 deaths were referred to these diseases, being 11 below the corrected average weekly number. Different forms of violence caused 50 deaths; 37 were the result of negligence or accident, among which were 17 from fractures and contusions, 6 from burns and scalds, and 10 of infants under one year of age from suffocation. In Greater London 3,571 births and 1,896 deaths were registered, corresponding to annual rates of 33·7 and 17·9 per 1,000 of the estimated population. In the outer ring 9 deaths from measles, 7 from "fever," 6 from scarlet fever, 6 from diphtheria, and 6 from whooping-cough were registered. Three fatal cases of fever occurred in Croydon, and 3 in Tottenham sub-district, and 3 of measles in Tottenham sub-district.

ON VERNATION AND THE METHODS OF DEVELOPMENT OF FOLIAGE, AS PROTECTIVE AGAINST RADIATION.

A Paper read by the Rev. George Henslow, M.A., F.L.S., F.G.S., before the Linnæan Society.

(*Concluded from p.* 506.)

THE tile-like arrangement of the uppermost stipules and subsequently of the leaves themselves, thus protecting the edges of the vertically placed leaves beneath them, reminds one of a very similar method of protection in *Trifolium repens* when asleep. In this plant the two basal leaflets rotate so as to bring their upper surfaces in contact and their blaces vertical, while the terminal leaflet revolves through half a circle and comes down upon the upper edges like an arched roof above them* (figs. 5 and 6).

Fig. 5.

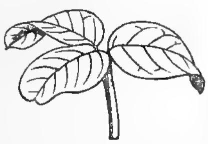


Fig. 6.

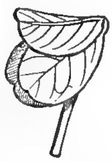

Trifolium repens.

Fig. 5.—Leaf during Day-time. Fig. 6.—Asleep during Night-time (after Darwin).

In the case of the Hazel the process is much the same, but with *Ampelopsis Veitchii* the blade spreads out at once, however young, and is not conduplicate; but as it hangs vertically from its very birth to its fall, it does not require any further protection beyond what the leaves above it happen to supply by overhanging it. The branches of this species cling so tightly to the wall that very possibly a good deal of heat is radiated

Fig. 7.

Fig. 8.

Fig. 9.

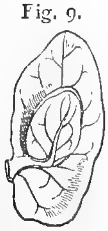

Fig. 7. Rose. Younger leaf erect; older with petiole curved and half-developed leaflets.

Fig. 8. Pea. Leaf emerging from between the stipules; the leaflets conduplicate.

Fig. 9. One stipule removed to show the erect bud within and protected by the stipules.

from the wall itself on to the back, *i.e.*, the underside of the leaf. The Beech differs from the Lime in having its young leaves dependent only, and not protected. They are feebly conduplicate, but with a plicate surface, and the stipules do not form any protection; and, contrary to what takes place in the Lime, the older, basal leaves, instead of covering the younger ones, hang below them the slender shoot curving at the apex so that the terminal and younger leaves have a tendency to be vertical, but not to so pronounced an extent as in the Lime. It may be noticed that the Beech does not open its buds till a later period than the Lime, and at a time when spring frosts are nearly over. The Spanish Chestnut agrees closely with the Beech, the leaves being at first subconduplicate, and similarly plicate, while each leaf on expansion is spread out below the terminal shoot. Both trees belong to the same section of the Cupuliferæ.

II. Compound Leaves (1) Opposite: (i) *erect.*—The Ash and the Elder are illustrations. As with simple leaves, the leaflets of compound leaves are almost invariably conduplicate; the Elder, however, as stated above, having the margins of the leaflets involute as well. They all stand erect at first and only gradually assume

Fig. 10.

Fig 11.

Fig. 12.

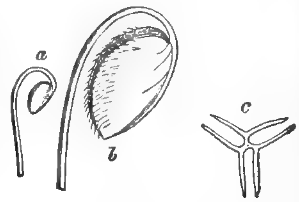

Fig. 10. Laburnum. Fig. 11. Clover.

the horizontal position on their complete development. The leaflets of the Ash are at first similarly clustered together, but simply conduplicate. With Weeping Ashes, in order to place the young leaves erect, the petiole is obliged to make a very strong curve upwards, not necessitated in the ordinary form of the tree.

(ii) *pendulous.* I have not met with an instance of

Fig. 13.

Horse Chestnut.

Fig. 14.

Lupinus pilosus. Leaf, seen laterally, asleep at night-time. (After Darwin.)

Fig. 15.

Walnut.

opposite compound leaves being pendulous in the young state.

(2) Alternate; (i.) *erect.*—Of compound leaves there are the two types, digitate and pinnate. Of the former, Lupin will illustrate this position. A specimen with white flowers had the leaflets all conduplicate at first and erect, forming a small but dense mass. Of the pinnate type with erect leaflets many instances might be mentioned, as, *e.g.*, Goutweed, Chervil, Sumac, Raspberry, and Rose. As a rule, besides being conduplicate and, in some cases, plicate in addition, the leaflets are all pressed together laterally, thereby affording a certain amount of mutual protection. This is well seen in the Rose

In the case of the Rose the developing bud is protected by the adnate stipules (fig. 7), and the young leaf, when

* Darwin, "Movem. of Plants," p. 349, fig. 141.

it merges, is at first erect (as in the Pea, figs. 8 and 9). The leaflets are conduplicate, and all five are pressed together laterally; for at this stage the petiole has not elongated sufficiently to allow of the pairs of leaflets being separated. As the petiole grows the whole collection of leaflets becomes more pendulous until they expand, and the leaf ultimately assumes the horizontal position. In the Garden Bean the leaves are conduplicate; but the margins are involute as well, so that the leaflets resemble so many quills.

(ii.) *pendulous.* Of the two types the following may be selected:—The French Bean, Wood-sorrel (*Oxalis*), Clover, and Laburnum as being ternate, and the Horse Chestnut and Virginian Creeper as being digitate; while the Walnut will exemplify the pinnate type.

The French Bean (*Phaseolus vulgaris*) bears at first a pair of unifoliate leaves; but those which succeed them are ternate. While very minute in size (one half to three quarters of an inch in length) the leaf is horizontal, but the leaflets are conduplicate with their edges uppermost. When a little larger (say, one and a quarter inches) the petiole bends down angularly, and the leaflets are in vertical planes, holding identically the same positions as when adult and asleep. As they increase in size, the leaflets rise up and take a horizontal position. They now become subject to hypnotism, falling at night and rising again by day.

The Wood-sorrel (fig. 12), Clover (fig. 11), and Laburnum (fig. 10) all agree in having their three leaflets conduplicate, pressed close together laterally and suspended vertically. The petiole is suberect in the Laburnum and Clover, but strongly curved at the apex in the Wood-sorrel, so that the minute leaf is under the concave end (fig. 12, *a* and *b*). When the leaf of the Oxalis is asleep, the leaflets fall vertically and bring their undersides in contact (fig. 12, *c*), but never resume the conduplicate condition again. The sleeping condition of Clover has been described above; but here, as in all other instances, conduplication once lost is never resumed.*

This seems to indicate that the danger from exposure in the very young state being much greater than in the adult, the protection is correspondingly more perfect.

In the Horse Chestnut (fig. 13) the digitate leaf has at first all the leaflets dependent and more or less covering one another. This is exactly similar to the condition of the leaflets of *Lupinus pilosus* when asleep, as described by Mr. Darwin† (fig. 14). It may be added that the leaflets of Lupin are at first clustered together and conduplicate. The Virginian Creeper has its five leaflets at first conduplicate and suberect; they gradually curve over and spread themselves vertically like a star, not unlike the method adopted by *Lupinus pubescens*, as described by Mr. Darwin.

The petiole of the Walnut-leaf (fig. 15), on emerging from the bud (the scales of which, like those of the Ash, are petiolar), curves strongly downwards, so that the leaflets, which are conduplicate, stand in a vertical plane. As the basal ones expand they still remain with their surfaces vertical, and it is not until they are approaching maturity that the petiole rises up and the leaflets spread themselves out horizontally.

Besides vernation, conduplication, and the subsequent vertical position of leaves and leaflets, as calculated to protect them from the evil effects of radiation, hairs and tomentum, etc., must not be forgotten as being bad conductors of heat, and therefore very important aids to protect the organs clothed with them. Foliar organs and axes, when young, are often very hairy, silky, or woolly, as the case may be, which in older states become glabrous, either by the hairs becoming more sparsely scattered by epidermal growth, or by vanishing altogether. Similarly the stellate pubescence or woolly clothing, which is not an unfrequent character of the young condition, often disappears as soon as the surfaces thus protected are sufficiently advanced to require such additional aids no longer. As examples may be mentioned the young shoots of Poplar, Apple, Ivy, etc., while the leaves of Coltsfoot are at first densely villous, but soon lose the cottony webs from the upper surface as they become adult.

Conclusion.—The examples given in this paper could, of course, be multiplied indefinitely; but enough seems to have been stated to justify a belief in the general accuracy of the deduction that vernation, conduplication, the various positions taken up by developing leaves, etc., all conspire to protect them from the evil effects of radiation.

* This is due to the fact, at least in Clover, that a thick layer of chlorophyllaceous tissue is developed over the fibro-vascular bundle of the midrib, thereby preventing the two halves closing again.

† *L. c.* p. 341, fig. 137.

THE URANIA RIPHŒUS.

THIS moth is interesting from two points of view. Firstly, it would be at once pronounced a butterfly, and a very brilliant one, by all persons who are not specialists in insect-lore, and, secondly, because, whilst the individual species in question is peculiar to Madagascar, the other members of the genus Urania are found only in the neotropical region. The Rev. Paul Cambroné, S.J., who has already forwarded to our contemporary, *Cosmos*, an account of this insect in its mature condition, is now enabled to give an account of its caterpillar and chrysalis. He writes:—"M. E. Perrot having lately made a small journey of exploration to Alakaty found some caterpillars of *Urania riphoeus*, which he has forwarded to me. The caterpillar of *Urania riphoeus* is long, and nearly uniformly cylindrical. It is five centimetres in length and about seven millimetres in mean diameter. It is beset with isolated hairs or filaments over its segments, characterised by their spatula-like form, the narrower part protruding from the body of the insect. The legs are sixteen in number, the three anterior pairs being chitinous, and the five posterior membranous pairs being yellow, speckled with black on the outer side. The thick, broad head is also of a yellowish colour, speckled with black. The scutellum is of the same colour as the head. The stigmata are black. The underside of the caterpillar is yellowish. The first segment of the back is yellowish, speckled with black; the second is black, and the nine others are of a yellowish white, also dotted with black. The caterpillar feeds upon a plant called by the natives *hazomalay*.

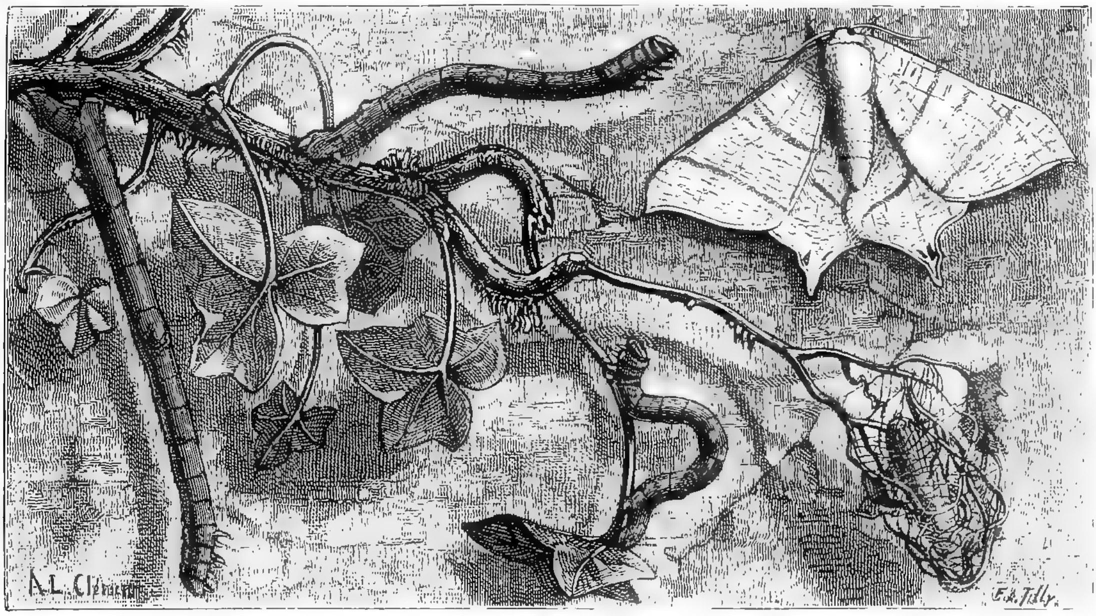
"The caterpillar is transformed into a chrysalis in a cocoon formed of a very transparent tissue of open meshes, around which it collects the fibres of the leaves. The pupa of the *Urania riphoeus*, as in most moths, is rounded, cylindric-conical, and measures about three centimetres in length by eight millimetres in its maximum diameter. It is of a brown colour.

"It remains in the pupa state for a fortnight, and the mature insect issues from its cocoon at midnight. In its perfect state it flies from January to May."

Natural History.

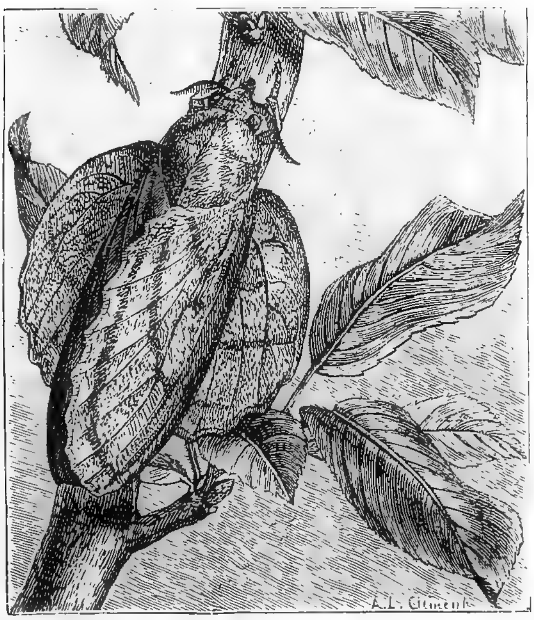
MIMETISM IN ANIMALS.

ONE of the most interesting as well as prevalent phěnomena of the animal world is that which in its



BROWN CATERPILLARS OF ELDER MOTH (*Uropterix Sambucaria*), ASSUMING THE APPEARANCE OF BRANCHES OF THE TREE.

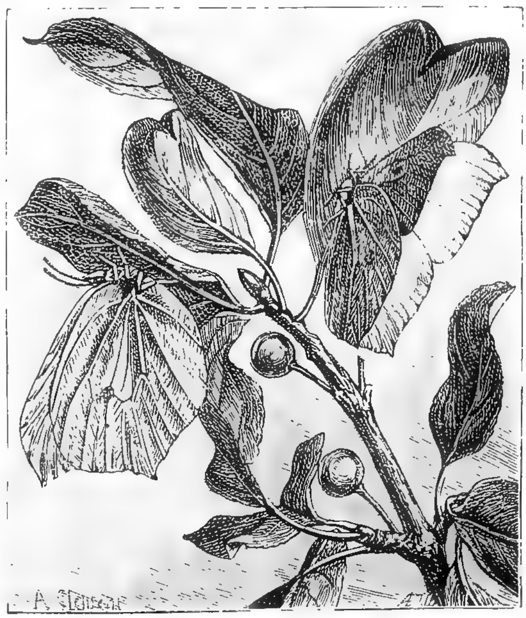
most intensified form is known as mimicry, or mimetism. Multitudes of animals when in their natural haunts are found to bear so close a resemblance to the objects



GONEPTERYX RHAMNI.

with which they are surrounded or in actual contact that, without close scrutiny, they escape being seen. The likeness may be either to some other animal of very different nature or to some plant or part of a plant, or to a portion of lifeless matter. It may further be permanent, depending on the shape and colour of the creature concerned, or it may turn upon some position, attitude, or action capable of being assumed or performed when wanted.

These various forms of mimicry can be more easily rendered intelligible by examples than by any kind ot general description.



LASIOCAMPA QUERCIFOLIA.

One of the most striking cases of mimicry which have lately been brought to light is that of a yellow spider which inhabits flowers in California. This creature spins no web, but catches its prey by surprise. In the region which it frequents, a yellow composite flower, of exactly the same shade as the spider, is very common. The creature accordingly takes up its position in the middle of the flower, where its legs are confounded with the anthers. If, as it frequently happens, a fly or a butterfly alights on the flower, it is at once seized and devoured. At the same time the spider escapes the notice of passing birds. On leaves, tree-trunks, or on a flower of any other colour this spider would be at once seen and avoided by his prey or seized by its enemies.

There is a gaily coloured mantis in Assam and Burma which by the attitudes it assumes deceives butterflies into paying it a visit. The moment they alight on the supposed flower they find themselves in the grasp of their enemy.

No less formidable a creature than the Bengal tiger, conspicuous as he looks on open ground, is, on account of his vertical stripes, very hard to distinguish among the stems of reeds, bamboos, and other jungle plants. The markings of the leopard, which lurks amidst the foliage of trees, are equally adapted for concealment. Every one must have observed that when the sun is shining through the head of a tree the shadow presents the appearance of rounded spots, dark and light intermingled. Thus among the foliage of a tree any animal with eye-like spots, such as the leopard or the jaguar, is not readily detected.

The tiger, in addition to the jungle-pattern of his skin, if we may so call it, has another method of deceiving his intended prey. He can imitate the whistle of the sambur deer with great nicety, and thus sometimes entices these animals to come unsuspectingly within the reach of his spring. The leopard allures a smaller species of deer in a similar manner. But the most numerous cases of mimicry hitherto placed on record are defensive, not offensive. The species in question simulate the colours, the shape, or the movements of some much more formidable creature, and thus escape attack.

The pretty beetle, *Clytus arietis*, not uncommon on old posts and rails in some districts, is very generally taken for a wasp by the non-entomological public, on account of its black and yellow livery. As if aware of its advantage, it does not seek concealment. On the contrary, *Callidium violaceum*, an insect very similar in habits, size, and means of defence, but not mimetic, is exceedingly shy, and on the approach of an observer quietly disappears around a gate-post or underneath a rail.

An admirable case of mimicry is afforded by the caterpillar of the "lobster moth," *Stauropus fagi*. From whatever side this larva is viewed, it has a most uncanny appearance. Four of the anterior legs are very long, and closely resemble those of a spider. If an ichneumon approaches these legs are turned towards her, and moved in a manner like those of a spider when about to seize its victim. The ichneumon having a wholesome dread of spiders, declines the offered embrace, and flits away to find a safer subject into which to insert its egg, and the caterpillar has saved its life by a clever fraud.

But perhaps in the most numerous cases an insect finds its advantage in mimicking a leaf, dead or living, a turf of moss, a twig, a splash of mud, or the droppings of a bird. One of the commonest of these imitations is shown in fig. 1, which we owe to the courtesy of our contemporary *La Nature*.

The caterpillars of the moths belonging to the numerous tribe *Geometra* (loopers, or spanners) attach themselves by their hindmost pair of feet to the branch of a tree, and remain sometimes for hours in an erect position, very closely resembling a dead twig.

Our figure represents caterpillars of *Uropteryx sambucaria*, a very common species, known to lovers of moths as the "swallow-tail" in such attitudes.

Other species display a remarkable likeness to leaves, and be it noted, of the leaves of the trees which they feed upon or frequent. Thus the brimstone butterfly (*Gonepteryx rhamni*), when at rest on a buckthorn bush shows a considerable resemblance to the leaves of that shrub. The lappot moth (*Lasiocampa quercifolia*) when at rest may readily be confounded with a tuft of sere leaves. Even the most gaily coloured butterflies when at rest often remain unseen. The upper surfaces of the wings are hidden by being brought together in an upright position over the insect's back, and it often heels over at a small angle to the horizon, so as to present a less prominent appearance.

Not a few moths contrive to render themselves practically invisible by taking up such a position, *e.g.*, on a papered wall, that their outline may coincide with some line in the design.

There are beetles, especially of the families *Rhyncophori* and *Chrysomelidæ*, which, without very close examination, cannot be distinguished from a crushed berry or the droppings of a bird. Mr. H. Drummond, in his "Tropical Africa," gives an amusing account of his mystification at seeing a white splash on a boulder suddenly, but slowly, begin to move, and how he could scarcely believe his own eyes until he had turned the insect over and detected a head, six legs, and a segmented body.

We, along with not a few naturalists of much higher standing, have occasionally been deluded into picking up some little bit of refuse in the belief that it was an insect.

It will probably be found that instances of mimicry are far more numerous that we are yet aware, and that each has its lesson awaiting the patient inquirer.

But there are evidently some animals, especially insects, unprovided with any arms, offensive or defensive, and not protected by any form of mimicry. But such species, we suspect, are preserved from extirpation by their wonderful fecundity. Accordingly, though the individual falls a victim by myriads to birds, spiders, and carnivorous insects the type survives.

Mimicry is a fine subject for the young naturalist to study, especially if he has the good fortune to take up his abode in a country but sparingly explored.

THE TSETSE.—M. Channon, writing to *Cosmos*, desires to mention facts concerning this dreaded insect which may have a certain interest. "In a journey which I recently made to Zanzibar I had to suffer much from this inconvenient Dipteron. (How many Diptera are other than inconvenient ?) I had to traverse a great plain which extends between the mountain mass of Oukami and that of Ngouron. This plain is dry, barren, and uninhabited, but herds of beasts abound, buffaloes, zebras, giraffes, antelopes of all sorts, and even some elephants have been seen. In all this desert as soon as the sun touched the horizon the Tsetse gave me no rest. It is a truly provoking beast, but to many it is nothing further. Still, I must remark that after these attacks (I have been bitten more than 200 times) I had to suffer from an affection like nettle-rash, which lasted too. At the places where I had been bitten there were raised spots whiter than the skin and occasioning a very intense and unpleasant irritation.

"In another journey, and under similar conditions, I had to suffer from the same affection, which redoubled in intensity at night and completely prevented sleep.

"The most interesting fact is that in this desert, just before the passage of our caravan, the Tsetse had put to rout an army. The Massai, to the north of Zanzibar, constitute a numerous nomadic pastoral tribe extremely dreaded on account of their warlike disposition. This tribe, in the intention of attacking Mrogaro, had encamped in the desert plain which has just been mentioned, having with them a herd of 300 oxen. The people of the country were much alarmed, when they suddenly learnt that the Massai had retired with precipitation. The Tsetse had interfered, and the destruction of their oxen had compelled the Massai to withdraw.

"I have just read that Dr. Laboulbene attributes the effects of the bite of this fly to its settling upon putrid carcases. I doubt whether the experiments which he is about to make will confirm this hypothesis. In any case the difficulty is to explain why the bite is deadly to the ox and not deadly to man."

THE HORSES OF THE PAMPAS.—Sen. J. Solveyra forwards to *La Nature* some interesting information concerning the horses of the Pampas of La Plata. In that region there are three millions of horses of Arab blood, since their progenitors were originally imported from Andalusia. Their peculiar beauty, strength, and staying power are well known, and many of them have been lately purchased for the French army. Mounted upon such horses, good riders have been known to travel 200 kilometres (=120 miles) in twenty-four hours. Races have been instituted at Ayacucho to test the endurance of these horses. The horses were to travel for ten hours; the riders might at pleasure stop, dismount, and go at a walk, a trot, or a gallop. The winner was Recluta, belonging to Sen. Bandrix. This horse travelled in ten hours 143 kilometres, *i.e.*, 88 miles.

A NEW WEED.—A novel pest has appeared in some districts of the State of New York. It is a species of house-leek, known to botanists as *Hieracium pracaltum*, unfavourably known in Europe, and apparently of recent introduction in America. It has there become more rampant, and on account of the annoyance it occasions, it has received the name of the "King Devil." When it once appears in a field it covers the entire surface with its leaves, so that nothing else can grow.

THE DIET OF THE PHEASANT.—A correspondent of the *Field* gives an interesting account of the animal diet of the pheasant. Upwards of 1,200 wire-worms have been counted in the crop of a single pheasant, and in another there were found 440 larvæ of the daddy-long-legs (*Tipula oleracea*), a most destructive insect. From another three young vipers have been obtained. Hence the pheasant, quite independently of its value as food, merits public goodwill and protection.

MISCHIEVOUS INDUSTRY.—Mr. Walter Hough, in a letter to *Science*, mentions that he has caught ants in the very act of transferring scale insects (*Coccidæ*) from one plant to another.

THE TEETH OF WHALES.

PART I.

THERE are very few families of tooth-bearing animals in which the dentition varies so greatly as in the whales. Generally speaking, the dental formula, to use the technical expression, is very much the same in all the members of a given group. There may perhaps be variation in individual species; that is not unusual. But it is seldom noticeable in any great degree. And so true is this as a general rule that in many cases the dental structure is considered, and justly considered, as one of the strongest and most unfailing of family characteristics.

But in the order of the Cetaceans, which comprises the whales and their allies, many ordinary rules are partially or wholly abrogated; and this among them. And there are scarcely any two species whose teeth are of similar character. A whale may have teeth—and almost any number of teeth—or it may have none. If it possess them, they are quite unlike the teeth of other mammals. There is no distinction between molars, canines, and incisors, for all are alike in form and in size. A greater number may be present upon one side of the mouth than upon the other; and, more remarkable, perhaps, still, different individuals of the same species may very possibly exhibit quite a different tooth-armature. Thus it is quite evident that, as far as these animals are concerned, we must not look for family characteristics in the teeth; and the only respect, indeed, in which we can employ those organs for purposes of classification is by dividing all living cetaceans into two great groups, or sub-families, the one comprising those species which possess teeth, and the other those which do not.

I purposely employ the adjective "living" for the good and sufficient reason that in earlier days of the world's history a group of cetaceans existed whose teeth presented very well-marked characteristics, the molars being perfectly distinct from the incisors, and the incisors from the canines. Such were the Zeuglodons, the Phocodons, and the Squalodons, the former of which seem to have dwelt in New World waters, their fossil remains being not uncommonly found in the Eocene and Miocene strata of Northern America, while the members of the two latter genera had a wider range, and have left their relics behind them in most European countries as well as in Australia and the United States. All these, however, have long died out, in company with most of the giants which were on the earth in those days, and our latter-day cetaceans are represented by two groups only, the one of the Denticetes, or toothed whales, and the other of the Mysticetes, or those whose mouths are furnished with whalebone.

Much discussion has arisen over this most curious substance, its nature, affinities, and uses. It is scarcely necessary to state that its title is a most misleading one, and that it has nothing to do with true whale's bone at all; but many have been puzzled by the question as to whether it is, or is not, a modification of the teeth. Not that it exercises any of the ordinary functions of those organs. It is obviously useless for purposes of mastication, and, although it certainly assists in the capture of prey, it does so in a manner very different to that in which the teeth of any other animal are employed. And the material of which it is composed is undoubtedly quite distinct from either bone, dentine, ivory, or enamel, the only four substances which enter into the composition of true and actual teeth. It is, in fact, little or nothing more than a mass of long hairs agglutinated together into a series of plates, some broader and some narrower, fringed at their tips, and set closely side by side. And equally convincing testimony in favour of the argument that it is in no sense a modification of the teeth we find in the fact that it springs, not from the gums or the jaw-bones, but from a layer of vascular substance lying *upon* the former. And, if still further proof than this be required, it may be found in the presence, in certain whales, of whalebone and true tooth-germs together, although these latter are very small and rudimentary, and never project beyond the gums. The mere fact that they are there, however, tells its own story, and effectually disposes of the theory that the whalebone represents them, although in a singularly modified form.

In other words, this whalebone, or "baleen," to bestow upon it the title employed by those instrumental in procuring it, is a special apparatus provided for a special purpose, and not a mere modification of organs which, in all other animals possessing them, are of a widely different character. Yet no account of the teeth of whales would be at all complete without a description of this most curious substance. Although not structurally analogous to teeth, and fulfilling none of the ordinary duties of teeth, it yet takes the place of teeth, and performs a most important duty which no true tooth-apparatus could satisfactorily fulfil. And this duty, as already stated, lies in the capture of prey.

Now, strange as it may seem, and indeed almost incredible, it is nevertheless a fact that the mysticete whales, although numbering among them some of the very largest of all created beings, find their food, and the whole of their food, in the very smallest. They are living exemplifications of the proverb that "extremes meet." And there is a common saying among sailors, and a saying which is strictly and absolutely true, to the effect that a whale sufficiently large to float a jolly-boat in its mouth would yet be choked by a herring. For the gullet of a fully-grown Greenland whale, an animal eighty or ninety feet or so in length, is little more than two inches in diameter! The animal, therefore, which is strictly predacious, must perforce content itself with victims of minute dimensions; and these it finds in the form of certain small marine creatures, such as shrimps, medusæ, and the young of crabs and lobsters, which herd together in enormous shoals, consisting, very often, of many millions of individuals. Now were its mouth of ordinary character the whale would have, and could have, but little success in the chase. One can scarcely imagine a shark or a walrus pursuing such victims, and making a satisfactory meal upon them. But the possession of the whalebone plates enables the whale to do so without difficulty. All that it need do is to open its mouth to the fullest extent, drive at full speed through the shoal, and enclose a vast number of the tiny creatures. Then the mouth is partially closed, and the whalebone forms a close network around its margins, through the interstices of which the water is ejected, while the little prisoners are retained. As soon as the water is expelled the captives are gradually swallowed, and then the process is repeated again and again until hunger is fully satisfied.

The amount of this whalebone, and the length of the plates, of course varies very much in accordance both with the species and with the size of the individual specimen. In a very large whale indeed some of the plates, of which there are about three hundred upon either side of the mouth, may be twelve feet or more in length, and their total weight upwards of two tons. But whales such as this, in these days of persecution, are exceedingly rare, and half that amount is a very fair quantity to be taken from the mouth of a single specimen; more especially as, so lately as 1884, the best whalebone sold at the rate of £2,500 per ton. But this is a somewhat exceptional price, and from £600 to £800 may be quoted as the ordinary rate.

Whalebone of the first quality is only to be procured from one species of whale, viz., the Greenland, or Right Whale; but many other whales possess it. Thus it is present in the Rorqual, that giant of his race, but seldom attains to a length of more than four feet; as there are some eight hundred plates, however, it is still of some little value. It is also found in the Hump-backed, or Bunched Whales, but is generally brittle, and of little service for commercial purposes. And the Pike Whale, Biscay Whale, Japan Whale, and many others possess it, although neither in quantity nor quality sufficient to render their capture desirable.

The true teeth of the whales we must leave for a subsequent paper.

THE PINEAL OR PARIETAL EYE.

In a recent number of the Scientific News, whilst giving an account of the *Pelosaurus laticeps*, we mentioned, amongst the other remarkable features of this extinct reptile, that it shows evidence of having possessed an eye in the middle of the skull, between the two parietal bones. The existence of such eyes in a variety of vertebrate animals has been exhaustively studied by Professor Baldwin Spencer, who made known his remarkable results in a lecture delivered at Sydney during the late meeting of the Australasian Association for the Advancement of Science. Of this lecture we are able to lay before our readers only a meagre outline, as it is not reported in detail in the Sydney papers, and as the proceedings of the Association have not yet been printed. Professor Spencer said that in the brains of the vertebrate animals there exists a small special part known as the "pineal gland." The meaning of this part has been a problem. Among the suggestions propounded one of the wildest was that it must be the seat of the soul. But it is now ascertained to be the rudiment, or we had better say the remnant, of an eye. This part is much better developed in some species than in others. It varies in structure in mammals, birds, and amphibians, in which it is not very highly developed. In lizards and certain fishes it has become transformed into an eye, the pineal or parietal eye.

Professor Spencer explained the gradual development of the eyes in lizards, and the ultimate production of two lateral eyes and one intermediate eye. He then described the structure of the pineal eye in various lizards, especially in *Hatteria* (the tuatera of New Zealand), *Varanus*, and *Chameleo*. The extinct reptiles and amphibians possessed the pineal eye, the use of which has been lost by their descendants, so that in species which now exist this third eye has become a mere rudiment, and as far as we can detect, it does not exert any function.

But a very curious phase of the subject yet remains. It would seem as if this eye had been met with in animals much higher in the scale of creation than lizards. Among various human races there are traditions of men with a median eye, either in addition to the ordinary pair or in their stead, as in the fabled Cyclops. All the old mythologies refer to such eyes. In India the gods, especially Seeva, are adorned with this feature, and to this day it is painted on the foreheads of the dancing-girls. The question at once arises, how have such traditions originated and been handed down? Leaving mankind on one side, we have no specimen of a mammalian skull with the aperture necessary for such an eye to act as a light organ. Yet it is difficult to understand that ancient nations can have invented the existence of such an organ, and have assigned to it the place which it would have to occupy.

FLUORESCENCE AND PHOSPHORESCENCE.

As the terms "fluorescence" and "phosphorescence" often occur in scientific and semi-scientific literature without any satisfactory explanation of the nature of the phenomena to which they are applied, we extract from *Wiedemann's Annalen* the substance of a memoir on the subject by Dr. E. Wiedemann. This physicist points out that we have to distinguish two principal forms of the development of light. The normal production of light ensues when the motion of the molecules of any substance is so intensified by the accession of heat that it occasions luminous vibrations of the atoms of the ether. But in addition to this kind of production of light there is another in which illumination is manifested without any accompanying rise of temperature. Wiedemann proposes for this kind of the development of light the general name *luminescence*, and calls the bodies which possess this property luminescent. Luminescence includes fluorescence, phosphorescence, the electric illumination of gases, and the light produced during certain chemical processes and when certain crystals are slightly heated.

Whilst in normally luminous substances of any given absorptive power the intensity of the luminous vibrations is completely determined by their temperature, this does not hold good in luminescent substances. But we may for comparison speak of a temperature of luminescence for rays of any given wave-length. It is namely that temperature at which the body in question, if heated alone without any external excitement, would send out light of the same intensity as that derived from luminescence. We thus obtain a standard for the strength of the vibrations which produce light as compared with the other existing molecular motions.

As hitherto fluorescence has been observed only in liquids, and phosphorescence only in solids, Dr. Wiedemann proposes a method for converting fluorescence into phosphorescence by the gradual addition of colloid substances.

It appeared in his experiments that nearly all substances which are luminescent in solution by incident light, do the same if their solutions are mixed with gelatine and allowed to dry up. Whilst watery solutions are luminous only during the incidence of light, or in other words are fluorescent, the dried up gelatinous solutions retain their light for a considerable time afterwards, that is, they are phosphorescent. Sulphate of quinine displays this property in a beautiful and prolonged manner. Gelatine to which a little glycerine has been added is distinctly phosphorescent after an admixture of fluorescent substances, as it lies on the boundary between liquids and solids. Experiment therefore shows that a fluorescent body may be rendered phosphorescent by restricting more and more the free mobility of its molecules.

Reviews.

An Introduction to Practical Inorganic Chemistry. By William Gage, F.C.S., F.I.C. London: Longmans, Green, and Co.

If we do not surpass every neighbouring nation in the quantity of original chemical research which we produce, we certainly exceed all the rest of the world collectively in the number of elementary treatises, handbooks, and manuals which we put forth. This phenomenon is not without its difficulties. It may be asked how the authors persuade themselves that there is room for works which cannot and do not contain anything novel in point either of fact or theory? And, again, how are publishers found willing to undertake the issue of these publications? As a rule, these gentlemen are somewhat shy of scientific books. We suspect the solution of the problem must lie in the unhappy character which higher education has assumed in England.

In the little work before us there is nothing to which exception can be taken as erroneous, but, on the other hand, we do not find in it any feature which gives it a marked superiority over its rivals.

Handbook to Breeding, Diseases, Treatment, Care, and Choice of Foreign Aviary Birds, including how to Tame and Teach Birds to Speak, and Chapters on Management, Cages, Seeds, Insect Foods, Pastes, Dainties, etc. By Dr. Karl Russ. (Authorised Translation.) London: Dean and Son.

This little work, which is not written in the most idiomatic English, will prove very useful to those who attempt the establishment or management of an aviary. The author utters a much-needed protest against the cruelties practised in the importation of live birds. The way in which parrots are brought over in confined boxes, neither cleaned nor ventilated, is truly painful. Few of them die on the passage, but many carry in their systems the germs of fatal disease, and perish soon after they have been sold.

EARTHQUAKES.—A severe earthquake was felt in Sikkim on the 9th inst.

THE ECLIPSE OF THE SUN IN 1887.—The Physico-Chemical Society of St. Petersburg has published (*La Nature*) the observations made by Professor Mendelejeff during his balloon ascent at Twer. From photographs obtained on the shore of Lake Baikal, and at the Bay of Possiet on the frontiers of Corea, it appears that the corona is not a simple phenomenon of diffraction, but is produced by objects existing around the sun. A portion of the rays of the corona seems to be connected with the spots and the protuberances of the sun. During the eclipse the barometric pressure was reduced by $\frac{2}{7}$ of a millimetre, owing to condensation in the earth's atmosphere. The thermometer fell 1·6 degs. in the shade, and 8·6 degs. in the sun. The force of the wind was diminished. As to the alleged effects upon the magnetic needle the reports are contradictory.

Abstracts of Papers, Lectures, etc.

ROYAL SOCIETY.

At the meeting on November 15th a paper "On the Mechanical Conditions of a Swarm of Meteorites, and on Theories of Cosmogony," was read by G. H. Darwin, LL.D., F.R.S., Fellow of Trinity College and Plumian Professor in the University of Cambridge.

Mr. Lockyer's recent investigations have led the author of this paper to make a suggestion for the reconciliation of two apparently divergent theories of the origin of planetary systems.

According to the nebular hypothesis the solar system originally consisted of a rotating globe of gas, which, as it cooled, rotated faster, until it became so much flattened that a ring of gas was detached from the equatorial region. This ring then coalesced into a planet, and subsequently other rings were formed, which in their turn became planets.

But notwithstanding the high probability that some theory of the kind is true, the acceptance of the nebular hypothesis presents great difficulties, and other speculators on the origin of the planets have attributed their existence to a gradual accretion of meteoric matter.

The very essence of the nebular hypothesis is the conception of fluid pressure, since without it the idea of a rotating globe of gas becomes inapplicable. Now, at first sight, the meteoric condition of matter seems absolutely inconsistent with a fluid pressure exercised by one part of the system on another. We thus seem driven either to the absolute rejection of the nebular hypothesis, or to deny that the meteoric condition was the immediate antecedent of the sun and planets.

The object then of this paper was to point out that by a certain interpretation of the meteoric theory a reconciliation may be obtained between these two orders of ideas, and it may be held that the origin of stellar and planetary systems is meteoric, whilst the conception of fluid pressure is retained.

It is now well established that a gas consists of minute elastic molecules moving with great speed and continually coming into collision with one another.

According to this so-called kinetic theory of gases, fluid pressure is the average result of the impacts of molecules. If we imagine the molecules magnified until of the size of meteorites, their impacts will still, on a coarser scale, give a quasi-fluid pressure. It is suggested then that the fluid pressure essential to the nebular hypothesis is, in fact, the resultant of countless impacts of meteorites.

Problems involving gases could hardly be attacked with success, if it were necessary to start from the beginning and to consider the cannonade of molecules. But when once it is proved that the kinetic theory will give us a gas which, in a space containing some millions of molecules, obeys all the laws of an ideal non-molecular gas filling all space, the molecules may be put out of sight and the gas treated as a plenum.

In the same way the difficulty of tracing the impacts of meteorites in detail is insuperable, but if such impacts give rise to a quasi-fluid pressure on a large scale, it may become possible to trace out many results by treating an ideal plenum. Laplace's hypothesis implies such a plenum, and it was maintained by the author that this plenum is merely the idealisation of the impacts of meteorites.

The paper contained an examination of the justifiability of the suggestion, but the details are of too special a character to admit of discussion here. The author showed how the actual velocities are determinable of the meteorites which made up the globular swarm from which the sun originated, and he concludes that the collisions between them must have occurred with sufficient frequency to permit us to treat the swarm as in many respects mechanically analogous with a gas, even at a time when it was as widely diffused as the orbit of the planet Neptune.

Messrs. J. W. Largley, M.A., F.R.S., and H. M. Fletcher, B.A., read a paper on the "Secretion of Saliva.' The salivary gland cells pour forth during secretion, water containing in solution various salts and various organic substances, the latter being in the case of the sub-maxillary gland of the dog chiefly mucin. The experiments given in the paper are in the main directed to determining the conditions which affect the rate of secretion of the different constituents of saliva, viz., water, salts, and organic substance.

It has previously been shown (Heidenham and others) that when the chorda tympani — the secretory nerve proceeding from the brain to the sub-maxillary gland—is stimulated, the saliva alters its character the faster it flows. The more rapidly secreted saliva contains a higher percentage of organic substance and within limits a higher percentage of salts. Messrs. Langley and Fletcher confirm the above, except as regards the limit to the increase in the percentage of salts. They find that however rapidly the saliva is flowing, and it can be made (by stimulating the secretory nerve) to flow still faster, the percentage of salts will increase. But each successive equal increase in the rate of flow causes a less increase in the percentage of salts in the saliva. Because of this and because the rate of flow of saliva cannot be indefinitely increased, the percentage of salts in saliva never reaches the percentage of salts contained in blood plasma. In the saliva from the sub-maxillary gland of the dog, the maximum percentage of salts known to occur is ·77, whilst blood-plasma usually contains ·85 per cent. of salts. Since there is reason to believer that the lymph from which the glands secrete also contain about ·85 per cent. of salts, it follows—and this is well known—that the gland cells are able as it were to refuse to take up some part of the salts contained in lymph. The behaviour of the sub-lingual gland of the dog is in striking contrast to the sub-maxillary gland. The sub-lingual saliva contains about 1 per cent. of salts (Werther, Langley, and Fletcher), *i.e.*, it contains a higher percentage of salts than that in blood-plasma.

When pilocarpin—1-10th to 1-20th of a grain—is injected into the blood, a rapid secretion of saliva results. Messrs. Langley and Fletcher find that when a mixture of pilocarpin, lithium citrate, potassium iodide, and potassium ferrocyanide is injected into the blood, lithium can be detected in the first drops of the saliva secreted, the iodide can be detected after the first six drops, and is probably present in the earlier drops, whilst the ferrocyanide cannot be detected in the saliva at any stage of secretion.

It has been said above that the percentage of salts and of organic substance increases as the rate of flow of saliva increases. Messrs. Langley and Fletcher point out that this is only the case under certain conditions. The alterations in the character of the blood, or of the normal blood flow through the gland, modify the percentage composition of the saliva. Thus an insufficiency of oxygen, as in dyspepsia, decreases the rate of secretion of saliva, but the saliva has a higher percentage of salts, and usually a higher percentage of organic substance. Loss of blood also decreases the rate of flow of saliva, but very markedly increases the percentage of organic substance. The dilution of the blood by sodium chloride solution ·2 to ·6 per cent. leads to a much more rapid flow of saliva, but the percentage of salts in this saliva falls, instead of rising. If, however, strong salt solution is injected into the blood, the percentage of salts in the saliva rises somewhat.

It appears then from these experiments that the character of saliva is determined by (1) the strength of the stimulus, (2) the character of the blood, (3) the amount of blood supplied to the gland.

Messrs. Langley and Fletcher point out concerning the theory of secretory nerves, that "nearly all the arguments which have been adduced to prove that the secretion of organic substance is governed by special nerve-films have their counterparts with regard to the secretion of salts, so that we might imagine at least three kinds of secretory films to be present. The experiments, on the whole, indicate that this complicated arrangement does not exist, but that the stimulation of a single kind of nerve-fibre produces varying effects according to the varying condition of the gland cells."

THE INSTITUTION OF CIVIL ENGINEERS.

At the meeting held on Tuesday, the 13th of November, the President, Sir George B. Bruce, being in the chair, the proceedings commenced with the distribution of the medals, premiums, and prizes awarded by the Council at the close of the last session.

A paper on "Friction-Brake Dynamometers" was then read by Mr. W. Worby Beaumont, M.Inst.C.E. The author stated that the indications of any apparatus depending on friction must be as variable as the causes of friction and the conditions affecting it, and hence the value of the measurements, obtained by means of a friction-brake dynamometer, must depend on the completeness with which these causes and conditions were taken into consideration or were eliminated. In a friction-brake, the causes of friction were similar to those which generally obtained in other applications of materials brought into rubbing contact; but the conditions were more variable, and chiefly due to variation in pressure and in lubrication, both being affected by the rate of work-absorption and temperature. The friction-brake dynamometer in nearly all its forms was essentially that devised by Prony. In it the friction between a system of wood blocks and the surface of a wheel rotated by the motor whose power was to be measured, was employed in maintaining a weight, suspended at a point on a horizontal line, level with the centre of the wheel. For most practical purposes, this brake was capable of sufficiently exact determinations of power, ranging from 5 to 200 h.p., but it presented some of the elements of inaccuracy which pertained to the friction type of absorption-dynamometers, especially when used for the measurements of variable powers. For measuring the power of a motor, capable of running at a uniform speed with a constant load, the inaccuracy of its indications might be very small and often quite insignificant. With a truly circular wheel and uniform turning power, this brake gave very nearly accurate results, provided the lubrication was regularly maintained; but slight variations in this respect, due to variation in quantity, quality, and temperature of the lubricant and rubbing surfaces, made it difficult to keep the tension of the strap in strict accord with the total friction necessary to maintain the load at a constant level. The frequent change of this tension by the screws, for the purpose of meeting these variations, introduced further inaccuracy.

A simple form of friction-brake, much used as a dynamometer for testing engines by running them against a known load, consisted simply of a thin iron or steel strap, or a pair of straps, to which were attached a number of blocks of wood. A hook was fastened to the straps for the suspension of the load, and the ends of the strap were connected by a right-and-left-handed screw for the adjustment of the tension on the strap or pressure of the blocks upon the wheel, so as to obtain the necessary frictional grip to carry the otherwise unsupported load. With a truly turned wheel, and with uniform lubrication, this brake would run for hours with a variation of but a few inches in the level of the load, if the engine was of good design and had a proper fly-wheel. The variations from several causes were, however, sufficient to make adjustment by the hand-screw necessary, sometimes frequently. The errors in estimating the work done by the engine, which resulted from these causes, were generally small; but it was desirable to remove them for very accurate tests. It had been with this object that devices, for automatically varying the tension in the belt with the variation in the total friction, had been introduced. At an early date a brake-wheel, with an internal water-channel, was used to avoid the mechanical difficulties which resulted from the heating of the brake-wheel, and the variations due to the heating of the lubricant. One form of automatically-adjusting or compensating brake, suitable for small powers, was due to Mr. Deprez. A simple self-adjusting brake dynamometer had been devised by Mr. J. Imray, M.Inst.C.E. In this, the compensating action was due to the increase in total friction which accompanied increase of circumferential surfaces in contact. A modification of this brake consisted simply of a belt provided with wood blocks, but bearing only on the upper half of the circumference of the wheel. At one end of the strap was the load to be lifted by the motor, and at the other end was a spring under sufficient tension to give rise to enough friction to enable the motor to lift the load. This arrangement was very simple and useful. One of the best known friction-brake dynamometers, fitted with a compensating device, was that designed by Mr. C. E. Amos and Mr. Appold, used for the larger powers by the Royal Agricultural Society. Besides the hand-adjusting screw, it was provided with a compensating lever, by means of which the rise or fall of the load was attended with a decrease or increase in tension on the brake-strap, so that a position of equilibrium was automatically attained without causing inaccuracy in the indications. The compensating action could not, however, come into play except by the rise or fall of the weight from its proper position, and hence the value of the device was confined to its power of limiting that rise and fall. In practice, generally speaking, the adjustment required by means of the screw was as necessary with the compensating lever as without it, and its value might therefore be questioned for this reason alone. A further objection to this compensating lever was that it introduced an element of error, which must be variable almost directly in proportion to the extent to which the lever came into play. With a heavily-loaded brake the error must exist; and with a lubricant which materially lessened the total friction of the wood blocks upon the wheel, it must amount to a considerable part of the whole indicated power, unless adequate allowance was made for it. This allowance had seldom been made. In a better form of compensating brake, designed by Mr. Balk, and used by Messrs. Ransomes, Sims, and Jefferies, the compensating lever was outside, instead of within, the circumference of the brake-strap. It connected the ends of the strap, and to its outer end was suspended a scale-pan, and a weight sufficient to keep the lever floating. This weight became a measure of the tension upon the belt, at least at the parts to which it was attached; but it must be varied with change of condition of the brake-blocks, the lubricant, and the temperature of the blocks and wheel; and it must be taken as acting in favour of the motor. The great advantage of this brake was that the experimenter could always ascertain the actual load, although the tension-lever acted as a compensating lever. There was considerable variation in the scale-weights with the same gross load. This, Mr. H. A. Byng explained, was due to the heating of the brake-wheel. When much heated, more grease had to be used, and in consequence the coefficient of friction was reduced, and the weights in the scale had to be augmented to give more tension in the brake-straps. Figures given appeared to show that the larger the number of revolutions, the smaller the tension for a given total friction, and this inference was supported by experience. Mr. Byng had found that with the higher speeds less weight was required on the scale for a given load, or the higher the speed the less the necessary tension in the brake-belt. By the Balk brake the tension at the ends of the brake-belt was measured directly; and for accurate trials a higher speed was preferred with less gross load, and with a scale-weight below 7 lbs. A water-cooled brake was used by Messrs. Richard Garrett and Sons. The wheel was 5 feet in diameter, and 11 inches wide between the flanges within which the wood blocks ran. An annular trough was formed by internally projecting flanges 3·5 inches in depth. The straight form of Appold compensating lever was employed, though under conditions which seldom, if ever, brought it into play sufficiently to affect materially the accuracy of the indication of the brake. Experiments with this brake showed that the water evaporated in the wheel represented thermodynamically 71 per cent. of the mechanical work done. A brake used by Messrs. J. and H. McLaren had been devised by Mr. Druitt Halpin, M.Inst.C.E. In it the brake-wheel was 5 feet in diameter, and 7 inches in width. Water was constantly supplied to the trough, and constantly taken away by a scoop pipe. Reference was made to a simple form of friction-brake dynamometer, proposed by Professor Thomson, consisting of a cord or rope passed over the upper half-circumference once, or taking one complete turn round a smooth wheel, the one end carrying a load and the other attached to a spring-balance, the rope bearing directly upon the wheel without the intervention of blocks. This brake worked exceedingly well for small powers, and there seemed to be no reason against its use for large powers if a number of separate ropes were used. All the ropes might be attached to a cross-head at either end, from which the weight would hang, and to which the spring-balance could be attached.

The author then proceeded to investigate the tension in the brake-strap, straps, or belt, and the pressure upon the wood-blocks, and considered the effect of the introduction of the Appold compensating lever, with the object of ascertaining whether it was a desirable feature or not. Some information on this point, obtained by Messrs. McLaren, was cited, and the paper concluded with an investigation on this subject, for which the author was indebted to the Consulting Engineers of the Royal Agricultural Society of England.

GEOLOGICAL SOCIETY.

At the meeting held on Nov. 7th, 1888, W. T. Blanford, LL.D., F.R.S., President, in the chair, the following communications were read:—

The Permian Rocks of the Leicestershire Coal-field. By Horace T. Brown, Esq. The Author considers that whilst rocks belonging to the Carboniferous and Trias have been mapped as Permian, true representatives of the Permian do exist in the district to a considerable extent. The Bunter Conglomerates rest for the most part upon the truncated edges of Carboniferous strata; but intercalated between them and the Carboniferous, at various points, are thin beds of purple marly breccias and sandstones, seldom exceeding from 30 ft. to 40 ft., but differing in lithological character from the overlying and underlying rocks. The brecciated series rests with striking unconformity upon the Carboniferous. Moreover, the Boothorpe fault, which throws the coal-measures 1,000 ft., affects the overlying brecciated series to an extent of not more than from 20 ft. to 30 ft. The unconformity between the brecciated series and the Bunter is less obvious. Sections establishing the double unconformity were described in considerable detail. Attention was also called to other localities within the coal-field where Permian rocks exist, the author having in many cases mapped their boundaries.

He further called attention to certain beds which have been erroneously classed as Permian by the Survey. The first of these is a patch at Knowle Hills. Making extensive use of the hand-borer, he found that the greater part of the so-called Permian consists of a wedge-shaped piece of Lower Keuper let down by a trough fault. The so-called Moira grits belong to and are conformable with the ordinary coal-measures of the district.

The Author concluded that the Permian rocks of the Leicestershire coal-field belong to the same area of deposition as those of Warwickshire and South Staffordshire, all having formed part of the detrital deposits of the Permian Lake which extended northwards from Warwickshire and Worcestershire, and which had the Pennine chain on its eastern margin. He pointed out the dissimilar nature of these deposits to those of the eastern side of the Pennine chain from Nottingham to the coast of Durham. There were proofs of the existence of a land barrier, owing to the uprising of the Carboniferous, between the district round Nottingham and the Leicestershire coal-field. He indicated the probable course of the old coast-line of the western Permian Lake. Denudation had bared some of the older Palæozoics of their overlying coal-measures, and it is the rearranged talus from the harder portions of these older rocks which now form the brecciated bands in the Leicestershire Permians.

In an Appendix some igneous rocks found in the Bosworth borings were described.

The President referred to the derivation of the materials of the Permian breccia as an important instance of results due to investigation by local students, and the light thereby thrown on ancient physiography. He was sceptical as to the lacustrine origin of these breccias. Why not subaerial, like those in the interior of Asia? —subangular masses, transported by rainwash to a distance of 10 or 12 miles.

Professor Bonney agreed as to the existence of a barrier of land linking the old area of Warwickshire with Charnwood, and that the breccias did not obtain materials from the Lickey, the east side of which he believed to have been partly covered by coal-measures at that period. The specimens were not exactly of the Hartshill type, and he was prepared to believe that they came from a ridge now no longer visible. He thought, from the nature of the cleavages in the older rocks of Charnwood, that there must have been pre-Carboniferous movements also in that district.

Mr. Whitaker said it was unreasonable to suppose that Conglomerates should always have been derived from exposures now visible. Therefore the alleged underground extensions may easily have furnished these materials. Were the Charnwood rocks of fairly indestructible material?

Professor Blake agreed as to the relations between these beds and the Carboniferous. Was the Permian age so very distinct from that of the Trias? Mr. Wilson regarded the Permian and Trias as really one physical sequence. Are they, then, really separated by such a wide gap? He commented on the appearances at the Swadlincote section. Why might not these Permian beds represent the base of a new epoch? The stones in the deposits on the eastern side were quite different. When the Trias escapes from the Permian it becomes irregular. Were the Coal-basins separated by the Permian movements? If so, the materials dispersed should form the base of the Permian. Is there evidence that these beds belong to a distinct epoch from the Trias, and are not merely its base?

Mr. Topley observed that the main point of the paper was the relation of the beds called Permian to those above and below. The author had well traced out the underground ridge, but what is the evidence of its being a faulted anticlinal?

The Author, in reply, stated that he was not prepared to uphold the lacustrine origin of the breccia; but if subaerial it would make no difference to his argument. With regard to the age of the Charnwood anticlinal, the post-carboniferous movements took place along old lines of disturbance. The scarcity of Charnwood rocks he thought due to the drift having been from the south, and this would help to account for their exceptional abundance at Hartshorn. He had originally been prejudiced in favour of the Permian being the base of the Trias, but found the theory untenable. The material was different from that of the Eastern Permians, and from the material which makes up the basement breccia of the Keuper at Castle Donnington. The maximum angularity of the breccia in the southern part of the area was another point in favour of its derivation from a southern source. As regards evidence of a faulted anticlinal in the subtriassic ridge, the shales were found to be in a smashed condition, and instead of coming to quartzites below, something altogether different was found—appearances which could only be explained on the supposition of faulting.

On the Superficial Geology of the Central Plateau of North-Western Canada. By J. B. Tyrrell, Esq., B.A.

The drift-covered prairie extends from the west side of the Lake of the Woods to the region at the foot of the Rocky Mountains, rising from a height of 800 feet on the east to 4,500 feet on the west, the gentle slope being broken by two sharp inclines known as the Pembina Escarpment and the Missouric Coteau, giving rise to the First, Second, and Third Prairie Steppes.

The Author described the older rocks of this region, referring especially to his subdivision of the Laramie Formation into an Edmonton Series of Cretaceous age, and a Pascapoo Series forming the base of the Eocene, and then discussed the Superficial Deposits in the following order:—

1. *Preglacial gravels* occurring along the foot of the Rocky Mountains, composed of waterworn quartzite pebbles.

2. *Boulder-clay* or *Till,* having an average thickness of 50 to 100 feet, and filling up pre-existing inequalities. The clay is essentially derived from the material of the underlying rocks. The smoothed and striated boulders of the western region are largely quartzites derived from the Rocky Mountains; these gradually disappear towards the east, and are replaced by gneisses and other rocks transported from the east and north-west. Some of the surface erratics of gneissose rock have doubtless been derived from the Till, whilst others are connected with moraine deposits, and others, again, appear to have been dropped from bergs floating in seas along the ice-front. The Till is sometimes divisible into a lower massive and upper rather stratified deposit, separated occasionally by

3. *Interglacial Deposits* of stratified material, with seams of impure lignite, and shells of *Pisidium, Limnœa, Planorbis,* etc.

4. *Moraines,* which are intimately associated with the Boulder-clay, and represent terminal moraines of ancient glaciers which originated upon or crossed the Archæan belt. One of these is the well-known Missouric Coteau.

5. The *Kames* or *Asar* generally occurring at the bottoms of wide valleys, and which resemble in structure those of Scandinavia.

6. *Stratified Deposits* and Beach-ridges which have been formed at the bottoms and along the margins of fresh water lakes lying along the foot of the ice-sheet. The principal of these occupied the valley of the Red River, and has been called Lake Agassiz; it had a length of 600 miles and a width of 170 miles.

7. *Old Drainage-channels.*—Throughout the whole region old drainage-channels appear to have been occupied by southerly running rivers (where the present drainage is northerly), and are considered to have carried away the waters draining from the foot of the ice.

The President spoke of the interest of studying these American deposits. The determination of the age of the Laramie beds by no means did away with the interesting fact of the interstratification of beds containing Tertiary plants with others holding Cretaceous reptiles.

Dr. Hinde remarked that the opinion was formerly held by some Canadian geologists that many of the superficial deposits were produced by marine Arctic currents in a period of depression.

Mr. Topley referred to the rich alluvial deposit filling up the old Lake Agassiz, and its effects upon agriculture. He stated that good alluvial soil occurred along the North Saskatchewan and Peace Rivers, districts which have a great agricultural future. The Laramie coal occurs as pure anthracite in the disturbed districts. He asked whether the flora of a country was not of a later type than the fauna.

PHYSICAL SOCIETY.

At the meeting held on November 10th, 1888, Professor Reinold, President, in the chair, the following communications were read: "On the Calculation of the Coefficient of Mutual Induction of a Helix and Coaxial Circle," by Professor J. V. Jones. In arranging some experiments for determining resistance absolutely by Lorenz's method the author had occasion to consider what form of standard coil was most suitable for accurate calculation, and chose a helix of large diameter, with a single layer of wire. To obtain a sufficient number of turns requires considerable axial length; and Lord Rayleigh's approximate method of calculating the coefficient was found to be insufficient where an accuracy of $\frac{1}{100}$ per cent. is required. A more accurate method of calculation is given which, applied to a circle of 10 ins. diameter, placed concentric with a helix of 20 ins. diameter and 4 ins. long, yielded the value of $M = n.53{\cdot}259$, whereas Lord Rayleigh's formula gives $n.53{\cdot}317$.

Professor Perry asked if the thickness of the wire had been considered, and whether the author could give any information as to practical working formulæ for the mutual induction between the ordinary cylindrical coils in any position.

Dr. Fleming described a wooden anchor ring wound like a gramme armature, and having a secondary coil added, which he had devised as a standard of mutual induction, and used for determining capacity absolutely.

In reply, the author said he had not considered the wire to have thickness, as he felt sure this would not affect the result for his coil by one part in 100,000. With respect to Dr. Fleming's anchor ring, he considered the difficulty of winding it sufficiently uniformly to be a great drawback to its general adoption.

A paper on "The Upper Limit of Refraction in Selenium and Bromine," by Rev. T. Pelham Dale, M.A., read by Mr. Baily. In a former communication (read February 11th, 1888) the author showed that an upper limit of refraction for selenium should theoretically exist about the middle of the visible spectrum, and the present communication describes some experiments which tend to confirm the prediction. On placing a thin, transparent film of selenium under a spectro-microscope, it was found to be opaque to rays above the green, and previous calculations had given 5295·7 as the limiting wave length transmissible.

Sulphur at ordinary temperature should have its upper limit beyond the visible spectrum, but theory indicates that increased temperature will lower the limit. It is well known that sulphur darkens when heated, and when a film of boiling sulphur was examined under the spectro-microscope all but the red end of the spectrum was absorbed. On cooling, the region of absorption gradually retreated towards the violet end.

Selenium is also found to become more transparent as it is cooled, and its refractive equivalent is equal to that of sulphur multiplied by the ratio of its chemical equivalent to its density. Important optical, as well as chemical relations thus exist between the two elements.

The results obtained by bromine films were remarkably similar to those of selenium, the violet rays being entirely cut off.

A method of solving the equation $a \sin \theta = \sin m\theta$ (on the limiting solution, of which the upper limit of refraction depends) by a table of Eulerian integrals is given in the paper, and an analogy between total reflection and the upper limit of refraction is traced.

Professor S. P. Thompson, D.Sc., exhibited some Experiments on Glass in Polarised Light. Irregular pieces of glass can be tested for internal strain by immersing them in a liquid of equal refractive power. Various specimens of tubing, rod, and thermometer tubes were examined in this way, all of which showed defective annealing. One piece of ordinary rod bent zig-zag produced remarkable effects when rotated in the liquid. Prince Rupert's drops, a glass wedge, and a model of the "Regency diamond" showed vivid colours, and the stems of broken incandescent lamps exhibited various degrees of annealing.

Mr. Hilger wished to know whether parallel plates had been tested, and with what result, for he had always found pieces of shapes approaching to roundness, to show greater defects than parallel plates. For this reason he always cut his prisms and lenses from rectangular blocks.

Mr. Blakesley said that no perfectly annealed thermometer had been shown, and he was anxious to know whether any existed.

Mr. Wilson expressed a doubt as to whether it was possible to anneal anything so as to be perfectly free from internal strain, and thought the act of breaking rods and tubes necessarily introduces strains.

Professor Rucker asked whether the usual method of detaching a mercury column for calibrating thermometers produced any injurious effect, but the author was unable to speak decisively on the subject.

In answer to the President, Dr. Thompson said the liquid used was a mixture of carbon bi-sulphide and alcohol. His experience with parallel plates coincided with that of Mr. Hilger. As an example of the remarkable effects which could be produced in glass by various methods of cooling, he directed attention to the fact that Professor Esener, of Vienna, had produced lenses having plain faces.

Dr. J. A. Fleming, M.A., described a new form of standard resistance coil. Considerable difficulty had been experienced with coils of the ordinary B.A. construction when immersed in water or melting ice, due to leakage across the paraffin wax caused by condensation of moisture. To overcome this, various forms have been tried, and the best yet devised is made by winding the coil in the space between two shallow annular casings screwed together by projecting flanges. The joint is formed by indiarubber, and can be tested for leakage by immersing in water and applying air pressure through a small testing-tube. The rising part of the terminal rods are enclosed in long brass tubes soldered to the upper casing and insulated by air, excepting at the top and bottom, where ebonite rings are placed. The top ring forms a corrugated cap, and an annular channel in its upper surface serves as a fluid insulator. The wire, which is triple silk covered, is baked for some hours at a temperature above 100° C., and then soaked in anhydrous paraffine wax containing about 3 per cent. of resin.

ENTOMOLOGICAL SOCIETY.

At the meeting held on November 7th, 1888, Dr. D. Sharp, F.L.S., President, in the chair, Mons. A. Wailly exhibited a large and interesting collection of butterflies recently received from the Gold Coast and other parts of West Africa. The collection included about forty-seven species belonging to the genera *Papilio, Diadema, Salamis, Romalœosoma, Charaxes, Harma, Eurypheme, Junonia, Aterica, Hypanis, Eurytela, Mycalesis, Cyrestis, Nepheronia, Mylothris, Belenois,* etc. Mons. Wailly stated that several of the species were undescribed, and were not represented in the British Museum collections.

Mr. Jenner Weir exhibited four bred specimens of ant-lions, two of which were from Saxon Switzerland, and the other two from Fontainebleau. He stated that that he believed the specimens belonged to two distinct species. Mr. M'Lachlan said that the specimens all belonged to one species, viz., *Myrmeleon formicarius,* Auct. = *Europœus,* M'Lach.

Mr. W. C. Boyd exhibited an example of *Pterophorus zetterstedtii,* taken at Sydenham. He remarked that this species had hitherto only been recorded from Lynmouth and Folkestone.

Mr. Enock exhibited specimens of *Cecidomyia destructor* (Hessian fly), illustrating the life-history of the species, and made remarks on them.

Mr. Wallis Kew exhibited a specimen of *Dytiscus marginalis* having a small bivalve shell attached to one of its legs. The bivalve had apparently attacked the *Dytiscus,* and refused to relax its grasp.

Mr. W. E. Nicholson exhibited several specimens of *Acidalia immorata,* Linn., caught by him near Lewes. Mr. Jenner Weir remarked that the species had only recently been added to the British list, and that it was remarkable how so comparatively large a species could have been hitherto overlooked. It was also remarked that a specimen of this species from the collection of the late Mr. Desvignes had been exhibited by Mr. Stevens at the meeting of the Society in November, 1887.

Dr. Sharp exhibited a large number of species of Rhynchophora, collected by Mr. George Lewis in Japan.

Mr. F. P. Pascoe read a paper entitled "Descriptions of New Longicorn Coleoptera."

Dr. Sharp read a paper on "The Rhynchophorous Coleoptera of Japan."

LIVERPOOL GEOLOGICAL SOCIETY.

At the meeting held on November 13th, the President (Mr. H. C. Beasley) in the chair, Dr. C. Ricketts, F.G.S., described some interesting specimens of liassic fish remains and other fossils from fissures in the carboniferous limestone at Holwell, near Frome, obtained by him during the recent meeting of the British Association at Bath. Mr. O. W. Jeffs then exhibited an old atlas, kindly lent by Mr. E. K. Hayward, dated probably about 1720, and engraved by Tobias Conrad Lotter, of Augsburg. The features of the maps consisted in the principal meridian being taken from Teneriffe, and the delineation of the great lakes of Africa (supposed to have been only recently discovered), which are placed in their approximate positions as feeders of the Nile. In the map of Great Britain, Liverpool was not shown, but small places like Par and Leigh, near St. Helens, were duly marked.

A paper by Sir James Picton, F.S.A., entitled "Notes on the Local Historical Changes in the Surface of the Land in and about Liverpool," was then read. Sir James first called attention to a series of maps illustrating the topography of the neighbourhood. These were of various dates, the oldest representing Liverpool in 1650, and showed the gradual extension of the docks and buildings and development of the inhabited portion of the region depicted. He then proceeded to explain how the cultivation of the land, draining of the marshes, improvement of watercourses, and construction of canals and railroads have imparted to the country an entirely different aspect to its natural character. Geology showed the effects of natural forces, ever at work, in altering the surface-contour of the land, and these changes were often aided by the direct operations of man. Since the foundation of Liverpool there had been many changes in its superficial contour well worthy of notice. At the close of the glacial period the landscape on the eastern side of the Mersey presented a picturesque aspect, resembling the rocky slopes of Bidston Hill on the opposite side of the river, and the high lands at Everton, Low Hill, and Edge Hill were broken up into crags and precipices with deposits of clay in the hollows. This declivity was interrupted by two ancient sea margins, referred to by Mr. Robert Chambers, one of which was stated to occur near the summit of William Brown Street. The upper sea margin constituted the flat ground at the foot of Low Hill, on the summit of which was a pre-historic tumulus. The author gave a mass of topographical detail of an interesting character, in the course of which he referred to the old Moss Lake and other physical features which have long become obliterated. On the subject of the post-glacial geology of the two basins of the rivers Dee and Mersey, Sir James occupied an important portion of his paper, and called attention to one or two aspects not usually considered by geologists. He claimed that the valley of the Dee had for many ages been undergoing a process of shallowing and silting, and that the channel of the Mersey had been gradually deepening. Thus, whilst one valley was sinking, the other had been gradually rising, such diverse action going forward in two estuaries so near to each other being a very remarkable phenomenon. The globe which we inhabit was not a mere inert mass; forces of elevation or depression were continually in progress. The greater or less depth of water in a river channel might change the entire course of commerce, and affect the welfare of millions. It was necessary, therefore, to watch these processes of nature, and aid by science and skill whatever makes for the benefit of our race and age.

A long discussion followed the reading of this paper, in which Messrs. T. Mellard Read, F.G.S., G. H. Morton, F.G.S., W. Hewitt, B.Sc., C. Potter, Rev. S. Gasking, and Dr. Ricketts took part.

ROYAL HORTICULTURAL SOCIETY.

At a meeting of the Scientific Committee, on November 13th, a report was read on the "Jensen System of Moulding Potatoes."

During two successive seasons elaborate experiments and careful observations were made as to the effect of the Jensen system of moulding. The experiments were made at Chiswick under the superintendence of the Scientific Committee. Although results of considerable practical interest were obtained, yet the primary object of the experiments was frustrated by the non-appearance, or rather, by the scanty development, of the Potato-mould. Moreover, it became apparent that the cost of the experiments, as then carried out, would be such as to preclude their imitation on a large scale for practical purposes.

During the present season the potato disease set in at Chiswick with virulence about July 29th. Up to that time no attempt had been made to check its course or to note the conditions under which it occurred; but, at the suggestion of Mr. Plowright, two rows in juxtaposition were submitted to experiment on August 10th.

The rows were 30 yards in length, the variety selected Schoolmaster, and the conditions as absolutely identical as possible, except that the one row was left moulded in the ordinary way, while the other was "high moulded"—that is to say, banked up on one side to form a ridge, while the haulm was slightly bent over to the other side. In the ordinary system of moulding, a furrow is left along the top of the ridge into which it is surmised that the spores fall, washed off by rain from the foliage. The high moulding, it is supposed, obviates this by securing the fall of the spores on the ground between the rows, and not on the rows themselves. As the disease appeared to be equally severe on both rows, and was, moreover, far advanced, but little expectation was indulged in that the results would be of any value.

Nevertheless, on September 29th, the potatoes in the two rows were lifted and examined, as dug, by Mr. Barron and Dr. Masters. It speedily became apparent there was a considerable difference between the two rows, and that the tubers from the high-moulded row afforded a much cleaner and more even sample. With a view to put this general impression to a numerical test, fifty tubers from each row were taken indiscriminately, twenty-five by one observer, the remainder by the other, so as to equalise, as far as possible, the "personal equation."

These hundred potatoes were then examined with a more careful scrutiny, each one being cut open to ascertain whether or no it was diseased. The result was as follows:— Out of fifty taken from the row moulded in the ordinary way, thirteen were found diseased, or 26 per cent.

Out of fifty taken from the high-moulded row five only were noted as diseased, or ten per cent. No doubt a more careful examination by the microscope would have indicated a larger proportion of disease in each case, but it is not likely that it would have very materially altered the proportion either in one direction or the other. In order, however, to obtain further information upon this point, twenty-five tubers from each row were put aside for future examination.

Bristol Naturalists' Society.—At the meeting held on November 6th, Dr. Dallinger delivered a lecture on "Putrefactive Organisms." The Rev. T. Hinks, F.R.S., President of the Society, occupied the chair. The lecturer, who was most cordially received, said his chief embarrassment was the abundance from which he had to select. He should, however, not dwell on the method by which he had pursued his inquiries, or the results of labours undertaken with the vastly improved means of later years compared with those with less perfect instruments, but would detail to them one of the most remarkable results that had been brought out by him in his investigations. Passing to the main point of his subject, the lecturer said the larger of the group of minute organisms with which he should deal were so small that in a square box, having the diameter of a human hair for each of its sides, a hundred millions of these organisms could easily exist. Some of them, however, were five, ten, and even twenty times less than these. If a drop of animal or vegetable matter under putrefaction were placed in a small quantity of pure water, and was inspected with the microscope, organisms of beautiful forms were seen moving about in ceaseless activity. Dealing with the organisms themselves, he explained that various species followed each other as the process of putrefaction went on, each preparing that pabulum on which its successor lived, and spoke of the marvellously rapid rate of their reproduction. Pictures were shown illustrative of the characters of the organisms and the method by which they did their work—some by rising up and darting down on the putrefying mass and tearing it with hooks, others by bringing their weight upon it and acting as hammers. So this unceasing change and activity went on until the putrefaction was exhausted, when the mass, in the shape of carbonic acid and water, became part of the protoplasm of living things once more. Occasionally the deposit or *debris* of exhausted fermentation became subject to further fermentive action, particularly in warm climates, and the tiny organisms, by their continuous rising and striking down and twisting, absorbed in themselves and dissipated the *debris*. In conclusion, the lecturer urged the young members to studiously pursue microscopic or kindred studies, from which they would derive unspeakable pleasure and profit.

The Leeds Naturalists' Club and Scientific Association.—At a recent meeting held at the Yorkshire College, the President (Professor L. C. Miall, F.L.S., F.G.S.) presiding, the evening was devoted to "Practical Microscopy," when, under the direction of the President, the process of preparing and mounting animal sections in celluloidine was fully elucidated, this forming a supplement to an evening on the same subject some three or four weeks ago. On this occasion the object under treatment was the "Honey Bee," which presents several difficulties over animals of softer bodies, as the chitinous integument and the two large air sacs on either side of the body offer a firm resistance against the celluloidine penetrating the internal tissues; but by disconnecting the head, thorax, and abdomen and careful manipulation, the fluid celluloidin can be got to permeate and render the object sufficiently solidified to allow it being cut into sections by the microtome. This was demonstrated with the most encouraging result before the members, transverse sections being made through the head, and sections through the abdomen were mounted and examined. An interesting description of some of the important features of the slides was given. After the demonstration, the President gave a comprehensive lecture on the entire process, commencing with the mode of killing the object, passing on to subsequent methods of treatment and the reagents necessary.

Royal Botanic Society.—At the meeting held on Nov. 10th, Mr. J. P. Gassiot, Vice-President, in the chair, among other exhibits upon the table were plants of *Abrus precatorius*, the so-called "weather plant." The Secretary, in explaining the action of the plant, said he could not do better than quote his respected friend, the late Michael Faraday, who, during a lecture on table-turning, remarked that effects noticed were often incorrectly attributed to a certain cause, and thus the movement of the table was ascribed to some mesmeric influence rather than to the unconscious mechanical act of the operator; and thus the action of the weather plant was put down to atmospheric or other influences at a distance of time or place rather than that of the immediate habitat in which the plant might be at the moment.

behaviour of the weather plants in the Society's lens varied at one and the same time, according to special conditions under which they were growing.

Liverpool Astronomical Society.—At the meeting l on November 12th, Mr. W. H. Davies, F.R.A.S., in chair, the Secretary read a paper on "The Limits of Stellar Universe," by Mr. W. H. S. Monck, M.A., .A.S., which excited a very interesting discussion. aper on "Micrometrical Measures of 200 Double s," by Mr. Kenneth J. Tarrant, was next read. A t interesting report, by Mr. W. F. Denning, .A.S., on "Observations of Jupiter during opposition 887-8," was also read.

RECENT INVENTIONS.

e following list has been compiled especially for the SCIENTIFIC *'s by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents, of High Holborn, London, W.C.; Newcastle Chambers, Angel Nottingham; Ducie Buildings, Bank Street, Manchester; ', Lord Street, Liverpool.*

ondensing Gases.—Mr. D. Herman has patented ensers or towers, for condensing acid and corrosive s. It consists essentially in constructing the con- ers of a series of glass pipes carried by bearers, each having at one end an external flange, and at the r an internal flange, the whole being placed in a ble casing. The ends of the pipes having internal ;es are made of less diameter than the ends having rnal flanges, so that the pipes may be fitted one in the other.

bmarine Cables.—Mr. R. Haddan has patented ns for the insulation of submarine telegraph cables other electrical conductors on behalf of Herr E. G. witz. The invention consists in covering the cable strips of tinfoil having on the side towards the a comparatively thick coating of powdered glass, on the tinfoil by a suitable adhesive substance. layer is further covered with a layer of caoutchouc ised in incombustible impregnated silk or other rial according to requirements.

stons.—Mr. P. W. Williams has patented a piston single acting vertical engines. The object is to ly remove the fluid which condenses in the cylin- The top of the piston is therefore made with an ied surface sloping downwards, so that the parts of piston which are contiguous to the exhaust port are lowest, whether the port be in the cylinder or in the n-rod. The result is that the fluid collecting on the top f the piston runs down to this point, and is blown out immediately the exhaust port is opened.

ring Jack.—Messrs. A. Coleman, H. F. Jackson, and E. L. Dudley have patented a spring jack for tele- ic and other electrical purposes. The object is to de means for ensuring proper electrical connections een the spring slipper, in ordinarily constructed g jacks, upon the removal of the plug, even though pring may fail to bear properly on the slipper. This tained by the provision of a secondary spring, which ed at its forward end permanently in contact with the slipper, and, when the plug is not inserted within the jack, bears up at its hinder end against the under side of the main spring.

Electric Accumulators.—Mr. A. Stetson has patented an electrical accumulator. A thin case of lead is formed, into which is introduced the peroxide of lead or active material. To allow access of the liquid in the battery to the peroxide, the case has holes punched through it and the peroxide. The puncturing is so done that small pieces of lead will be partially detached and bent inward to retain the peroxide in the case. On charging the accumulator, these pieces of the lead case and the edges around the holes will be converted into peroxide, so that the case and the plate will be chemically united.

Spinning Machines.—Messrs. H. Whitwam and H. Taylor have patented a method of stopping spinning and other machines. When this invention is applied to a mule a band running the length of the machine is employed and placed on the front of the carriage; this band is connected to and supports a piece of metal near the "head-stock" of the mule. A slot is made in this piece of metal, through which passes a wire running alongside the head-stock and holding a lever which is connected to the strap-guide which moves the strap from the fast to the loose pulley, or *vice versa*, for stopping or starting the machine.

Trimming Specimens.—Mr. F. H. Butler has patented an apparatus for cutting and trimming specimens of rocks and minerals. It consists of a cast-iron base with a head-stock at each end, connected by two rods with nuts at their ends. One head-stock is grooved on its inner face and perforated to receive spanner bolts to hold the cutter; the other head-stock carries a screw with a lever through its head. On the rods connecting the head-stocks is a movable poppet head with the cutter, which is propelled by the screw passing through the second head-stock. For cutting large stones two or more screws may be used, working simultaneously by means of cogwheels.

Electrical Currents.—Mr. W. H. Douglas has patented a meter for measuring electrical currents. It consists in creating heat in proportion to the current by resistance in the coil, and placing in near proximity thereto a thermometer which will, by indicating the temperature, show the intensity of the current, the normal temperature of the atmosphere being indicated by another thermometer, so that the difference between the registration of the movements of the two thermometers will indicate the intensity of the current. To obtain a permanent registration a strip of paper is employed which is moved by a motor upon which the hands of the thermometers are made to leave a record.

Chlorine.—Messrs. L. Mond and G. Eschellmann have patented a process for the manufacture of chlorine from hydrochloric acid or ammonium chloride by means of magnesia, and its object is to prevent the retrograde formation of hydrochloric acid. For this purpose a certain amount of a fixed alkaline chloride is mixed with the magnesia before it is treated with hydrochloric acid. The quantity requisite is about 5 to 10 per cent. of the magnesia. If the magnesia be then treated with hydrochloric acid, magnesium chloride, steam, and ammonia gas are formed. This chloride is then treated to set free all the chlorine, in such a manner that by employing the mixed magnesia and alkaline chloride, no water is absorbed by it, all the chlorine is obtained as such, and free from hydrochloric acid.

ANNOUNCEMENTS.

The Intercolonial Publishing Company, Limited.—Publishers of the *Eastern, Australasian, and South African Journal of Commerce*, and of the *Periodico de Espanol, Mejicano, y Sud-Americano* have removed to Intercolonial House, 131, Leadenhall Street, E.C. The new premises contain large reading, reference, and conference rooms for the convenience of merchants and others visiting London, and provide a centre from which all information upon matters of British, colonial, and intercolonial trade may be obtained free of charge to clients and correspondents.

Worcester.—Dr. Nicol (Mason Science College, Birmingham) gave the second of the series of science lectures arranged for by the Worcester Students' Association on November 9th. The subject was "The Chemistry of Combustion," and it was illustrated by a number of interesting experiments.

DIARY FOR NEXT WEEK.

Friday, Nov. 30.—Greenock Philosophical Society. — *Earthquakes, Volcanoes, and Geysers*, by Commander Charles Reade, R.N., London.

SELECTED BOOKS.

Elementary Commercial Geography. A Sketch of the Commodities and Countries of the World. By H. R. Mill, F.R.S.E., Lecturer on Commercial Geography in the Heriot Watt College, Edinburgh. London: C. J. Clay and Sons. Price 1s.

On the Senses, Instincts, and Intelligence of Animals. With Special Reference to Insects. By Sir John Lubbock, Bart., M.P. With 100 illustrations. London: Kegan Paul, Trench, and Co. Price 5s.

A Class-Book of Elementary Chemistry. By W. W. Fisher, M.A., Demonstrator of Chemistry, Oxford. London: Clarendon Press. Price 4s. 6d.

Kirke's Handbook of Physiology. Twelfth edition. Thoroughly revised and edited by W. Morrant Baker, F.R.C.S., and Vincent Dormer Harris, M.D. London: J. Murray. Price 14s.

An Elementary Treatise on Geometrical Optics. By R. S. Heath, M.A., Professor of Mathematics in Mason Science College, Birmingham. London: C. J. Clay and Sons. Price 5s.

The Principles of Agricultural Practice as an Instructional Subject. By J. Wrightson, M.R.A.C., F.C.S., etc., Professor of Agriculture in the Normal School of Science and Royal School of Mines, etc. With Geological Map. London: Chapman and Hall, Limited. Price 5s.

NOTICES.

The Title Page and Index to Vol. I., now ready, price 3d.

Binding Cases for Vol. I., price 2s. each.

Cases and Binding, Vol. I., including Title Page and Index, price 3s.

FOR GENERAL READERS.

Vol. II. | NOVEMBER 30, 1888. | No. 22.

CONTENTS.

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

On page 486 of the current volume of this magazine is a review of the proceedings of the Royal Society of Edinburgh, concluding as follows: "Prof. R. Wallace communicates a memoir on the 'Colour of the Skin of Men and (Lower) Animals in India.' The author notes that in India cattle, sheep, pigs, buffaloes, and horses, whatever the colour of their hair, have black skins, and of this fact he seeks an explanation."

An explanation was offered by Surgeon-Major Alcock, in a paper published in *Nature*, August 21st, 1884, which has not received the attention that I think it deserves. The title of the paper is, "Why Tropical Man is Black."

After enumerating some of the theories that have been expounded by physiologists in struggling with this problem, he states his own, which summarily expressed is "that the black skin of the negro is but the smoked glass through which alone his wide-spread sentient nerve-endings could be enabled to regard the sun."

The well-established law that surfaces of given material exposed to the solar rays become heated in proportion to their darkness of tint has rendered the colour of the negro an apparent physical paradox. The demand for coolness under tropical sunshine should give such advantage to the white man that under conditions of primitive nakedness he would have there survived as the fittest for such conditions.

This conclusion, however, is based on reasoning that only includes one of the factors of the problem, viz., the *heat* of the solar rays. The experience of shampooers and other attendants in Turkish baths shows that men may be continually exposed to higher temperatures than those prevailing in tropical countries without suffering any injury to health, or even any inconvenience. Many of our English workmen do heavy work in temperatures exceeding that of the Sahara. During the hot summer of 1868 I was engaged in making experiments in the reheating and other furnaces at Sir John Brown and Co.'s works, Sheffield, and carried a thermometer, which I suspended in various places where the men were working. Where I was chiefly engaged it stood at 120 degs. with the furnace-doors shut. The men were exposed to much higher temperatures from radiant heat when charging and withdrawing the great armour-plate piles—over 200 degs. At enamelling works and at glass works the temperature is still higher; 145 degs. is a common temperature in the stoke-holes of steam-packets in the Red Sea. Such work is, of course, exhausting, but not injurious; such temperatures are enjoyable when no muscular efforts and no clothing are demanded, as in a Turkish bath.

On the other hand, at the Creusot Steel Works, where an electric furnace is used which gives out a light of 100,000 candles, the men who are exposed to the glare at a distance of ten or twelve yards suffer severely, though the heat is but nominal. They have to work with great caution and intermittently. Nevertheless, after such intermittent exposure of one or two hours, the effect is "a painful sensation in the throat, face, and temples, while the skin assumes a copper-red hue." The *British Medical Journal*, from which I quote this, describes other symptoms, including a discharge of tears, in spite of using coloured spectacles, which is "very copious for twenty-four hours. Simultaneously headache and sleeplessness are experienced, which are caused partly by the copious discharge of tears and partly by pain and the feverish state of the body. Finally, during the next few days the skin of the face begins to peel off." These and the irritation of the pupil of the eye, lasting for forty-eight hours, followed by "a very painful sensation, as if some foreign substance were introduced under the eyelids," are symptoms quite familiar to myself and others who have exposed themselves to the glaring light reflected from mountain snow in summer-time. I have suffered a complete peeling off of all the skin of face and ears, *i.e.*, of all the skin exposed to the snow-glare.

What, then, would be the condition of the Creusot workmen or the Alp climbers if the whole surface of skin were exposed?

The seat of all this irritation is obviously not in the cuticle, which is merely a protective covering of the body, as insensible as the hair and finger-nails. But immediately beneath it is the *cutis vera*, the true skin, a membrane involving so close and intricate a tissue of nerves and blood-vessels that we cannot insert a needle-point without doing violence to a nerve-ending and rupturing a blood-vessel, *i.e.*, without pain and bleeding.

The cuticle is translucent, quite as translucent as the plates of horn used as the windows of old-fashioned lanthorns. The blush of the cutis is visible through it. A multitude of other facts besides those stated above might be cited to show that the tissue of nerves and blood-vessels constituting the cutis is painfully sensitive to the action of light exceeding a moderate degree of intensity.

Our most advanced physiologists now regard vision as a specialised skin function that has been gradually developed and concentrated in the organs of sight; that the optic nerve which now sees has been evolved from skin nerves that originally could only feel. This conclusion has been reached by observations on animals which display by comparison a gradual process from localised skin-vision to rudimentary eyes, and onwards to fully differentiated optical apparatus.

Earthworms, for example, as proved by Darwin, although without eyes, distinguish readily between light and darkness, and this power is only possessed by the anterior portion of the animal. Examples of the progress from this to the rudimentary eyes of the medusa, starfishes, etc., are quoted in Surgeon-Major Alcock's paper.

The carbonaceous colouring-matter of the negro is situated in what Malpighi called the *rete mucosum*, or mucous net-work, which constitutes the inner basis of the cuticle or epidermis where the horny cells of the cuticle are formed. This is just where such opaque matter is required for protecting the sensitive nerve-endings of the true skin from the injurious action of excessive sun-glare.

The position and known functions of the iris appear to me to present another argument in support of this theory. At the back of the eye, in a position corresponding to that of the true or under-skin, we have a similar membrane, similarly including a tissue of outspread nerve-endings, those of the specialised optic nerve. In front of this we have the cornea, corresponding to the cuticle, between them the iris. The work performed by the iris is that of a dark, adjustable screen, which admits the quantity of light demanded for the purposes of vision, but excludes any excess that would produce painful and mischievous nervous irritation. The colour of the iris varies, like that of the skin, with the original habitat of the races of men. The tropical races have dark eyes as well as dark skin. Those of higher latitudes have light eyes and skin.

This variation proceeds regularly up to a certain latitude, and then comes a remarkable and very suggestive exception. The arctic races, the Esquimaux, the Lapps, or Finns, and the "Hyperborean," or Mongolian races generally have dark eyes, "are olivaceous in colour, the skin varying from a kind of sallow lemon peel through various shades of greater depth, but is never entirely fair nor intensely swarthy" (Colonel Chas. Hamilton Smith, "The Natural History of the Human Species").

Why this exception? My answer to this question is that it fits these people to endure the snow-glare to which they are exposed during more than the first half of their long summer daylight.

They have migrated very widely even to sub-tropical and tropical regions, and there they have more or less dispensed with clothing and have readily developed a darker skin. The Papuans and black Kalmucs are examples of this.

Canals of Mars.—An American exchange states that Professor Pickering, of the Harvard College Observatory, regards the so-called "canals" of Mars as areas of vegetation—possibly immense cultivated tracks.

ROMAN REMAINS AT LLANTWIT-MAJOR.

(*Continued from p.* 502.)

PERHAPS the discovery of most general interest is the room numbered 14 on the plan. Its interior measurement is 27 ft. by 20 ft.; its walls, standing at present some 2 ft. 6 ins. to 3 ft., are covered with plaster, which in earlier periods of splendour evidently had a very carefully prepared surface, with a graceful and artistic floral design painted in beautiful and varied colours, In course of time this plastering appears to have been injured, and in a subsequent period of less splendour the walls of this room had been re-plastered, the renewed surface being coarse, greyish blue in colour

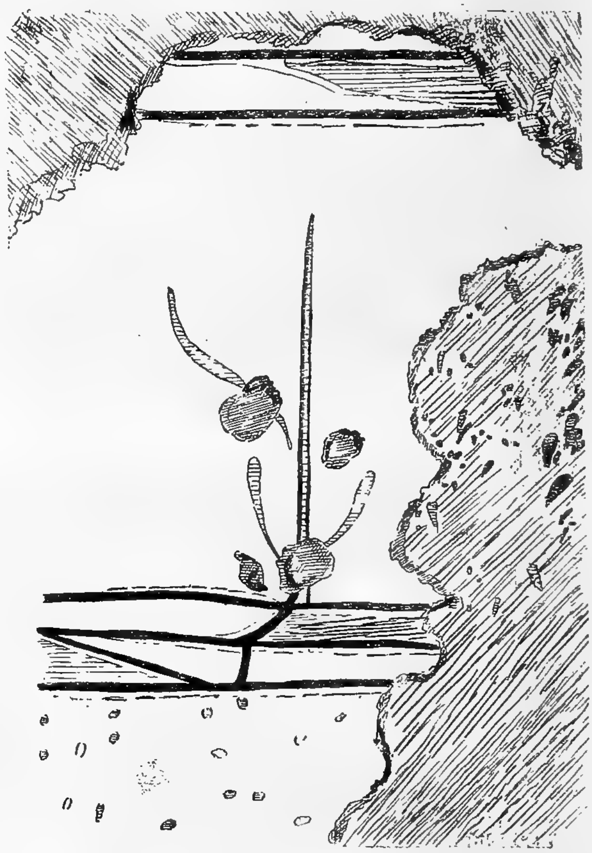

Fig. 6.—Wall Decoration.

with a splash ornament of red and dark blue. In fig. 6 a patch of the more recent plastering, with the splash decoration, is shown to the right and shaded diagonally, whilst the other part represents a place where this coarser plastering has fallen off and exposed the superior and more ornamental but injured under surface. In this the ground is deep ochre yellow, the conventional floral design is red, the central spike having a black outline; the lower bands are respectively orange, yellow, and red, whilst the dividing lines between them are black and white, the lines at the top being also black and white, enclosing an orange and yellow band, separated by a white line. The spots on the dado are red and white, the ground being pink. The irregular patches are injuries which the plaster has sustained. It is noteworthy that the colours are bril-

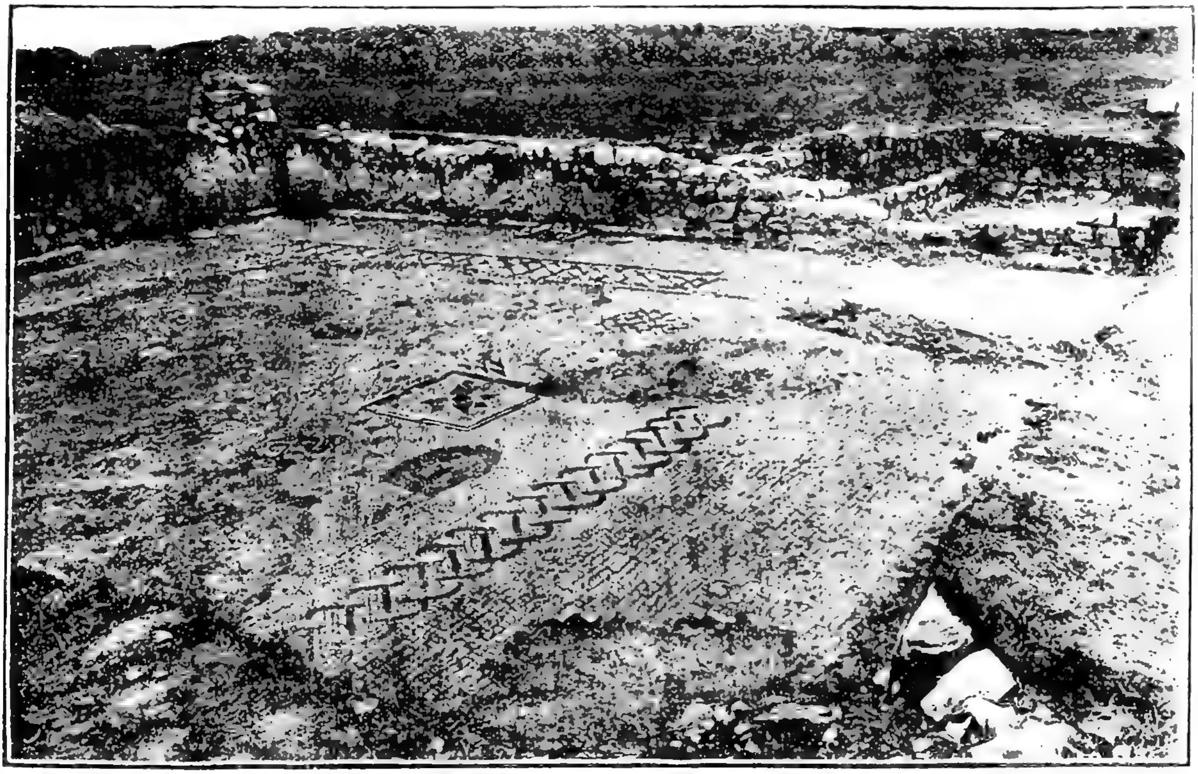

Fig. 7.—General View of Room.

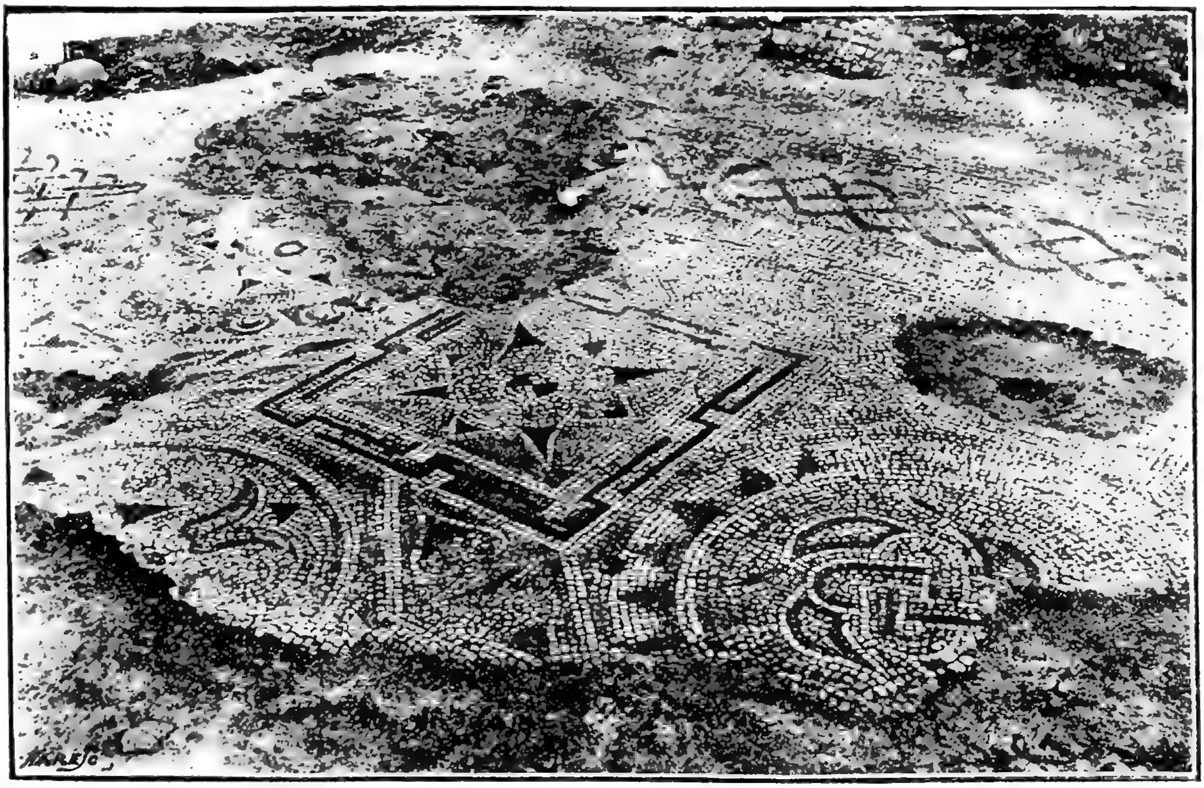

Fig. 8.—Details of Tesselated Pavement.

liant and beautiful at the time of excavation, and from their appearance seem remarkably pure, but unfortunately they very soon fade after exposure. Mr. Thomas has, whenever an opportunity occurred, seized the opportunity of making a permanent register in his own studio of both the colours and designs.

Passing now to the floor, the beautiful and elaborate character of the design of this pavement will best be gathered from the illustrations figs. 7 and 8, which are from a photograph taken by Mr. W. H. Kitchin, of Cardiff. Owing to loss of notes, we are unfortunately not able to set before our readers such a full description as we wished to do. But a little attention will reveal the elaborate and beautiful character of the geometrical designs; for instance, in the portions shown, octagons enclosing circles and a central design will be seen to alternate with square-bordered patterns, whilst no two adjoining circles or squares, as the case may be, contain tessellæ arranged in the same order either as regards shape or colour, whilst the intervening loops or spaces are equally varied in pattern and arrangement of colour. The border which immediately surrounds these figures consists of straight-line designs, triangles, and diamonds, which appear to have been repeated at frequent intervals, whilst this, in its turn, is encompassed first by plain rows of tessellæ, then by the fret border, the space between this and the wall being filled up by plain tessellæ. The colours employed are white, cream, blue-grey, red, and two shades of green. Some indication of the colouring may be gathered from the lights and shades in the illustration. It is on this point that notes are wanting, but it is certain that the effect as a whole showed considerable artistic skill both in arrangement of colour and design; take, for instance, the intervening border of various straight-line designs between those replete with varied and numerous curves. Attention might be called to many instances of well-thought-out contrasts, but space will not permit of more just now It seems probable that the whole series of designs repeated themselves at each corner, and probably there was a very fine centre-piece. Anyway, it will be noticed that the pattern at the north-east corner resembles that at the south-west angle opposite it. There is evidently no doubt that the pavement belongs to the palmy days of the art, and is probably the work of the second century A.D. It is noteworthy that all the tessellæ are nearly or absolutely cubical, and most of them were obtained from the neighbouring rocks, cream-colour and blue from the limestones, red from tiles, green and white are marble, the former stained. The cream-coloured tessellæ prevail.

Midst all this beauty, the excavations revealed an overwhelming quota of horrors, for in this and the adjoining room (17 in the plan) no less than forty-one human skeletons and the remains of at least two horses were unearthed. With the exception of one, all the skulls were found fractured, which seems to indicate that all these people, including men, women, and children, were massacred, receiving a mortal blow on the head. Only three skeletons showed any signs of the corpses having received any attention; one of these, a female figure, had been carefully placed in a rough grave broken in the tesselated pavement, and banked round with stones (15 in the plan and the somewhat obtrusive blemish in our illustration), whilst the other two were buried in the adjoining room in a similar manner (18 in plan). The latter room is about 16 ft. 5 ins. by 22 ft., and was connected with the other by an arched opening; it is also tesselated with cream and grey tessellæ without design; the walls were plastered with coarse plaster with splash decoration. The plastering shows ranging characters in the various chambers encountered along the course of the trench. It seems as if the quality of the plastering would indicate the standing of the room in the estimation of the Roman inhabitants of a habitation. In the present instance we find fine plastering associated with the magnificent pavement, coarser plastering with simpler pavement, and still coarser plastering in some other parts already exposed. Another point about these people, a personal one: it is remarkable in what good preservation all their teeth must have remained during life. It is quite an exception to see them decayed; in fact, it is quite possible to judge the age of these folks by their teeth, the older ones having these useful organs more worn down by the years of grinding or tearing they have performed. The skull of the skeleton of the old woman found on the steps leading to the hypocaust (plan, 12) was also battered about, and when unearthed her head was resting on her hand. The coins discovered are of the reigns of the Emperors Tetricus, Victorinus, and Constantius Chlorus, and give another clue as to the date of the remains, which of course must have been in existence as a habitation during the circulation of the coins of the reigns indicated, and would fix the date of the destruction of the place some time after the reign of the last-named emperor. Several opinions as to the origin, use, name, and collapse of this Roman habitation have been given in the local press and by individuals, and as they may interest our readers, we will give briefly one or two.

The *South Wales Daily News*, when noting the fact of the great number of broken skulls found in the two rooms (14 and 17), remarks, "It is presumed that this place was the scene of a massacre by the Irish in A.D. 446, when they over ran the country during one of their periodical invasions."

The *Weekly Mail* suggests that it may have been the residence of Claudia Ruffina, the daughter of Caractacus, after her return from captivity in Rome. Her Welch name Eurgan is connected historically with the spot; in fact, the latter part of the name Caer-urgan seems to be a corruption of her name. Some say it is the site of the town Bovium; some think it a villa, others a military station.

THE GRINNELL FIRE EXTINGUISHER.

"A STITCH in time saves nine," and the immediate application of water to a fire just beginning will prevent a serious conflagration. With this in view, several systems of spraying or sprinkling of water have been introduced, but none, so far as we are aware, equal in certainty and efficiency that perfected by Mr. Grinnell. As in the case of many inventions connected with the extinguishing of fires, this one also was first brought out in the United States, and the satisfactory results obtained with it there led to its introduction into England and other countries. It is stated that at present there are over 5,000 buildings in various parts of the world which are under the protection of this system; it is added, moreover, that 330 fires have been successfully extinguished by it.

The system adopted is to have lines of horizontal pipes, from eight to ten feet apart under the ceiling of each room, and these pipes are connected with larger vertical pipes which are supplied with water at pressure, from the street main or from an overhead tank. The sprinklers are attached to the horizontal pipes at distances about ten feet apart, so that there is one for every 100 superficial feet of floor area. Thus a building 120 feet fastened at its lower extremity by solder which melts at about 160 degs. F. An elastic seat is at the same time pressed against the valve by the pressure of the water, so that there is no leakage, and the greater the water pressure the tighter is the valve closed. The elastic seat not only serves to close the valve, but when

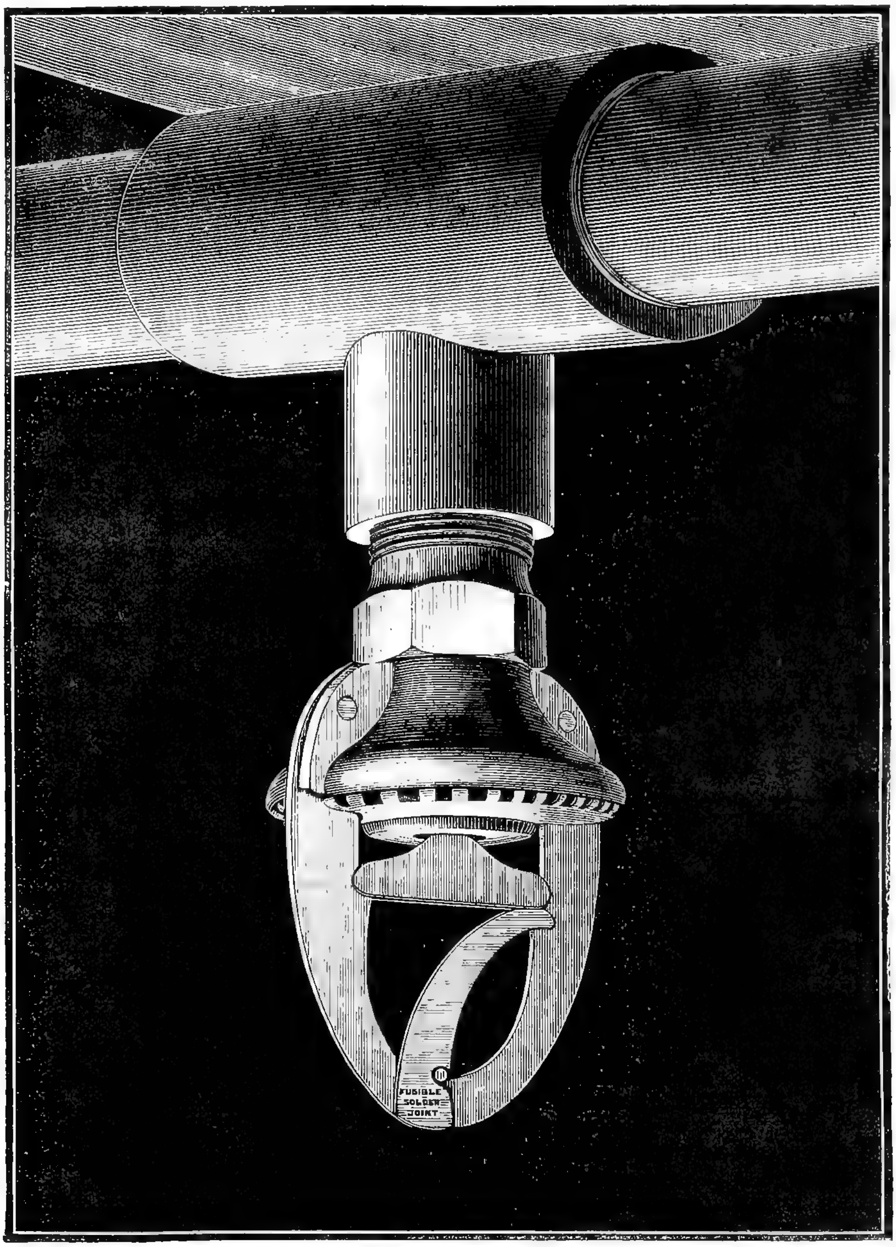

FIG. 1.—GRINNELL'S SPRINKLER IN POSITION.

long by 60 ft. wide, and four floors in height, should have 72 sprinklers in each room, or 288 for all the rooms. The accompanying illustration (fig. 1) represents the sprinkler as seen when not in action, and fig. 2 is a sectional view of a sprinkler discharging water. Its construction is at once simple and ingenious. A well-fitting and specially contrived valve is held in position by the curved lever shown in fig. 1, and this lever is the soldered joint of the lever begins to yield, the seat moves simultaneously with the valve, to the extent of its elasticity, and thus keeps the valve opening covered until the soldered joint is completely severed. This is a detail of much importance, for if a slight escape of water were possible before the soldered joint were quite broken the solder might be cooled and reset, and the action of the sprinkler would be defeated.

From the foregoing it will be readily understood that as soon as the temperature of the room in which the sprinkler is placed is high enough to melt the solder joint, the valve is opened by the pressure of water in the pipe, and the sprinkler is at once in full operation. The sensitiveness of its action has been tried in many ways, and it has been proved beyond doubt.

In buildings which are not artificially heated, and in

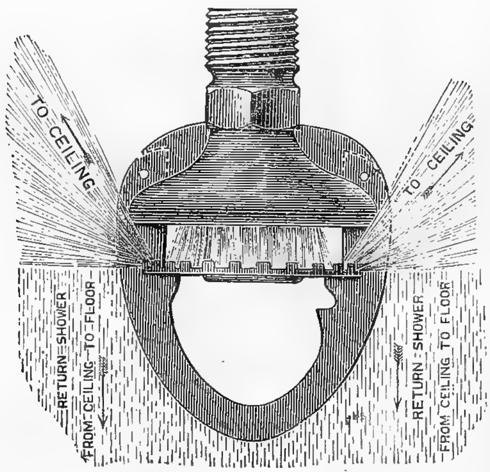

Fig. 2.—Sectional View of Grinnell's Sprinkler in Action.

which the water in the pipes might freeze, the pipes are kept charged with compressed air. In case of fire, when the valves of the sprinklers open, the air instantly escapes, and by an automatic arrangement it is at once followed by water. In places where the town water supply is intermittent, or does not give a pressure of 10 lbs. per square inch, on the top floor, it is usual to provide a tank high enough above the highest sprinkler to give the pressure required. In many country districts there is an overhead tank and an ordinary pump. Last, but not least, is the automatic alarm gong which gives warning immediately there is any escape of water inside the buildings where the sprinklers are. This alarm gong is actuated by the flow of water set up when there is an escape from any cause whatever, and its action continues so long as the escape takes place. This is a most useful adjunct, and is only second in importance to the sprinkler itself. The agents in London for the Grinnell system are Messrs. A. Ransome and Co., Stanley Works, Chelsea.

CABBAGES.

HERE and there along the south coast of England and the Welsh coast we find a plant known as the sea-cabbage (*Brassica oleracea*). It grows in tolerable plenty on the chalk cliffs of Dover, and is also recorded from the Isle of Wight, Cornwall, South Wales, and Great Orme's Head. It is about 20 inches high. The leaves are large and jagged, covered with a blue-green bloom. The stem is tough and woody. The flowers are of a pale yellow colour, and are succeeded by pods. The plant belongs to the order of Cruciferæ, the same large and important order which yields the turnip, radish, mustard and water-cress.

From this wild original (or possibly from it and one or more closely allied forms not easily distinguished) have been derived the countless varieties of the cultivated cabbage. Red cabbages, Brussels sprouts, with their crowds of little leaf-buds, cauliflowers, with their dense masses of imperfect flowers, brocolis, savoys, and kohl-rabi, are all cultivated forms of the weedy ragged sea-cabbage. In Jersey, Mr. Darwin tells us, a cabbage-stalk has grown to the height of 16 feet, and had its spring-shoots at the top occupied by a magpie's nest, while the woody stems are often 10 or 12 feet long, and have been used as rafters and walking-sticks. A cabbage-stalk fashioned into a walking-stick may be seen in the Museum of Economic Botany at Kew. The principal varieties were established before botanical curiosity had been excited, and we can only get chance bits of information as to the time and place of their first appearance. Theophrastus knew of three cabbages, Pliny of six. Regnier has collected evidence that cabbages were cultivated by the Celts of ancient Gaul. There is no hint that cabbages were known to the ancient nations of the East, and De Candolle, who has made laborious researches into the subject, believes that the cultivated cabbage is of European origin.

No more curious instance is on record of the conspicuous changes which may be effected by long-continued cultivation and selection. But the cabbage has a more direct and more human interest than belongs to any mere botanical curiosity. It is a factor of appreciable weight in the early civilisation of Western Europe. We can imagine some old European savage, wandering dinnerless along the sea-shore, until at length he was pressed by hunger to experiment upon unfamiliar plants. That savages do thus gain knowledge at the risk of their own lives we may infer from the well-known fact that they are well acquainted with the properties of the common plants of their own country, and can point out which are poisonous, which useless, which good for food. Our savage sees the tall, weedy sea-cabbage, and finding nothing more tempting, he tries its flavour. There is a slight pungency of taste, which raises misgivings, but no ill-effects follow. Next day the sea-cabbage is again resorted to, and in time becomes a regular article of food. Presently some ingenious fellow—the Watt of his age—saves himself the trouble of a daily journey to the shore by transplanting a few cabbages to a patch of ground near his cave. Years, perhaps centuries, later another great advance is accomplished, and men begin to raise the cabbage from seed. Gardens and fences follow. It is no longer necessary to spend whole days seeking food, and the man's hands are set free to make himself shoes, and a coat, and a house.

We have perhaps given to the cabbage some share of the credit which rightfully belongs to barley or some other nutritious plant, but there is no doubt that the cabbage played a considerable part in the early civilisation of Western Europe. Cultivated plants and domestic animals are the very foundation of primitive society. As the plants grow more juicy, and the animals more docile, man too rises to something higher than he was. He becomes able to lead the life which pleases him, and not that which is imposed by climate and the wild productions of the soil. He learns by slow degrees to shape his own circumtances and habits. But his intellectual gifts and his social aptitudes cannot be developed without certain simple natural resources. Of these the chief are plants worth cultivation and animals worth domestication.

General Notes.

THE PYRENEEAN ASSOCIATION.—According to *La Nature*, an association has been formed under this name for the study of the geology, botany, ornithology, and entomology of the Pyrenees. It includes among its members a number both of Spanish and French naturalists.

THE EXPLOSIONS AT KRAKATOA.—In the report on this outburst issued by the Royal Society it is stated that the noise of the explosions was heard at a distance of 2,000 miles from the volcano in all directions, whilst to the south-west it was heard at Rodriguez very nearly 3,000 miles from Krakatoa.

THE NATURE OF MILK.—M. A. Béchamp, in a memoir read before the French Academy of Sciences, shows that milk is not an emulsion, but that its globules are vesicles formed on the type of the cellule, being provided with coatings which hinder them from being separated from the milk by means of ether.

BRICKS FOR PAVING STREETS.—According to the *Chicago Journal of Commerce*, bricks steeped in bituminous matter are used in many cities in the United States for paving the streets with very good results. In localities where there is a very heavy traffic such pavements are found in good repair after being in use for six years.

ABNORMAL SENSE PERCEPTIONS.—The peculiar association of a colour with a sound, so that a certain sound heard at once vividly arouses the sensation of a given colour, is, according to *Science*, not uncommon. The association of colours with smells is a much rarer phenomenon, and that of colours with tastes rarer still. Dr. Féré gives an account of a woman who, after tasting vinegar, saw everything red for a few minutes, and then everything bright green for more than an hour.

NOVEL PHENOMENA WITH GLOW-LAMPS.—According to the *Electrical World*, glow-lamps in the vicinity of apparatus giving considerable static discharges have a very short life. On holding near a Weston lamp (110 volts) the end of a wire connected with a Holtz machine, if the lamp be burning and the machine is turned rapidly, the filament will break in from one to five minutes. The life of lamps can be prolonged by putting over the bulb a wire netting connected with the earth.

QUACKERY RAMPANT.—Dr. B. F. Davenport, chemist the Massachusetts State Board of Health, has been analysing some fashionable tonics or bitters, and has obtained startling results. Of forty-seven of these concoctions which he has examined, forty-six contain alcohol in proportions varying from 6 to 47·5 per cent., the average being 21·5 (!). This is the more deplorable as several of them are stated by the vendors to be free from alcohol. One tonic, containing 41·6 per cent of alcohol, is, as we learn from *Science*, wickedly recommended to "inebriates struggling to reform."

FETISHISM.—Major A. B. Ellis, in his work on the "Tshi-speaking Peoples of the Gold Coast," takes a new view of fetishism. He does not think it characteristic of primitive peoples, or of races low in the scale of civilization, but believes that it is reached only after considerable progress has been made in religious ideas, when the older form of religion becomes secondary. It owes its existence to the confusion of the material with the immaterial; to the belief in an indwelling God being gradually lost sight of, until the power originally believed to belong to the God is finally attributed to the tangible and inanimate object itself.

RESTRICTIONS ON HYPNOTISM.—We find the following good examples recorded in *Science*: The Belgian Academy of Medicine, after a prolonged discussion, has recommended a law prohibiting public hypnotic performances. Austria, Italy, Denmark, Germany, and most of the Swiss cantons have already adopted similar measures. The public have become strongly impressed with the dangers of an unskilled or evil-minded use of hypnotism, and a healthy sentiment prevails in favour of its restriction to experts. At the last session of the French Association for the Advancement of Science it was voted in the section of Hygiene that all public exhibitions of hypnotism should be legally prohibited in France.

ENCROACHMENTS OF THE SEA IN BRETAGNE.—In a letter read at a recent meeting of the French Academy of Sciences, M. Dechatellier described a submarine peat-digging near Pont l'Abbe. The fact is not novel, and in 1882 Alexandre Chévremont wrote, in his work on the "Movements of the Ground:" "From the mouth of the Loire to that of the Cœsnon, all round the Peninsula, there are found imposing vestiges of forests beyond the present coast lines. M. Dechatellier describes Roman remains 800 metres in advance of the coast, at a point which is now always under water. MM. Gosselet and Rigaux have found on the Flemish shore marine deposits covering remains of the Roman epoch.

THE EARTH'S CLOUD BELTS.—We learn, from the researches of M. Teisserene de Bort, that there is a marked tendency of the earth's cloudiness throughout the year to arrange itself in belts parallel to the equator. A belt of maximum cloudiness may be traced near the equator, two bands of light cloudiness extending from 15 to 35 degrees of latitude north and south, and two zones of greater cloudiness between 45 and 60 degrees, beyond which the sky seems to become clearer towards the poles. These zones have a noticeable tendency to follow the sun in its change of declination, moving northward in spring and southward in autumn. The zones of clear sky correspond with regions of high pressure. The distribution of cloudiness, according to M. De Bort, is a direct consequence of the course of the wind.

VULCANO IN A STATE OF FRESH ERUPTION.—Shortly before November 15th this island showed fresh signs of volcanic activity, and at present its many craters are in a state of eruption more intense than that of last August. Every two minutes ashes and stones are thrown high into the air, each outburst being accompanied by tremendous noises and falls of rock. No one is now on the island, nor does any one approach it, save an old man who goes for a few minutes each day to trim and light the lighthouse lamp. Stones from Vulcano are said to fall frequently at Milazzo, the point of Sicily nearest it, whilst at Messina clouds of volcanic dust, driven thither by the wind, blacken the streets and irritate the eyes of passengers. If these violent outbursts continue, it is said, the whole of the island itself must go to pieces.

Inauguration of the Pasteur Institute.—The magnificient establishment, which is the result of a universal subscription, in honour of the labours of the illustrious savant, was inaugurated on November 14th. The President of the Republic, many eminent strangers, and a great number of notabilities of the official world, of science, and of the Press were present at the ceremony. The Pasteur Institute is situate in a large plot of ground in the Rue Dutot, in the quarter of Vaugirard. The ceremony was held in the large hall of the library, which had been decorated for the occasion, and around which were placed busts of the Emperors of Russia and Brazil, Madame Boucicaut, Madame Furtado-Heine. Discourses were pronounced by MM. Bertrand, Perpetual Secretary of the Academy of Sciences, Christophle, Governor of the Credit Foncier, Dr. Grandcher, and Pasteur. The Institute consists of two large blocks of buildings connected by an intermediate wing.

A New Chromotype Process.—Our attention has recently been drawn to a new patented process for producing letterpress blocks in colours, which is being introduced into this country by Messrs. Hare and Co, of 7, Bride Court, and 31, Essex Street. In this process, owing to the much greater degree of contrast from light to dark which can be obtained, the number of colours required to reproduce any copy is reduced, on the average, from five to eight, whereas in ordinary lithographic work many more would have to be used. Not only is the cost of the blocks less than the cost of the lithographic stones, but there is also a saving in the relative cost of lithographic and letterpress printing. In addition to these advantages, the inks used in the latter method of printing are usually more brilliant than those employed in the former, hence the finished picture is very bright and vigorous. Indeed, the specimens we have seen leave nothing to be desired in this respect. We anticipate this invention will, before long, play an important part in the illustration of scientific and artistic journals.

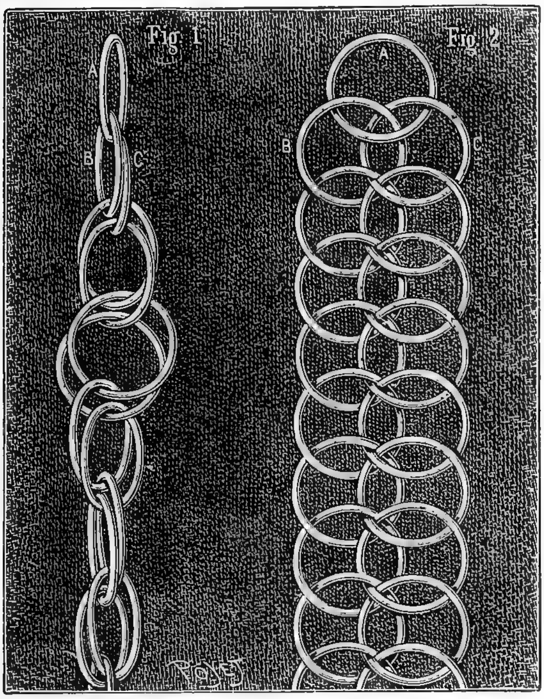
An Extraordinary Phenomenon.—According to a letter in the *Times*, on the night of Saturday, November 3rd, at a time as near 8 o'clock as possible, the tens of thousands of sheep folded in the large sheep-breeding districts north, east, and west of Reading were taken with a sudden fright, jumping their hurdles, escaping from the fields, and running hither and thither; in fact, there must for some time have been a perfect stampede. Early on Sunday morning the shepherds found the animals under hedges and in the roads, panting and frightened as if they had been terror-stricken. The extent of this remarkable occurrence may be judged when we mention that every large farmer from Wallingford on the one hand to Twyford on the other seems to have had his sheep thus frightened, and it is also noteworthy that with only two or three exceptions the hill-country north of the Thames seems to have been principally affected. The writers, Messrs. Oakshott and Millard, suggest that a slight earthquake was the possible cause of the panic. The matter had already come under the notice of Mr. G. J. Symons, F.R.S., of 62, Camden Square, N.W., who will be glad to receive and consider any information bearing upon the subject.

Interesting Discovery at Sherborne Abbey.—On Saturday week, while the workmen at Sherborne Abbey were engaged in excavating along the main aisle, they came across a heavy lead coffin resting in its vault, and which, unless removed, would have been in close proximity to the heating apparatus. The medical officer of health was consulted as to whether there was any danger of gases emanating from it if it were left where it was. On being opened, the coffin was found to contain the body of a young lady, apparently about twenty years of age, and evidently a person of high social rank. The body was wrapped in a coarse kind of flannel, the head being enveloped in a frilled head-dress of the same material. On removing a portion of the flannel placed over the face, the features of an exceedingly good-looking person were found to be perfect. The front teeth, slightly showing themselves, were found to be perfect and regular, but almost black. The churchwardens decided to have it carefully removed and buried in the cemetery. The coffin lay in a brick vault at the west end of the main aisle, and had been buried in the orthodox fashion, with the feet towards the east. There was no plate, and the probability is that it had been stolen during the early history of the church, or had somehow disappeared. The outer oak encasing the lead had entirely rotted away, leaving a dark powdery substance lying on the lead about two inches in depth. The body was lying in a shell of oak, which had also nearly decayed. Having regard to the oxidised appearance of the lead, which was of great thickness, and the general appearance of the remains, the opinion is that they must have lain where they have been for seven or eight hundred years at least.

The Public Health.—The Registrar-General's return for the week ending November 17th, shows that the deaths registered during that period in 28 great towns of England and Wales corresponded to an annual rate of 19·7 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The six healthiest places were Brighton, Bristol, Leicester, Derby, Nottingham, and Birmingham. In London 2,606 births and 1,619 deaths were registered. Allowance made for increase of population, the births were 188, and the deaths 75, below the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had been 21·2, 19·7, and 18·5 in the three preceding weeks, rose again last week to 19·7. During the first seven weeks of the current quarter the death-rate averaged 19·2 per 1,000, and was 0·5 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,619 deaths included 124 from measles, 31 from scarlet fever, 44 from diphtheria, 17 from whooping-cough, 15 from enteric fever, 16 from diarrhœa and dysentery, and not one from small-pox, typhus, ill-defined forms of fever, or cholera; thus, 247 deaths were referred to these diseases, being 30 above the corrected average weekly number. In Greater London 3,394 births and 2,028 deaths were registered, corresponding to annual rates of 32·0 and 19·1 per 1,000 of the estimated population. In the Outer Ring 12 deaths from measles, seven from diphtheria, five from "fever," and four from scarlet fever were registered. Three fatal cases of scarlet fever and three of measles occurred in West Ham sub-district, and two of measles and two of diphtheria in Enfield sub-district.

THE MAGIC CHAIN.

A CURIOUS little thing is to be seen occasionally offered for sale in the streets, and as it is easy to make, and is the subject of a very remarkable optical illusion, it may interest our readers. It consists of two chains, the links of which are crossed, as shown in fig. 1. By holding in one hand the highest ring A, and raising the ring B with the other, if the ring A be dropped it will appear to fall through the ring C, and so through the remaining rings, until it reaches the bottom of the chain. The fall of the ring is really an impossibility, and is only



THE MAGIC CHAIN.

an optical illusion. In raising the right chain the rings are in some measure turned, and the movement is transmitted from one ring to the other, so that the first one seems to fall from the top to the bottom of the chain, when, in reality, each ring drops successively. The movements, however, are so rapid that the eye cannot follow them, and receives the impression that the same ring is descending throughout the chain. Fig. 2 is the plan of the two chains of which we have only shown one end. The chain, however, can be made of any length.

THE VENOM OF SERPENTS; ITS NATURE AND ITS ACTION.

M. LAVERUNE has communicated to *Cosmos* an article on the venom of serpents, which calls for certain remarks. He states that "no serpent is large enough to devour a man, and that if serpents occasion so many deaths they are impelled neither by hunger nor by malice. They bite when they are surprised."

Now, leaving all doubtful stories out of the question, pythons and boas exceeding 30 ft. have certainly been captured; and if we consider their enormous muscular power, we can scarcely doubt their ability to destroy a man. Waterton, in his "Essays," tells us that when in Angustura a Spaniard showed him part of a serpent's skin, "which, judging from its amazing thickness, could not have been less than 70 ft. in length. The colonists have appropriately given to this serpent the name of *matatoro*, or bull-killer." Making all due allowance for the fact that Waterton did not actually measure, but merely estimated the size of this serpent, such a record, given by an experienced out-door naturalist, makes us doubt whether there may not exist larger specimens of serpents than have as yet been exhibited in our museums.

Nor can we say that the venomous species never act on the offensive. More than 20,000 persons perish annually in India from the bite of the cobra and of the kerait (*Bungarus cœruleus*).

Even in Europe the deaths from snake-bites are not trifling in number. Within six years M. Viand-Grand-Marais collected in the French departments La Loire and La Vendée 321 cases of the bites of vipers, of which sixty-two, or in round numbers one in five, proved fatal. With this proportion our own estimates, based on observations in the south-east of Europe, will fairly agree. At the same time we must bear in mind that the stings and bites of all the less venomous animals are very much affected in their activity by the constitutional state of the sufferer. In this season two cases have been recorded in each of which a man died from the sting of a single wasp.

The bite of the cobra is, however, hopelessly fatal even to the most healthy and vigorous man, unless the wound can be immediately cut out. The asp by means of which Cleopatra put an end to her life was a closely allied species, *Naja haje*. At the time when Galen was studying in the school of Alexandria this serpent was used as the public executioner. The condemned criminal was bitten by an asp. This method was more certain, though less rapid, than the electric discharge now introduced in New York.

The poison of serpents has been the subject of numerous investigatious, both biological and chemical. Inquirers have not been content to observe the effects of accidental bites, but ingenious experimentalists have collected the liquid from the fangs, and have sought to examine the mechanism of its action. In order to collect the poison certain physiologists have proposed to dose the serpent with chloroform and to extract the contents of the venom gland by pressure. This method is scarcely practical, as many of the serpents succumb to the effects of the anæsthetic vapour. The easiest method is that of Sen. De Lacerda. He coils cotton around a stiff rod, and incites the serpent to bite it between the grating of its cage. The cotton becomes charged with the venomous liquid, which can then be obtained by pressure. It is diluted with a little distilled water, and serves for experimental inoculations. If it is not wanted for immediate use it is preferable to keep the saturated cotton and to let it dry. If moistened with a few drops of water a long time after, it resumes all its virtues—or vices. Such a shred of cotton may thus be preserved in a ring, and may serve as the instrument of a "rapid and elegant" suicide. We query both the rapidity and the elegance. The soluble cyanides are far more rapid, and as for the "elegance" of this method of death, our readers may judge from the description of the symptoms which follow the bite of a death-snake. The method which M. Leverune describes

—we will not say recommends—is to bite the lip, and apply this murderous shred of cotton to the wound.

The venom, thus collected, is an article of commerce, and is used, we believe, successfully in treating the malignant fevers of tropical climates. Like many other products, it is not only sophisticated, but even counterfeited altogether. An eminent firm is said to have sold to a distinguished chemist, at a very high price, a quantity of alleged cobra venom which on examination proved to be merely distilled water mixed with a little gum.

"To whatever species it belongs," says M. Leverune, "the poison possesses approximately the same properties." This assertion we cannot accept without further evidence, since the effects of the bite of different serpents seem to vary, not merely in intensity, but in quality. It is a ropy liquid of a yellowish colour. If examined with the microscope it is found to contain numerous organised particles, micrococci or microzymas. But these microbian elements are not the active principle of the venom. If heated to 230 degs.—257 degs. F.—it retains all its virtues. If inoculated it does not reproduce itself, and it cannot be cultivated. It is, therefore, not a *virus* like the poisons of zymotic diseases.

Prince Lucien Bonaparte isolated from the venom of the viper a proximate principle which he called *viperine*. Mitchell has discovered the same principle in the venom of the rattle-snake, and has named it crotaline. Crotaline and viperine produce the same effects as the liquids from which they were extracted. If mixed with alcohol, ammonia, potassa, tannin, or iodine, they retain all their activity.

Iodine certainly diminishes the local affections, but the general effects remain the same. This explains the inefficacy of counter-poisons.

It must here be remarked that chloride of platinum if added to the venom of the cobra in a concentrated state destroys its virulence. But if the poison be introduced into the blood, and the remedy be then applied, it is useless, because it is too much diluted by the blood to exert its efficacy. Moreover, it is unable to *overtake* the poison if the latter has the start. The fact that serpent-poisons are not ferments, like disease-germs, explains that germicides, such as phenol, salicylic acid, etc., are useless.

Dr. Winter Blythe discovered in the poison of the cobra a principle to which he gave the name *cobric* acid. But the deadly secretion is now admitted to be very complex.

Armand Gautier considers the action of snake-venoms similar to that of the ptomaines, or putrefactive alkaloids, whose effects are analogous. It is known that under certain conditions the albumenoid molecule is split up with a production of alkaloids, for the most part poisonous. These alkaloids, produced in dead bodies, are known as ptomaines. But the living body produces similar bodies, the leukomaines, the residues of nutrition, which are eliminated by different channels. The production of poison is one of the general functions of the living cell, even when its life is not modified by extra-physiological or morbid causes.

In serpents this function is especially committed to certain cells, and thus contributes to secure the life of the species.

The venom of serpents is in some degree analogous to the saliva and the pancreatic secretion. But these analogies are superficial. Sen. De Lacerda even thinks that it assists in digestion. He injected the pancreatic liquid of venomous serpents into the saphene vein of dogs, which quickly fell victims. This experiment is not conclusive. It results from the researches of Béchamp that the microzymas of the pancreas of various animals are fatal if injected into the veins. The digestive action of the venom has no cause for existence, since the salivary glands and the pancreas exist in all serpents, whether venomous or not, and suffice for this function.

Viaud-Grand-Marais has carefully described the symptoms of snake-poisoning. He divides them into primary, secondary, and tertiary.

The primary results are pain—often very acute—and swelling. The part wounded becomes livid and grows cold. Then, if the case be severe, the swelling extends along the limb; then occurs an indescribable state of depression, accompanied with vomiting. The pulse and the respiration become slow, the extremities grow cold, the body is covered with a cold sweat, and the patient dies more or less rapidly after several fainting-fits. These states may follow each other very rapidly; the primary and secondary symptoms are blended together, and in a few hours all is over.

In other cases pulmonary congestion and paralysis succeed, and may last for months. Sometimes there remain very durable traces of the poisoning. This is what Viaud-Grand-Marais calls the tertiary effects. There is sometimes a periodical return of pain and swelling on the anniversary of the day when the wound was received.

Concerning the remedial treatment little can be said, as in case of the more deadly species instant amputation of the part bitten is the only safeguard. Partial success has been attained by keeping up artificial respiration. Some cases of the bite of the rattlesnake and of the puff-adder are said to have been cured by administering large doses of alcohol and keeping the patient constantly in motion. Ammonia injected and applied to the wound is said to have proved successful in Australia. The injection of permanganate of potash is recommended by Lacerda, in accordance with experiments performed in Brazil (with the labarra?) and in Africa with the horned viper (*cerastes*). But there is no instance on record of its proving of any value in case of the bite of a cobra, a hamadryad, or a kerait. Couty has thrown considerable doubt on the experiments of Lacerda. The natives of countries inhabited by death-snakes do not seem to have any remedies upon which they rely. If bitten they generally lie down and await their end in fatalistic apathy.

In certain parts of Southern France the country people treat the bite of a viper by rubbing the wound with any three herbs, no matter what, if only they are of different species!

The question may be asked, How, on the principle of natural selection, have certain serpents been able to develop a power of poisoning so far in excess of their needs? The bite of the cobra is fatal to a man, but the serpent cannot swallow its victim. Moreover, the person bitten has ample time to kill his assailant, so that the poison is of little service as a defensive weapon.

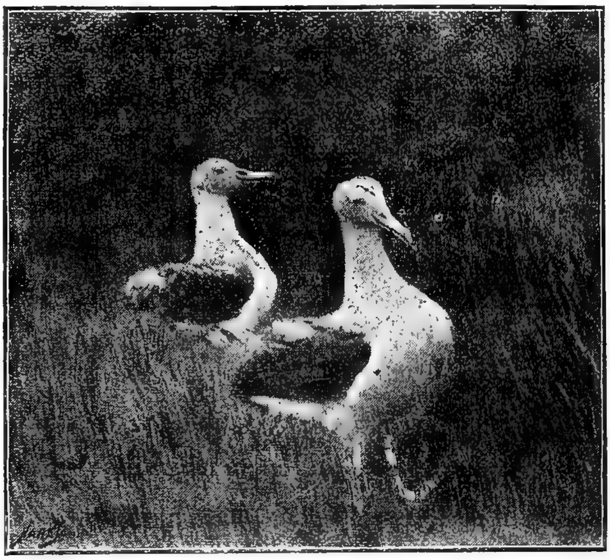
THE IDENTITY OF THE NATIVE AMERICAN AND MONGOLIAN RACES.—Dr. H. Ten Kate (*Science*) writes in reply to Dr. D. G. Brinton, who recently denied the Mongolian affinities of the American race.

Natural History.

THE ALBATROSS.

THE albatross (*Diomedea*), the largest and strongest of the petrel group, belongs to the family of *Longipennatæ*, or long-winged birds; order, *Natatores*. Its name *Diomedea*, assigned to it by Linnæus, is said to bear reference to the mythical metamorphosis of the companions of the old Greek warrior Diomedes into birds. Its popular name of albatross is a corruption of the Portuguese "alcatraz," a word applied by the early navigators of that nation to cormorants and large sea birds generally. The albatross is an inhabitant of high southern latitudes, but it frequently visits Behring's Straits and the vicinity of Kamtschatka, particularly the Kurile Isles, the Bay of Pentschinensi, and the Inner Sea, attracted thither by large shoals of migratory fish. Its chief home, however, is in the Southern Seas, and it breeds principally on the lofty cliffs of Tristan d'Acunha, in the South Atlantic Ocean, the Crozette Islands, Marion Islands, etc., flocking in great numbers round the Cape of Good Hope, where the sailors know them under the name of "Cape sheep." During the breeding season, which in the Southern hemisphere is about September, these birds assemble in considerable numbers in their favourite haunts, which then present a rather impressive appearance to the chance human observer. Mr. Earl gives the following description of a visit to one of these homes of the albatross:—"A death-like stillness prevailed in these high regions, and to my ear our voices had a strange unnatural echo, and I fancied our forms appeared gigantic, while the air was piercingly cold. The prospect was altogether sublime, and filled the mind with awe. The huge albatrosses here appeared to dread no interloper or enemy, for their young were on the ground completely uncovered, and the old ones were stalking calmly round them. They lay but one egg on the ground, where they make a kind of nest by scraping the earth round it. The young is entirely white, and is covered with a woolly down, which is very beautiful. As we approached they snapped their beaks with very quick motion, making a great noise. . . . I again visited the mountain about five months afterwards, when I found the young albatrosses still sitting in their nests as if they had never moved away from them." The rough nests of which Mr. Earl speaks are probably those of the wandering albatross (*Diomedea esculans*). The sooty albatross (*D. fulginosa*) bestows rather more care upon the construction of its nest, which is formed of a pile of mud some five or six inches high, with a depression on the top, while that of the yellow-beaked albatross (*D. chlororhynchus*) is, comparatively speaking, quite an elaborate affair, the mud at least a foot high, smoothly rounded, with a well-defined hollow at the top, and a little trench all round the base. All these species seem equally indifferent to the presence of human beings in their homes, and manifest but little irritation even when kicked aside or knocked off their nests, although occasionally one of less placid temperament than the rest may retaliate by squirting oil out of its beak on to the clothes of the intruder. The parent birds seem to have a large supply of this oil, and are said to sometimes feed their young with it. The eggs are about four inches long, and according to Sir James Clark Ross are esteemed great delicacies by the seal hunters in the Southern seas, who also pronounce the young birds delicious, which latter, however, would seem to be somewhat of an Esquimaux taste. The flesh of the older birds is distinctly unpalatable; it can only be rendered eatable by being laid in salt for a long time, and then boiling it with some piquant flavouring.

The plumage of the albatross is usually all white, save the wing-feathers, and some transverse bands across the back; its flesh-coloured feet are short and webbed; its yellow beak very strong and hard, as long as the whole head, and straight, save at the extremity, where it suddenly curves. The upper mandible is deeply furrowed, and the nostrils are placed laterally in the roll of the furrows. On examination of the skull of an albatross, a deep cavity is found just above the eyes, which during life contains a gland, whose use and purposes are still somewhat dubious. Dr. Bennet, after carefully dissecting several of these glands, announced that they were "formed of a hard granular substance of a pale colour, consisting of numerous distinct oval bodies, and on being cut are found abundantly nourished with blood vessels. The nerves supplying them come from the minute foramina seen on the floor of the cavity, and are distributed in and about the substance of the gland." The body of this bird is bulky, and averages about four feet in length, the total weight of the bird varying from twelve or fifteen, to sometimes as much as twenty-eight pounds. The chief feature of the albatross, however, lies in the immense spread of its narrow powerful wings. Foster estimates this alar extent at ten feet, Captain Cook thought eleven feet a fair average, Parker measured an albatross eleven feet seven inches across, while a specimen in the Leverian Museum measured thirteen feet. The list is crowned by the bird mentioned by both Ives and Parker Gillmore, which was shot off the Cape of Good Hope, and which measured no less than seventeen feet from the tip of one wing to the tip of the other. These great wings have about forty secondary quills, and the bones are perfectly hollow, and as the whole surface of the body is covered with innumerable air-cells, capable of volun-



ALBATROSS.
(From an instantaneous photograph taken by Mr. McDougall, of Invercargill, N.Z.)

tary inflation and diminution, the bird is thus rendered capable of a sustained and buoyant flight unequalled by that of any other living bird. The albatross is widely renowned for the grace and elegance of its flight, affording, as it sails majestically along, with wings outspread and motionless, and with its graceful head bending slightly from side to side to steer its course, a striking illustration of the "beauty of strength." It possesses an unrivalled power of "sailing" for a considerable time with no impetus but its own momentum. The stormy petrel, strong in the wing though it be, never sails at all, and even the night-hawk and other strong-winged birds can only do so for some five or ten minutes, but the albatross can sail without a single movement of its wings for upwards of an hour. Captain Hutton suggests in explanation that its shape, especially when the neck is stretched out, bears a close resemblance to Newton's "solid of least resistance," and that it steers itself carefully to avoid meeting any resistance from contrary currents; but the fact that the albatross can sail against the wind as well as before it, renders the latter theory somewhat unsound. These birds frequently follow passing vessels for the sake of any chance food that may be thrown overboard, or, as Figuier believes, because the agitation of the ship's track brings to the surface various forms of marine life which form the bird's favourite food. Be that as it may, navigators in the Antarctic Seas, where the nights are never dark enough to interrupt observations, assert that the same flock of albatrosses will sometimes accompany a ship for many successive days, without exhibiting the slightest sign of fatigue and without any perceptible relaxation in the strength and evenness of their flight. It was once an article of faith among sailors that the albatross always slept on the wing, poised, like Mahomet's coffin, midway 'twixt heaven and earth, a fanciful conceit which the poet Moore refers to in his "Fire Worshippers,"—

"The ruined tower tower'd so high
That oft the sleeping albatross
Struck the wild ruins with her wing,
And from her cloud-rock'd slumbering
Started—to find man's dwelling there,
In her own silent fields of air."

As a matter of fact, we believe that the monarch of sea-birds, when far out at sea, seeks his well-earned repose on the surface of the ocean, riding on the crest of the waves with his head under his wing, and often so oblivious of the watery world around him, that sailors sometimes stealthily approach a sleeping albatross armed with boat-hooks or harpoons, and succeed in capturing the unwary bird. Fishing for albatrosses—strange though old Isaak Walton might have thought it, to hear of angling for winged and feathered prey—is an amusement often resorted to to enliven the dull monotony of life in those unexciting seas. The albatross must plead guilty to the charge of unbridled gluttony and voracity, and its indulgence of its undiscriminating appetite often ensnares it to its destruction. Small shell-fish and fish spawn are supposed to be the staple article of its diet, but large fish and animal refuse of all kinds are greedily snapped up, and, justly or injustly, it is even accused of assisting at the happy despatch of one of its dead brethren, with no apparent qualms of conscience at its cannibalistic conduct. Thus it may easily be imagined that fishing for albatrosses makes far less demand upon one's patience and perseverance than any other branch of piscatorial sport, for the line being well baited with a good-sized lump of blubber, down swoops the hungry bird, and the bait instantly disappears. It is one thing, however, to induce an albatross to swallow the bait, and quite another to "land" him safely. Sometimes he takes to flight and soars aloft, when he has to be pulled in in kite-like fashion that calls forth no mean amount of muscular force in the fishermen's arms, whilst at others he remains on the water, squaring his wings, and often breaking the line with his fierce struggle. No amount of experience, however, ever seems to instil the slightest caution into an albatross; its size seems fairly balanced by its stupidity, and an albatross but just escaped from the line will sail down again upon another piece of blubber without a trace of hesitation. Indeed, birds who have been actually captured and liberated again with ribbon round their necks to identify them, have sometimes been recaptured more than once by the very same crew. The morals of the albatross are unfortunately not on a par with its noble appearance. It is, as we have seen, both stupid and gluttonous, and in spite of its size and strength, it is cowardly to a degree. When beset by gulls or other small enemies, who invariably attack it under the body, its most vulnerable part, it never fairly shows fight, but either resorts to the simple expedient of diving under water and thus ridding itself of its assailants, or betakes itself forthwith to ignoble flight. Despite these unheroic qualities, however, the albatross was in olden time an object of almost supernatural veneration to the early explorers of the Southern Seas, where it was often the only living thing to cheer their dreary solitude, and all lovers of Samuel Coleridge will remember the weird description given to the spell-bound wedding guest of the suffering and illhap of the man who

". . . with cruel blow did lay full low
The harmless albatross,"

the bird so loved by—

"The Spirit who bideth by himself
In the land of mist and snow."

In this prosaic nineteenth century, however, the albatross is no longer jealously guarded from harm as a bird of good omen, whose death will be followed by mystic and untold woe, but is heedlessly shot and slain as opportunity offers; by sailors, chiefly for the sake of its wings, which make imposing *souvenirs de voyage* for stay-at-home relatives, and by the natives of Kamtschatka for the sake of its intestines and its hollow wing-bones, the latter serving for pipe stems, and the former, well inflated, making excellent buoys for the rough Kamtschatkan fishing-nets.

British Wild White Cattle.—According to the report of the British Association for the Advancement of Science recently issued, it would appear that there are only three herds of the ancient British wild cattle now existing, which were originally enclosed on their own ground. These herds are: 1, Chartley Park, in Staffordshire, belonging to the Earl of Ferrers; 2, Chillingham, in Northumberland, belonging to the Earl of Tankerville; and 3, Cadzow, in Lanarkshire, owned by the Duke of Hamilton. The Staffordshire herd is larger now than it has been for some years past. It contains nine bulls, twenty cows, and five bullocks, making a total of thirty-four head. Chartley Park is a wild tract of some 1,000 acres in extent, and remains in its original condition. Many naturalists from all parts of England come to visit these remnants of the past. An interesting suggestion is made by the Sectional Committee of the

British Association to the effect that if examples of each of the three remaining herds were brought together and allowed to interbreed, they would more nearly revert to the aboriginal wild type, and we should have a better idea of what they were formerly. It is supposed that the fact of the several herds being confined to such a limited area as they now occupy, has caused them to become degenerated and somewhat smaller in size. The experiment, anyhow, is worthy of a trial.

Breeding Canary Birds.—This pursuit has become a business of some importance at Paris, and is conducted under the auspices of the *Société Serinophile.* On November 4th this society held its yearly exhibition of Dutch canaries. The competition took place in the Vautier Rooms, Avenue de Clichy. One hundred and fifteen Dutch canaries were exhibited in their cages, arranged on tables covered with green cloth, and forty-four have received prizes. These birds are worth from 3 to 500 francs each, and the members of the society rear more than 4,000 canaries annually. At Puteaux there are no fewer than 150 cultivators of chickweed for the use of these birds, and it is estimated that more than 10,000 francs' worth of this plant is sold daily in Paris.

The Plague of Mosquitoes at Bombay.—A correspondent of the *Medical Press* ascribes this plague with much probability to the existence of offensive swamps very near to the city. One of these is a stagnant lake of sewage "backed up by heaps of town-sweepings." It is expected that mosquitoes will not be the only result of this shameful neglect. The Bombay Natural History Society applied for the use of the waste and marshy ground at the foot of the Chompathy, intending to drain and reclaim it and convert it into a zoological garden, but their request was refused.

The Solom and its Products.—The attacks of the phylloxera upon the vine have not merely affected the supplies of grapes, of wine, and of raisins, but they threaten a scarcity of two products of great importance in the arts, tartaric acid and cream of tartar, the commercial supplies of which are entirely drawn from the grape. It is therefore very satisfactory to find that the solom (*Dialium nitidum*), an African tree, contains in its fruits both free tartaric acid and cream of tartar (potassium bitartrate), unmixed with any other acid.

The Star-fish and its Depredations —On the coasts of New England the star-fish are estimated to destroy several hundred thousand dollars' worth of oysters every year. These pests cannot live in fresh or brackish waters, and hence they do not infest the oyster-beds of Chesapeake Bay. In a great flood which took place in Rhode Island in the spring of 1886 an immense volume of water found its way into Narragansett Bay, and freshened the water to such an extent that all the star-fishes perished.

The United States Fishery Commission.—According to *Science,* the problem of restocking the coast of New England with in shore cod has been definitely solved. It is only a question of time before cod-fish can be made more plentiful on the New England coast than they were years ago, and a lost industry restored that will be worth millions of dollars to that section of the country.

THE BANDAI-SAN ERUPTION.

A CORRESPONDENT of the *Times* gives the following account of the results of the investigations made, by Professor Sekiya, a young seismologist already known to the world, and Mr. Y. Kikuchi, a geologist—both of the Imperial University—into this eruption, which formed the subject of a paper read by the former before the Seismological Society of Japan on October 11th :—

Sho-Bandai-san, the peak that was destroyed on the 15th July, is, or was, one of a group of four conical mountains, known collectively as Bandai-san, forming the walls of an old elevated crater basin, and rising to a height of some 6,000 ft. above the sea. Stratified volcanic rocks, of the most part gneiss and andesite, form the bulk of this mountain mass, and are mainly disposed in six great layers, the fruits of as many successive eruptions. Lava, apparently of prehistoric date, is found on the slopes. But, though Japanese records often speak of fire and smoke and poisonous vapours issuing from Bandai-san, the latest known active eruption took place 1,081 years ago, and all that remained to warrant the mountain's retention in the list of live volcanoes were a few *solfatara* in and near the old crater, Numanotaira, which from time immemorial have given off steam. On the morning of the 15th of July, however, this condition of tranquility was suddenly and violently disturbed. Soon after the mild preliminary earthquake, which took place at about half-past seven, there came a second and prolonged shock of fearful intensity. Then, while the ground in the whole region was still heaving and groaning and making the houses rock, a dense black column was shot forth from Sho-Bandai-san to a height of some 4,000 ft. During the next minute there were fifteen or twenty repetitions of this phenomenon, all of them accompanied by horrible and tremendous noises. In the last of them, the *ejectamenta* took a course highly inclined to the vertical. Zigzag flashes of lightning, resulting from the electricity generated by the steam explosions, were seen to shoot forth from the ascending columns. Then, for another half-hour, the thunders of minor explosions were heard at frequent intervals. Meanwhile, the lighter particles of the black columns, consisting of mingled steam and dust, rose steadily upward, attaining an altitude of some 12,000 or 15,000 feet above the volcano, and spreading out into a vast cloud like an open umbrella in shape, which shrouded the earth beneath it in midnight darkness, until dispersed and wafted away by the north-westerly wind. From this cloud descended the shower of blue-gray ash, so-called, which has been mentioned in every account of the catastrophe—in reality, volcanic dust or powder (augite-andesite), caused by the violent mechanical disintegration of ejected rocks, hurled swiftly through the air after having been rendered brittle and soft by the action of steam and gases. Highly heated itself, and mingling with the condensing steam, it assumed a fine granular shape and fell on the adjacent country in a solid, scalding rain, which caused shocking injuries to many individuals and clothed the ground with a hot mantle on which it was difficult and painful to walk. On the map this dust-strewn region has the shape of a half-open fan, and covers 1,040 square miles of land area, attaining at the Pacific shore, 62 miles from the volcano, a breadth of some 41 miles, and spreading yet farther over the ocean. About six inches deep at and near its origin, the layer gradually diminished in thickness, till at the coast it was a barely perceptible film. The noises of the explosions were heard some thirty miles to windward of Bandai-san, and 62 miles to leeward. But the earthquake which preceded and attended the outburst, though so prolonged and terrible in intensity, was, strange to say, not felt beyond a radius of thirty miles from the volcano—a fact accounted for by Messrs. Sekiya and Kikuchi on the ground that the seat of violent action was, doubtless, but a little way below the earth's surface, if, indeed, not above the mean periphery and in the bowels of the mountain itself. Steam—a well-known and powerful cause of seismic phenomena—was, as has been already indicated, the agent of the explosions. The great volumes of steam that must be generated whenever, from any cause, subterranean waters are brought into contact with the molten interior, expand and fill up the rock-fissures. If not deep enough down, or if lacking sufficient pressure and volume to break through the superincumbent masses, such ebullitions, though they may wrench and strain and tear the earth's crust internally, are yet hopelessly imprisoned, and can only produce on the surface the phenomena of earthquakes or minor seismic vibrations. But there are cases — happily none too common in this our day—when the pent-up vapour succeeds in bursting open its prison roof along some line of least resistance and working havoc on a prodigious scale. Of such was the explosion which lately rent Sho-Bandai-san in twain.

Besides the lighter erupted matter, whose nature and behaviour have been sketched above, there was the solid body of the peak itself, which, tossed in gigantic masses high into the air, fell upon the slopes and glens, and, rushing down them with fearful velocity until brought to rest on level or nearly level ground or by impassable obstacles, buried twenty-seven square miles of country fathoms deep in *debris*, in the short space of about ten minutes from the first explosion. One of the toughest of the many problems which beset the Japanese investigators was that of accounting for the wonderful and apparently eccentric fashion in which this mighty volume of matter had been propagated and disposed. Persevering examinations, however, soon brought them to intelligent conclusions; and these were confirmed before the very eyes of Professor Sekiya by an occurrence which, though doubtless gratifying to that ardent seismologist, was not, as he drily remarked, a particularly comfortable incident of a solitary ramble. One day, while he was at work in the crater, a huge slice of the precipitous rear-wall that had been bared by the explosions fell of a sudden, quite near to but happily clear of him, and crashed with a tremendous uproar down the steep mountain side. This slab was about 1,000 feet high and of considerable thickness. He witnessed its fall and its long descent. He saw how the great masses of earth and rock were shattered as they fell, and broken up into bits ever growing smaller as the velocity and the distance increased and as the fragments were dashed against one another and against obstacles in their way, until they finally lost cohesion, and were reduced to a pulverised, almost impalpable state, not very different from that of sand. The behaviour of the mass now resembled the rush of a headlong torrent. Tough boulders, able to survive the ordeal, were of course mixed with the finer matter, and great rock masses from 20 to 30 feet in diameter were floated down on the surface. But, as a whole, the movement approximated to that of a fluid. No words, says the Professor, can describe the "fierc ness and force" of that magnificent and impetuous dow pour—its mad surgings this way and that, and the bol leaps with which it would now and then bound over lo hills that hindered its progress, and shot onward dow the neighbouring depression. Similar, though on a vast greater scale, must have been the awful avalanch which darted down from Sho-Bandai-san in two pri cipal streams on the fatal morning of the 15th of Jul These, it is now known, dashed over hills and ridg fully 100 feet in height, and Professor Sekiya's estima that they must have attained a velocity of nearly 50 mil an hour sufficiently accounts for the swiftness of th fate that befel the doomed peasantry in the uplands an valleys below. A part, doubtless, of the descendi matter, mingling with the waters of ponds and lakes its course, became a kind of mud, and may have bee thus assisted in its flow; while that which reached t Nagase river and swallowed up so many of the Nagasa villagers, acquired the consistency of a paste. But by f the greater volume was never moistened, and must ha derived its fluid or semi-fluid properties from a rap process of pulverisation, after the manner witnessed Professor Sekiya.

As for the crater, the researches conducted by t Japanese explorers now assigned to the disrupted mat dimensions far in excess of all previous estimates. form, the crater-bed is roughly that of a horseshoe, op ing northward, and inclined slightly down from the ap to the mouth, where it is nearly 1·5 mile wide. whole area is about 950 acres. Round the crown of shoe is a nearly vertical wall, 1,660 feet high, in front which everything has been blown away. But the p itself, which was 540 feet higher than the summit of crown, lay within the now empty space. Thus, the th greatest dimensions of this gigantic projectile were, spectively, about 2,200, 7,500, and 7,800 feet. From th and other particulars it has been possible to estimate v approximately both the volume and weight of the rupted matter. In my former narrative I ventured the statement that, assuming the mean depth of *de* over the buried area to be 15 feet, its weight would be less than 700 millions of tons. I added, however, t this depth was probably far short of the truth. It pro to be only about one-fourth of the truth. No fewer t 1,587 millions of cubic yards, weighing 2,880 millions tons, and spread over 27 square miles of country to average depth of 57 feet, are the approximate figu with which to estimate the power exerted in this la manifestation of plutonic energy. A great fissure, dou less corresponding with the original line of least resista runs through the crater from its vertex nearly to its mou It is marked by a long range of steamjets, large small, which puff and hiss forth immense volumes white, pungent vapours. But Bandai-san is now p fectly at rest. Delicate tromometers fail to detect faintest throb upon its surface. Only that row of remains to tell of the fever that rages far beneath.

The terrible *coups de vent* that accompanied the plosions, and wrought such havoc in the forests villages, were, of course, corresponding phenomena those which break windows and lay low the grass plants at the firing of ordnance forged by men. difference was one of degree only, though some idea its vastness may be gathered from the fact that in case villages many miles from the scene were liter wrecked, while in the forests near the crater hundr of trees, three or four feet in diameter, were laid prostrate on the ground. Suddenness, from first to last, characterised the whole of this remarkable phenomenon. There had been slight shocks of earthquake on the 8th, 9th, 10th, and 13th; also a momentary spasm at about seven o'clock on the morning of the eruption, so feeble, however, that many persons failed to notice it. Strange rumblings, taken for distant thunder, were heard in the mountains soon after seven. But of palpable warning there was virtually none, with, perhaps, the bare exception that animals in the neighbourhood are said to have shown signs of uneasiness and fear just before the outburst. That animals are highly susceptibe to minute tremors of the ground is a well-established fact; and, as the earth in the vicinity must have been more or less affected before such an explosion as that of Bandai-san, it is quite conceivable that there may have been a succession of microseisms perceptible only to the delicate senses of quadrupeds and other dumb creatures. Well-waters are said to have diminished in some places before the eruption occurred. But neither before nor after did the large Lake Inawashiro, to the south of the volcano, give any sign of being affected by it. And, generally, it must be owned that the Bandai-san catastrophe and the phenomena preceding it have not brought us any nearer than we were before to the power of saying when—or even where—volcanic mountains may be expected to give vent to their hidden fury.

Reviews.

Handbook of Sydney. For the Use of the Members of the Australasian Association for the Advancement of Science. Edited by W. M. Hamlet, F.I.C., F.C.S., Government Analyst. Sydney: Turner and Henderson.

Although this little book did not reach us until after the first meeting of the Australasian Association was over, it yet possesses a permanent interest as a compendium of the natural history—taking the term in its widest sense—of the Sydney district.

After an Introduction by the editor, dwelling on the topography of Sydney and the picturesque character of its harbour and vicinity, we find an essay on the climate by Professor H. C. Russell, Esq., B.A., F.R.S., the Government Astronomer. The temperature is decidedly lower than we might expect from the latitude. The mean temperature in the shade is only 62° Fahr., which is not greater than that of Toulon or Barcelona. But the summer of Sydney averages only 71°, and the winter 54°, whilst that of Toulon reaches a mean of 75° in summer, and falls to 48½° in winter. In the interior of the country the mean summer temperature is 66°, running up to 120° F. in the shade.

The average rainfall at Sydney is 50 inches, and the average number of days on which rain falls is 152. Further inland the rainfall decreases rapidly, being only 38 inches at Paramatta.

The account of the geology of the district, by C. S. Wilkinson, F.G.S., the Government Geologist, brings to light the fact that in the Pleistocene period the rainfall must have been more considerable than it is now, and that the climate must have been more favourable for the continuous growth of a luxuriant vegetation.

Professor J. H. Maiden, F.G.S., the Curator of the Technological Museum, furnishes a very interesting account of the botany of the region. He notes the deplorable fact that "no instinct of pioneering man seems to be stronger than his love of felling trees." Hence, in the neighbourhood of Sydney the native flora is becoming sadly restricted.

The mammalia of New South Wales are described by Dr. G. Bennett, F.L.S. With the exception of the Monotremata, forming as they do a transition between mammals and reptiles, they are not very interesting.

One of the few animal nuisances in Australia is the flying fox (*Pteropus poliocephalus*), a fruit-eating bat, which is very destructive in orchards.

The birds of Australia are overlooked in this manual, a fact greatly to be regretted.

The marine fauna, described here by Dr. W. A. Haswell, F.L.S., is extremely rich. It is much to be regretted that the Aquarium, founded by the exertions of the late Miclucho Maclay, has been allowed to collapse. This establishment, like those of Naples, Hoboken, etc., and unlike every aquarium in England, save that newly founded at Plymouth, was a place for genuine scientific research.

The insects of the Sydney district are well described by A. Sidney Olliff, F.E.S., of the Australian Museum. This writer notes the affinity which exists between the fauna of Australia and that of the western coast of South America. The paucity of species of butterflies—only 320 known species in so vast and so sunny a country as Australia—is something remarkable. Three species of *Papilio* occupy themselves with damaging the orange orchards.

The Hymenoptera, the Orthoptera, and the Diptera of Australia are not sufficiently known to be summarised.

From this little handbook it will be seen that an immensity of work remains to be done in Australia. We hope that the new Association for the Advancement of Science will, in the language of a homely old proverb, "do the next thing," that is the work which can only be done in Australia, and not waste its time and its energies upon subjects which can quite as well be studied in Europe.

An Essay on Cramming. By Robert W. Davey and R. H. Thompson. London: John Walker and Co.

Among our many national peculiarities one of the most striking and perhaps the most unfortunate relates to our system of education. Every one knows that, according to a scheme primarily imported from China, we treat examinations not as a test of the progress made by any student, but as the main object of education. We hear constantly of students preparing for some particular examination, and passing it or failing so to do. We constantly meet with elementary treatises in different branches of science written avowedly in reference to some particular examination, and we have a numerous and highly paid class of examiners. Until lately the public flattered itself that all this was as it should be; that if a man had passed such an ordeal he must be competent and conversely that if he failed he must be ignorant.

From this dream we are beginning to awake. No less eminent an authority than Professor Huxley told us a few years back that in these days we study not to know, but to "pass," the consequence being that we pass and don't know! This saying has been found to be true. Almost all men of eminence in science endorse it, and admit that a man may have passed a brilliant examination, say in chemistry, and yet be utterly incapable of extending the boundaries of chemical science, or of effecting any useful application of its truths. He may be, in fact, impotent alike theoretically and practically. On the other hand, men who have done great things, who have conducted important researches, and have become renowned as discoverers, admit frankly that they could not pass an examination in their own memoirs.

Nor is this surprising. Examinations, however fairly and ably conducted, can test merely a man's power of appropriating and remembering the results of others. They can throw no light on his mental resources, his suggestiveness, his ability to carry on successfully the inductive process. In other words, examinations pick out the brass and reject the gold. For what we want are discoverers and inventors, not mere walking vade-mecums who can talk glibly about some science, but can do nothing in it. Of course, those who might confess "ye know that by this craft we have our wealth" do not see these alarming truths. But there is still a "lower depth." Misleading as is examinationism, "pure, simple" competitive examination is worse. This system was adopted some time ago as the only key to minor appointments, civil and military, in the service of the State. The motive for the change was not the honest desire to secure the best men for the public service, but a wish to diminish the influence of the upper classes. Whether this wish was justifiable or not is a question which it is not within our scope to discuss. But we may certainly say that this diminution of aristocratic influence is being bought far too dearly. In order to secure very mediocre men we submit an increasing part of our youth to an ordeal from which, whether successful or unsuccessful, they emerge with unfeebled vitality.

So severe are the examinations, so irrelevantly extensive, that to pass almost necessitates the employment of a professional "crammer." This crammer is one who, by careful and constant scrutiny of the examination-papers and of the idiosyncrasies of examiners, can give an approximate forecast of what questions will be put, or at least what phase of any subject will be brought into prominence.

Thus, one examiner never repeats a question which he has ever put before; another constantly revolves in a narrow circle of questions, which may consequently be expected to recur periodically. One fixes his attention mainly upon the fundamental theories of a science; another confines himself to facts, a third to recent discoveries, and a fourth to practical applications. One has peculiar catches and traps against which the student can be warned. In short, a clever crammer—and without great cleverness no crammer can survive—can always tell his pupils what part of any subject they must carefully get up, or what parts they may safely neglect. Hence such pupils have an immense advantage over competitors who have carefully worked up the whole of the subject.

This at first sight may seem an evil. So, in one sense, it is; but the sin lies not with the crammer, but with the examiners and with the pedantic legislators who have called them into being. It is an awful fact that of the successful candidates for the India Civil Service a considerable proportion are found to be incapacitated by *morbus Brightii*, a consequence of severe brain-work under the pressure of anxiety.

We can recommend the pamphlet before us to our readers. It cannot fail to set them thinking

Abstracts of Papers, Lectures, etc.

ROYAL SOCIETY.

At the meeting on November 15th a paper on "Combustion in Dried Oxygen," by Mr. H. Brereton Baker, Dulwich College, late Scholar of Balliol College, Oxford, was communicated by Professor H. B. Dixon, F.R.S.

In 1884 some preliminary experiments, published in the "Journal of the Chemical Society," convinced me that moisture exerted an important influence on the combustion of carbon. Since that time experiments have been made, not only with that element but with several others, and the same influence seems to be exerted on the combustion of some, while no such influence could be detected in the case of other elements. It was discovered very early in the investigation that hydrogen, both free and combined, aided the union of carbon with dry oxygen, and therefore for the new experiments on this and other elements, special attention was devoted to their purification from hydrogen. It was found that two of these elements, amorphous phosphorus and boron, have, like carbon, a very great power of occluding hydrogen. To eliminate it, some of the elements were heated in a current of pure chlorine, while others were heated in sealed tubes with the chlorides of the elements, special precautions being taken to free the purified elements from all traces of the agents used in their purification. In this way the elements—carbon, sulphur, boron, and phosphorus, the latter in both red and yellow modifications—were found to have their combustion influenced by the dryness of the oxygen. Some chemical union was found to take place, the extent of which varied with the dryness of the substances. In no case, however, did it manifest itself by flame. Ordinary phosphorus was obtained so pure as not to glow in the oxygen dried by phosphorus pentoxide, though the pressure was increased and diminished in every possible way. If water was added, rapid combustion at once set in.

The elements—selenium, tellurium, arsenic, and antimony—were purified with as much care as was expended on the elements mentioned above. Their combustion was, however, not found to be affected in any way by the dryness of the gas.

In the course of the investigation two facts were discovered about the combustion: (i.) of amorphous phosphorus, and (ii.) carbon in oxygen. Amorphous phosphorus is generally regarded as being incapable of true combustion. It is asserted that before amorphous phosphorus can be heated to its kindling point, it changes into ordinary phosphorus, which then burns. This has been proved not to be the case. Amorphous phosphorus was heated in a current of nitrogen, free from traces of oxygen, to 260°, 278°, and 300°, in three experiments, without undergoing any change to the ordinary modification. If moist oxygen was substituted for the nitrogen, combustion took place at 260°. It seems, therefore, probable that amorphous phosphorus undergoes a true combustion in oxygen without previous change to the ordinary modification.

With regard to the combustion of carbon, it has always been a doubtful question which of the two oxides is first formed. Is carbon monoxide the first product, undergoing further oxidation to the dioxide, or is carbon dioxide the first and only substance formed? The problem seems incapable of direct solution. It is, however, open to indirect attack. When carbon is heated in a current of partially dried oxygen, a slow combustion goes on, and, though the oxygen is in excess, both oxides are produced. The amount of monoxide, however, is twenty times the amount of the dioxide. Experiments also show that this occurs at temperatures at which dry carbon dioxide is not reduced by carbon. The carbon monoxide must, therefore, be produced by the direct union of its elements, its further oxidation being prevented by the dryness of the gases. Confirmatory experiments were performed in which carbon monoxide was found to be produced by the slow combustion of carbon in air at 440°, a temperature too low for the reduction of the dioxide by carbon. It is probable that the ordinary combustion of carbon goes on in two stages, that carbon monoxide is first produced, and, if circumstances are favourable, this is further oxidised to carbon dioxide.

LEEDS GEOLOGICAL ASSOCIATION.

In his inaugural address, Mr. J. E. Bedford, F.G.S., gave an interesting account of *Natural gas*. He stated that the earliest record he could find of the discovery of natural gas in America was in Washington county, Pennsylvania, some sixty-five years ago. Some workmen were making a boring to obtain brine for the manufacture of salt, when, after obtaining the brine, small quantities of the gas made their appearance, but not in such quantities as to excite curiosity or produce any unusual effects. But suddenly large quantities of the gas rushed out and obliged the men to leave off working. The old account says that "the gas resembled hydrogen to all appearances, and that in effect it is similar to all that species of air that frequently collects in mines, known by the name of firedamp, which all chemists agree is hydrogen." Then an account of an accident is given, which, igniting the gas, illumined the country for miles around. Still no value was attached to this gas, and for years it was allowed to escape into the atmosphere, until some ingenious individual conceived the idea of fixing pipes to the mouth of the well and conveying the gas to the brine pans and boilers as fuel. From this time its economic value was recognised, and it is now used to a very large extent in many manufacturing districts, and especially in Pittsburg. In this city it is used for a great variety of purposes, such as warming dwelling-houses, cooking purposes, heating steam boilers, fuel for blast furnaces, etc. The gas is under considerable pressure, and pipes of only moderate diameter are required to supply large quantities of gas. For instance, a 40-horse power boiler is supplied with gas by a 2-inch pipe, the gas valve, too, being only half-opened. When the boiler is sufficiently heated, and the supply of gas adjusted, then little further attention is required. Mr. Bedford then related an instance showing the great utility and economy of this gas as fuel. Messrs. Jones and Laughlin, of Pittsburg, have 72 steam boilers and 90 puddling furnaces. They turn out per month about 5,900 tons of puddled iron, from Siemens and other furnaces 13,000 tons, and of steel 7,300 tons. All this metal was reduced to bars, plates, etc., the steam to run the heavy machinery being produced by the gas-heated boilers. Before the use of gas fuel, the consumption of coal was over 300,000 tons per annum. The whole of this vast establishment (where about 5,000 hands are employed) is now fed by a single gas-pipe, 20 inches in diameter, the pressure on which is only about 1 lb. on the square inch. The pressure varies somewhat at times, but is under control. The entire concern has been run on a pressure of three ounces to the square inch. The wonderful heating power of this fuel is due to the fact that a very large percentage (in some cases nearly 90 per cent.) of it is hydrogen, and, as is known, a given weight of hydrogen will produce in burning three times as much heat as the same weight of carbon. The value of this fuel in establishments of this kind, in comparison with coal, is dependent upon the conditions under which the two fuels can be obtained. It is estimated, however, that there is an average saving of from 60 to 75 per cent., of which one half is represented by the cost of fuel, and as much more by the cost of labour and material. The remarkable purity of this gas is another important feature in its favour, and for this reason it is especially valuable in puddling furnaces, where the iron is very liable to be deteriorated by sulphur, etc., from inferior fuel. There are also large glassworks using this natural fuel, and the owners find that they produce better glass and with greater economy than with any other fuel. In fact, there is not a single manufacturing establishment in Pittsburg of any importance which now uses anything but natural gas as fuel. The number of private residents who are using this gas for cooking purposes and for heating their houses, is very large and rapidly increasing. The supply of natural gas is derived from the Palæozoic strata, although it has been found in newer formations. The Trenton limestone of the Lower Silurian is very productive, although gas in some quantity is found in the shales above the limestone. From these shales, however, there is not a continuous supply, as they are generally in pockets. The difference between a good gas well or a poor one is due to the porosity or density of the Tranton limestone. Mr. Bedford here showed three specimens of this limestone. The first example was of a very spongy, porous character, similar in appearance to pumice stone. This was from the Kary well at Findlay, which produces 12,600,000 cubic feet of gas every twenty-four hours. The second specimen was porous, but not so much as the first one. This was from the Heck well, in the same neighbourhood, which produces between five and six million cubic feet per diem. The third specimen was a compact, hard limestone, showing hardly any porosity, and was from the Eastern Findlay territory. This well only produces half a million cubic feet per day. These specimens showed most clearly the comparative difference in the porosity and the density of the Trenton limestone, and the relation which these circumstances bear to the flow of gas. What has the Trenton limestone to do with this natural gas? Is it the source of its origin, or is it only from its porosity a vast passage or natural pipe line, so to speak, for the distribution or conveyance of this enormous volume of gas? He adhered to the theory that the gas is generated far below the Trenton limestone, and it can easily be supposed that with the tremendous pressure it is subjected to at its point of origin, it would force its way through the intervening strata until it reached this limestone, and then become distributed through it. The shales and slates above the limestone act as an effectual barrier to its further passage, until, either by natural fissures or by the agency of man, it finds a vent. As to the tremendous pressure alluded to, the well at Canonsberg, Pa., may be mentioned as having the greatest registered pressure of any in the world. The gas looks like a solid piece of blue steel for some distance after it comes out of the pipe. Solid masonry, 12 feet thick, surrounds the well to hold the cap on.

Very little was said in the first section of this paper on the chemical theories for the origin of this gas and petroleum, and therefore with great advantage the opinion of that truly great chemist and experimentalist, Professor Mendeléef, may be quoted. He thinks that petroleum is produced by water, which penetrates the earth's crust, and comes in contact with glowing carbides of metals, especially those of iron. The water is decomposed into its constituent gases, the oxygen uniting with the iron, while the hydrogen takes up the carbon and ascends to a higher region, where part of it is condensed into mineral oil, and part remains as natural gas, to escape wherever and whenever it can find an outlet. If this assumption be correct, and a sufficient store of metallic carbides be contained in the earth's interior, petroleum may continue to be formed almost indefinitely, and yield a supply of fuel long after coal has become exhausted. The Professor supports his views by producing artificial petroleum in a manner similar to that by which the natural product is made.

As to the life of a gas well, or, in other words, the length of time when gas will issue from it, only theories can be indulged in. We know that the flow of gas from these wells does diminish, still not yet so far as to discourage investors. The natural gas territory is of such vast extent that, should the life of the first wells drilled be comparatively short, others may be drilled in other parts of the district, and (approximately) the same amount of gas may be obtained. This has been demonstrated to be a fact, so far as present experience teaches. However, there seems to be a general opinion that, in process of time, all the gas wells will be exhausted. It is stated that there is not to-day a single gas well in Pennsylvania which is giving out 50 per cent. of the volume of gas which it originally did, and in many instances gas wells of enormous pressure when first opened have been abandoned. Mr. Bedford gave the following analysis of natural gas from Findlay, Ohio:—Marsh gas, 92·61; olefient gas, 0·30; hydrogen, 2·18; nitrogen, 3·61; oxygen, 0·34; carbonic oxide, 0·50; carbonic acid, 0·26; sulphuretted hydrogen, 0·20. This must not, however, be taken as the standard composition of this gas; it is very variable. Samples taken from one well at different dates have been found to vary in nitrogen from 23 per cent. to 0 per cent.; in carbonic acid from 2 per cent. to 0 per cent.; in oxygen from 4 per cent. to 0·4 per cent., and so on. This fact of variable composition has given rise to many interesting questions and theories.

GLASGOW NATURAL HISTORY SOCIETY.

The 37th annual general meeting of this Society was held on Tuesday, 30th October, Mr. Thomas King, Vice-President, in the chair. The Secretary, Mr. D. A. Boyd, read the report of the Council on the progress of the Society during the past year, which stated that the names of 5 honorary, 10 corresponding, and 111 ordinary members had been added to the roll, the total membership being 342. The various departments of the Society's work continued to be maintained in a satisfactory state of efficiency. Reports by the Treasurer and Librarian were also submitted and approved. Mr. A. Somerville, B.Sc., F.L.S., was elected a Vice-President, and other office-bearers were appointed. Mr. James J. F. X. King exhibited a partial albino blackbird shot in the neighbourhood of Kilbarchan, Renfrewshire. Rev. John Muir exhibited a series of ophidia and scorpionidæ from the south of India, and described the various sub-orders which the specimens illustrated. Mr. R. Broom, B.Sc., made some remarks on the snakes, and referred particularly to the rarer and most interesting forms. Among these were specimens of *Cynophis malabaricus*, *Passerita purpurescens*, and *Trimeresurus anamallensis*. A very fine series of the shells of *Isocardia cor*, one of the rarer marine mollusca was submitted for exhibition. Among the specimens was an adult, dredged in July, 1887, between Lesser Cumbrae and Brodick, and especially interesting as the first living example recorded from the Clyde. This was kindly lent for exhibition by His Grace the Duke of Argyll, K.G., K.T., D.C.L., F.R.S. Numerous other specimens, from various marine districts, were shown by Mr. David Robertson, F.L.S., F.G.S., President, Dr. John Murray, F.R.S.E., F.L.S., honorary member, Mr. W. Anderson Smith, corresponding member, Mr. James Paton, F.L.S., Mr. D. Corse Glen, C.E., F.G.S., and Mr. A. Somerville, B.Sc., F.L.S. A paper was read by Mr. Somerville in which reference was made to the various specimens, and a general account given of the species and its area of distribution. Mr. John Renwick exhibited fasciated main-stems of the Austrian pine (*Pinus austriaca*) grown on the estate of Traquair, Peebles-shire.

THE BOURNEMOUTH SOCIETY OF NATURAL SCIENCE.

At a meeting held on November 9th, the President (the Rev. G. H. West) in the chair, a paper was read by Mr. C. Carus Wilson on "Musical Sand." The lecturer referred to the history of musical sand, which has been noticed in writings for the last 1,000 years, and mentioned various localities where it is found, as at the Isle of Eigg, Gebel Nakus, near the Red Sea, Reg-Ruwan, and other places. It has also been found on the beach near Studland, as noticed by Mr. Carus-Wilson in *Nature*. These interesting and peculiar sands, on being struck with the foot, or put in a bag and struck, or even on drawing the hand through them, have the power, when dry, of emitting a shrill musical sound, quite distinct from the dull thud given by ordinary sand under similar treatment. Mr. Carus-Wilson has examined a number of these musical sands from various localities, and finds they have certain physical properties in common. These are: The individual grains are rounded, polished, of uniform size, free from coating of other minerals, with but slight admixture of angular grains, and entire freedom from fine gritty particles. Hitherto no good explanation of the cause of the musical sound emitted by these sands on percussion has been advanced, and on this question Mr. Carus-Wilson has been working and experimenting. He was led to formulate a theory, which he hopes may lead to a true explanation of the cause of this phenomenon, by noticing the peculiar shrill noise made by the pebbles on Chesil Beach when walking over them. At any point on this beach the pebbles are of uniform size—rounded, smoooth, and free from admixture of gritty particles, so that when disturbed by the foot they tend to slide from and over each other, rubbing their surfaces together, and by that action emit a shrill sound unlike the grinding noise from rough or angular stones under like circumstances. The lecturer showed that the physical characters of Chesil Beach, except for size and composition of its particles, are identical with those of a singing beach; and he thinks the rubbing together of the rounded particles of sand may be the cause of the sound emitted by musical sand. Mr. Carus-Wilson detailed experiments he had made in the course of his investigations. He had endeavoured to make a musical sand by sifting ordinary sand through muslin of various degrees of fineness, and afterwards treating it with acids. By this means he had obtained a sand composed of clean grains of uniform size, but which was not musical. The grains, however, were angular, and not rounded. It would appear there must be considerable difficulty in obtaining a successful result to such an experiment, as the musical properties of sand depend on most delicate conditions. The mere handling of such a sand is enough to make it mute, or if brought home and damped with water it is made for ever mute, which is very curious, as the same sand, exposed on its beach, is constantly exposed to the action of sea or rain water, and yet when dry is again musical. The Studland Bay sand is musical only on its own beach. Mr. Carus-Wilson has ›ught away many samples from that locality, but has ›er been able to bring with it its musical note. The ›d from the Isle of Eigg, first described by Hugh ›ller, appears to be one of the best and most famous of ›se musical sands. Of this the lecturer had a sample, ›ich, on percussion with the wood handle of a seal, ›itted a loud shrill sound. This sand is the result of the disintegration of the rocks in that locality, and has, through long periods of time, been subject to a separating ›ion by wind and wave. The result is, the coarser ›nded particles are left high, and constitute the sing- beach; the finer are carried away to another part of the bay, where they are found. In much the same way the ›ging beach in Studland Bay has been formed by the ›ion of the prevailing wind separating and carrying ›ay the finer particles of sand, leaving the larger ones, ›nding and polishing them by attrition. The delicate ›ditions necessary for the formation of a singing beach ›well shown here, where it is a rather long interrupted ›ip not more fifteen yards wide.

An interesting discussion followed, in which the ›esident, and Messrs. Dolamore and Curtis took part.

FLINTS.

THE second of a series of lectures on Flints was given on Monday evening of last week in the theatre of the School of Mines, by Professor J. W. Judd, F.R.S. ›e lecturer commenced by saying that at their last ›eting he endeavoured to point out how, by a series ›analyses, the chemist arrived at the conclusion ›t quartz consisted of silica, and nothing but silica. He ›en proceeded to point out that the substance silica, or ›xide of silicon, consisted of two chemical elements— the gas known as oxygen, and the solid substance known as silicon. He remarked upon the great interest which ›ached to those two elements—oxygen and silicon ›arising from the fact that oxygen constitutes one-half the crust of the globe, while silicon constitutes nearly quarter, those two elements by themselves making , therefore, three-fourths of the earth's crust. He ›en proceeded to point out the wonderful analogy there ›is between the element silicon and the element carbon. ›showed that while carbon formed the basis of the organic world, silicon constituted the basis of the mineral or inorganic world. He showed further that those two substances—carbon and silicon—presented some remarkable analogies one with the other. Those two substances were each capable of existing in a number of different conditions known as allotropic forms of the substance. The diamond was one form of carbon; carbon was sometimes found as a black substance—charcoal—and sometimes crystallised as graphite; sometimes, again, it is found in meteorites, which come to us through space in the form called Cliftonite. He showed there were three forms of silicon, analogous to the diamond, Cliftonite, and charcoal. Proceeding from the condition of the element silicon to the compound substance silica, he pointed out that silica was the most abundant of the binary compounds in the earth's crust—that it constitutes, either alone or in combination with other substances, no less than two-thirds of the earth's crust. He had then proceeded to point out that silica, like silicon—they must keep clearly in mind the distinction between the compound of silica and the element silicon—and carbon could exist in other states, and he had also briefly indicated, in concluding his lecture, that that difference between substances having the same ultimate chemical composition was principally due to the way in which their atoms or molecules were arranged in building up the substance, so that if the arrangement of atoms or molecules be altered without changing the chemical composition, of the substance they might completely alter its properties. Now there were two forms of silica which were especially worthy of their attention. There were other forms of silica, as he should point out presently, but there were two forms which in their study of flints they must especially bear in mind—the substance known as colloidal silica, a kind of gluey, jelly-like substance; and the crystalline, or ice-like form of silica. Now, colloidal silica and crystalline silica have identically the same chemical composition, but in a great number of points they differ remarkably in their physical and other properties. First of all he would refer for a moment to the differences of their chemical behaviour under different conditions. If he were to put a piece of crystalline silica into a vessel of water he might leave it there practically for an indefinite time, and it would undergo no change. There would be no tendency for the substance to dissolve, and as he pointed out last time, he could not dissolve it directly in any substance except in the powerful acid known as hydrofluoric acid. But colloidal silica might easily be made to pass into solution. He would call their attention to the case of minerals in the gallery above the theatre, where they would see water containing a considerable quantity of colloidal silica in solution. It appeared perfectly bright and clear; and they could not tell it from pure water. Now, there was another chemical difference between crystalline silica and colloidal silica besides the tendency of the one to pass into a solution and the other to resist solution. Quartz showed no tendency to combine with water, but colloidal silica did very easily combine with water. It was true that by raising the temperature to a certain extent some of the water separates from colloidal silica, but it is very difficult indeed to separate the whole of the water from that substance. Chemists had found out that there are very definite compounds of this silica, or dioxide of silicon, with water—one known as silicic acid, and others containing larger proportions of water.

Now, besides that difference of chemical behaviour, he must now call attention to the fact that there were many curious physical differences between quartz, or crystalline silica, and colloidal silica. The first was the difference of density, or weight, to which he must call their attention; and in comparing those substances they must compare either equal bulks of substance or else refer both to one common standard, and the standard which was chosen for comparing weights of solid substances was water. Now if he were to take a small cubical vessel of such a size that when it was filled it would contain just one pound of water, and then take a piece of quartz and cut it out in a block of exactly the same size as the interior of the vessel, so that it would fit into it and fill it exactly, if we weighed that quartz it would be found that it weighed considerably over a pound—that it would weigh exactly $2\frac{2}{3}$ lbs., or putting it in decimal instead of vulgar fractions, 2·66. Now, if we took the other variety, the colloidal silica, and treated that in the same way, it would weigh $2\frac{1}{5}$ lbs., or in decimals 2·2. Now they saw that these two substances differed in a remarkable manner in their density or specific gravity. As a matter of fact, it was a very troublesome operation, as they might imagine, to cut blocks of colloidal silica, or quartz, into definite forms to weigh them, and they could arrive at the specific gravity by a very much easier method. If we take a block of crystalline silica and weigh it carefully in a delicate balance in the air, and get its weight, and then take the same mass and sustain it in the vessel of water while it is being weighed, it will be found that the water will buoy up the mass, and that it will weigh less than when it was weighed in the air. It had been found that the diminution of weight when it was weighed in water was equal exactly to the weight of the bulk of the water which the block displaced. That very remarkable discovery is ascribed to Archimedes. We can determine the specific gravity of a body at once by making use of this principle. If the crystalline silica was weighed in air and then in water, they would have the weight of the displaced volume of water, and if we divide it into the weight of the substance we shall get the specific gravity. If we treat a piece of flint in that way it will be found that the specific gravity is always something less than that of quartz, or more than that of colloidal silica. Flint has a density between that of quartz and colloidal silica. Now, if the matter was made up of atoms or molecules — molecules being built up of atoms—and if the atoms and the molecules of the same substance have the same weight, then, knowing that colloidal silica and quartz, or crystalline silica, were built up of the same elements in the same proportions, they would arrive at the conclusion that if the one substance was lighter than the other it must be because there are more particles in a given space in one case than in the other; they would arrive at the conclusion that in colloidal silica the molecules did not lie so close to one another as they did in crystalline silica. And there were many facts which tended to bear out that conclusion. The first which he would call their attention to was this: If he took a piece of quartz and put it into water or any coloured liquid, such as ink for example, it would be found there was no tendency for the liquid to be absorbed by the substance crystalline silica. The ink could be washed off the surface, and it would seem to have undergone no kind of change. There was no tendency in crystalline silica to absorb the coloured liquid; there was no evidence that it was in any degree porous. But if they took a piece of colloidal silica and put it into liquid they would soon find that the colloidal silica tended to absorb the liquid without undergoing any change in its own bulk, that it exhibited evidence of porosity; and if they used a coloured liquid for experiment they would see that fact proved by the circumstance that the coloured liquid would permeate the whole mass of the colloidal silica. When he said that crystalline silica did not absorb a coloured liquid he did not refer to the existence of exceptional cracks such as were to be found in specimens of crackle quartz. If the crackle quartz were put into a coloured liquid the liquid would find its way into the cracks, and then it might give a portion of it a pretty appearance, but the liquid only penetrated along the cracks, and not into the substance of the mass. But colloidal silica appeared to be an absolutely porous substance, though some forms of colloidal silica were much more porous than other forms. One of the most porous forms of colloidal silica was a very singular form of substance known by the name of tabasheer. Tabasheer is the Arabic name for a very curious substance, which had a singular origin. They had heard that silica passed into solution under various conditions, and in quarters of the globe there was a certain quantity of silica in solution. Silica was taken up by the roots of plants, especially by certain varieties of plants, such as the grasses, and these grasses were capable of absorbing this colloidal silica, and building it up into their structures. Many of the grasses contained a considerable quantity of silica, in their stems especially, and sometimes particles of it exuded from the surface of the stem. There was a gigantic grass—the bamboo—that absorbs silica, like all other grasses, and builds silica into its structure. When the grass on the bamboo was burnt they sometimes got a considerable quantity of silica. Now he had to refer to a curious circumstance that sometimes occurred in the case of bamboos. Bamboo, like other grasses, consist of a number of joints which were cut off from one another, there being a central hollow cavity between the separate joints. Those rings were solid, and the spaces between were hollow. Now it appeared that when bamboos were in an unhealthy condition or had suffered from some kind of injury, the silica which was taken up in them might accumulate in those hollow portions of the stem, and thereby they got deposits of hard silica in the bamboo. It was only now and then that it is found. From very early times the Eastern peoples had been in the habit of looking for these deposits of silica in the joints of the bamboo, and they gave to it the name tabasheer. It was very highly prized by Arab physicians; and was taken internally. One did not know what good or harm it was likely to do; but he did not know that that might not be true of certain Western medicines. However, that substance was highly prized, and was sold in all Eastern markets. Now, this tabasheer was a curious form of colloidal silica. It was so porous that the pores were two and a half times the bulk of the solid silica which enclosed them. They very seldom found any form of colloidal silica so excessively porous as that, though all forms of colloidal silica were more or less porous. Now let them see how they could prove the porous character of the substance tabasheer. Sir David Brewster, who was the first to call attention to the curious properties of tabasheer, indicated some very valuable experiments by which its nature might be illustrated. He showed that if one took a small portion of the substance and put it into a liquid which was coloured red or blue by some colouring matter, this colouring matter would permeate the mass, which would be coloured throughout by the liquid passing into it. He showed that it could be coloured in another way. If a piece of the substance be wrapped up in paper, and the paper set fire to, smoke was produced, and this smoke would enter in through the pores of the substance and blacken the whole of the interior of the tabasheer. He would show them how that absorption took place in the case of tabasheer, but before doing so he would point out that there were many other forms of colloidal silica which exhibited some porosity, though to a less extent. There was a curious substance called hydrophane, that appeared dull and opaque when looked at under ordinary conditions, but if it were dropped into water it became almost perfectly transparent, and sometimes glowed with all the beautiful colours of the opal. When it was taken out of the water it lost that wonderful property, and became dull and opaque. Lately a variety of this substance, hydrophane, had been made use of in the United States; it was found in Colorado, and was used by our American cousins for making "magic" rings containing photographs; a small plate of the hydrophane is placed over a photograph. Under ordinary conditions the white opaque substance concealed the photograph, but if it be put into water the water was absorbed, and the whole mass would become transparent. They would have to consider why the substance became transparent when it absorbed water. One had a familiar example of it in a piece of blotting-paper, which appeared quite opaque when dry, but it became more transparent when it was wet. Now this hydrophane acted in just the same way. The curious property that colloidal silica had of absorbing liquids had long been known, and made use of in the artificial colouring of agates and similar substances. They would learn presently that those agates were made of bands of colloidal silica alternating with others of crystalline silica. Crystalline silica did not absorb liquid, but colloidal silica did. Certain coloured liquids could be introduced into that portion of the agates which consisted of colloidal silicate. There was a very great demand for the black variety of agate, which constituted what was known as onyx. Mourning studs and similar articles of jewellery were formed of that material. Perfectly normal black examples of this substance were found in nature, but not in anything like the quantities that were required for the purpose of making this mourning jewellery, and so at Oberstein the people had learned to colour those substances artificially, taking advantage of the porosity of colloidal silica. He would try and illustrate how that was done. The workmen took a stone which might be of a dull grey tint, with no beauty about it at all, and put it into a substance like a solution of sugar or honey, keeping it at a gentle heat by placing it upon a stove. It was found that three weeks was often required for such a substance to pass into the pores of the dull-looking agate. When the sugar or honey has passed into the interior another substance is introduced—oil of vitriol or sulphuric acid—which penetrates in after the sugar and produces a wonderful change. When a solution of sugar was treated with sulphuric acid the water was taken away from the sugar and the black carbon was left behind.

Now, he thought he had brought forward sufficient facts to illustrate that colloidal silica which existed in agates was more or less porous in its structure. He must point out that there was a very interesting quality of colloidal silica, which was probably accounted for by the fact that it contained a great number of little pores. Colloidal silica possessed in a remarkable manner the property known as opalescence. If one looked at a mass of colloidal silica it would be seen that it had a milky-blue tint when the light was on it, but if the light be allowed to pass through it, it has more or less of a yellow tint. That peculiarity, that the object looked blue by reflected light, while it appeared yellow by transmitted light, was known as opalescence; and one of the most wonderful examples of this was the air itself. In the daytime the atmosphere, throwing back the light of the sun, appeared blue, and thus they saw the blue sky; but when the sun gradually declined in the heavens and passed towards the west the light passed through great thicknesses of atmosphere, and the sky then appeared first yellow, and then red, and all the beautiful colours of the sunset were displayed. He must not follow out the question which had been suggested by Dr. Tyndall and other physicists, who had shown that this opalescence of the atmosphere and all other forms of opalescence were due to minute foreign particles scattered through the atmosphere or through the liquid which exhibits the opalescence. A simple experiment would, perhaps, render that tolerably clear. He had a vessel of water, and in the bottle there was a quantity of resin dissolved in spirit. That substance remained dissolved in the spirit, but it would not dissolve in water. When introduced into the water it was broken up into a countless number of very minute particles, those particles acting upon the light in such a manner as produced opalescence. That quality had received the name of opalescence because it was exhibited by the special form of colloidal silica which was known as opal.

Both the colloidal forms and the crystalline forms presented very beautiful colours. Those colours were, like the opalescence appeared to be, in all cases due to the presence of very minute foreign substances. Sometimes quartz presented a beautiful greenish tint, at another time an amethyst or purple tint, at other times a bright yellow colour, and at other times it becomes dark and almost perfectly black. But he would strongly recommend them to examine the wonderful varieties presented in that substance in the horse-shoe case in that museum. He hoped that after some of these lectures they would take the opportunity of seeing the wonderful beauty and variety of the forms of silica which were there exhibited. How small a proportion of foreign substance might produce a large amount of colour was illustrated by two vessels on the table. In one he had placed a pennyworth of gold, and in another one-fourth of that quantity, yet it was sufficient to colour a large mass of liquid. Doubtless many of the colours found in quartz, which were very brilliant and beautiful, were due to equally small proportions of foreign substance diffused through it. Opal presented, in addition to the quality of opalescence, which was shown in nearly all forms of opal, a wonderful play of colours. There was every reason to believe that that wonderful play of colours was produced by the presence of excessively minute foreign particles, which gave rise to the wonderful phenomena known as interference colours.

While speaking of the colours of these substances he might point out that they had there sufficient proof of the excessive minuteness of these ultimate molecules or atoms of matter. If one took a piece of musk and put it into a room it would scent a large room for year after year, and every person who went into the room would smell the musk, because minute portions were separated and had come into contact with the membrane of the nose. Yet if one weighed the musk it would not be found that it had lost appreciably in weight. They could imagine how excessively minute must be the particles which, though being constantly separated, did not diminish the weight. Those minute particles of gold coloured liquid uniformly; they could not be discovered by the aid of a microscope, and they could thus form some idea of how minute those ultimate atoms and molecules of matter must be. Now, those molecules and atoms being so small they, could not study their positions and relations to one another, and the way in which they were built to form such a substance as colloidal silica on the one hand, or crystalline silica on the other, by the aid of the microscope or by any direct means; but there were means by which they could determine the way in which those ultimate molecules of matter were built up to make those substances, and he would endeavour to illustrate how it was done. Light comes to us through the undulations or waves produced in the ether which surrounds us everywhere. These minute waves, or pulsations, in the ether gave rise to the phenomenon known as light, and are of excessively small dimensions. The waves that produced sound or that they saw in liquid were all gigantic as compared with the waves and undulations in the ether. By allowing light to pass through the various substances, and studying the effects produced, they were able to tell how those particles were arranged.

By means of the lantern the lecturer then proceeded to show how light was used for making out the internal structure of solid bodies (polarisation of light). The reason why those colours were reproduced was that the molecules were built up in a certain fashion. Here they had the means of finding out the way of the building up of the molecules in the substance, and when pieces of quartz were examined in that way they were often found to have an exceedingly complicated structure. If they found opal, or colloid silica, occurring naturally, they never noticed in it any tendency to exhibit definite outward forms. The mass broke out into irregular fragments, without any tendency to form definite shapes; but when they found the other kinds of silica they constantly saw in it a tendency to take on those wonderful forms which belonged to what were called crystals. In virtue of the wonderful inward molecular structure they got produced an outward form. Crystal forms are, indeed, the outward and visible sign of the inward molecular structure which existed in quartz, and distinguished it from colloidal silica; and it was wonderful how completely its outward form did betray the inward structure. There were a great many internal structures in different kinds of quartz, giving rise to most wonderful appearances when examined by polarised light. When these different varieties of quartz were forming crystals they found the crystals possessed certain peculiarities, a little extra face or other abnormal character, that betrayed at once to the practised eye the fact that the quartz had its peculiar molecular structure; so that this tendency to take on the outward form of a crystal was connected with its wonderful molecular structure, which was betrayed by the substance und[er] polarised light. But the substance he had been referri[ng] to was not the only form of crystalline silica. Th[ere] were others. One was known as tridymite, and the[re] were other substances which were crystalline, all [of] which differed in their properties. So they could s[ee] what a wonderfully complicated substance the crystalli[ne] forms of silica were. In conclusion, he must refer [to] some physical properties which flint presented in a ve[ry] marked manner. As he pointed out in his first lectu[re] the character which distinguished flint above all oth[er] things was its hardness. The hardness of flint was n[ot] quite so great as that of quartz, but it was somewh[at] greater than that of opal. If a piece of flint was stru[ck] against another piece of flint or against a piece of steel [a] spark was produced. A minute portion of the flint or st[eel] was separated; the violent blow produced heat sufficie[nt] to cause this particle to become red-hot. Now, the hard[ness] of flint was combined with another property, whi[ch] gave rise to the uses to which flint had been appl[ied] in the past. It was not only hard, but it was to a certa[in] extent tough; therefore flint could be used as a cuttin[g] tool in a way that glass could not be used. But the mo[st] striking point about flint was its fracture—the way [in] which it broke. Different substances broke in ve[ry] different ways. Some crystalline substances broke ve[ry] easily in some directions, and they got what was calle[d] cleavage. Quartz would not break in a particular manne[r]. If one threw a pebble at a plate-glass windo[w] the result would probably be that on the other sid[e] of the plate-glass a little conical piece of gla[ss] would drop out, and with a larger piece of gla[ss] struck suddenly he might get a cone, the ang[le] of the cone being about 110 degrees. Sometimes a suf[fi]ciently violent blow might result in the forms of tw[o] cones, one having sides at an angle of 110 degrees, an[d] the other the sides at an angle of 30 degrees. Occasiona[lly] if a blow was struck obliquely he might get a cone lyi[ng] in an inclined position. This was a very peculiar pr[o]perty of flint. If a considerable mass of flint was struc[k] they might get the tendency of the forms of a con[e] giving rise to the appearance exhibited by the outside [of] a shell, and that fracture was known as a conchoid[al] fracture. Sometimes if a light tap was given on th[e] surface of the flint, instead of getting a single cone, the[re] was around it an inverted cone, producing a cup so th[at] it looked like a little cone and crater, such as one saw i[n] volcanic countries. The conchoidal structure of flint wa[s] a very remarkable one, and it was this property com[]bined with hardness and toughness which enabled the[m] to use it in various ways. If flint was struck with [a] hammer a flake was obtained (specimen exhibited). [It] was the fact of the flint having that peculiar fractur[e] which had enabled it to be employed for purposes whic[h] he would have to describe in a future lecture. He hope[d] in the next lecture to show how the microscope enable[d] them to learn more about the internal structure of flin[t] and its relation to those two substances which they had been considering that evening—colloidal and crystalline silica.

INSULARITY.—Says the Rev. H. H. Slater (*Midlan[d] Naturalist*), in a series of articles bearing this title, "I[n] no other country of which I have any experience is th[e] scientific worker treated by the Legislature with suc[h] contemptuous indifference as in this."

RECENT INVENTIONS.

The following list has been compiled especially for the SCIENTIFIC NEWS *by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents, of* 234, *High Holborn, London, W.C.; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester; and* 6, *Lord Street, Liverpool.*

GAUGE.—Mr. H. Nash has patented a liquid gauge for gauging the contents of vessels. It comprises a spiral rod, which is rotated by a nut sliding longitudinally thereon, and which cannot rotate. This nut is operated by a suitable float, to which it is attached, the float being guided by a tube forming a case for the instrument. An index is attached to the head of the spiral rod, and is adapted to move over a dial secured to the upper end of the tube.

INSULATING WIRE.—Mr. W. S. Smith has patented apparatus for insulating or covering wire. The apparatus consists essentially of a drum, into which the material is fed by rollers or other feeding mechanism, and within which are a toothed ring and a pinion gearing together, one of them being driven from without, and also a partition, past which the material is carried by the teeth of the ring and pinion, and is forced out towards a die, through which the wire is led.

ELECTRIC LAMP.—Mr. T. A. Edison has patented a cut-out device for electric lamps. The lamp is constructed, in the usual manner, of a glass vacuum chamber and a carbon filament placed therein, but in carrying out this invention it is also provided with a spring cut-out held out of action by a fine wire situated between the leading-in wires, whereby when the wire is fused, by the filament of the lamp breaking, the cut-out is released, and the lamp is cut out of circuit, which prevents the destruction of the lamp and its socket and the continuity of the series circuit.

CLEAR WATER FROM RIVERS.—Mr. S. A. Johnson has patented a method of obtaining clear or filtered water from rivers and other sources. For this purpose a float is employed which floats on the surface of the river and carries a perforated chamber at any distance below the surface. This chamber is connected by a flexible pipe with a filter, from which a pipe descends into a vessel which is at such a level as to enable the water to be drawn off by syphon action. By adopting this method both the surface *debris* and the bottom mud or other matter are avoided.

LITHOGRAPHY.—Mr. J. L. Mills has patented a method of lithographing by sand-blast. The lithographic stone is coated with gum of suitable thickness, upon which, when dry, is placed a tracing of the picture it is desired to engrave on the stone. Then by directing the sand-blast in proper manner the gum is punctured in an artistic manner until the whole of the tracing and light and shade appear to be perforated through the gum and into the stone. After this, lithographic grease is poured over the coated stone, thus imperforating the punctures. The gum is then washed off with water and the stone etched in the ordinary way.

REMOVING SCALE.—Mr. H. J. Haddan has patented an apparatus for removing scale from pipes and tubes, on behalf of Herr A. Rast, of Austria. This implement comprises a shaft adapted to be rotated by a crank handle at one end. Its other end carries a block sliding thereon which has pivoted on it plates ending in gudgeons, on which rotary cutters or files revolve. Upon the end of the rod is a plate which is arranged to bear upon and press radially the plates of the gudgeons. The latter are preferably inclined, so that the cutters revolve in planes inclined somewhat spirally to the walls of the tube within which the implement is inserted and operated.

PHONOGRAPH.—Mr. G. L. Anders has patented a phonographic apparatus. The invention relates to the preparation of surfaces for receiving a phonographic record. The diaphragm employed in this improved apparatus is perfectly flat, and is made of lighter materials and more sonorous than the iron plate usually used; the recording instrument has a cutting or shaving edge, and the recording material is hard wax. This material has a continuous projection, and in combination with the cutting of the diaphragm forms the phonographic record. To guide the material against the style or cutting edge a threaded or toothed guide is employed, which is fastened to the frame carrying the diaphragm.

DISTRIBUTING MOTIVE POWER.—Herr V. Popp has patented an improved method for distributing motive power by compressed air, and for utilising this motive power for generating electricity. It relates to the arrangement of the apparatus employed, and its object is to ensure great efficiency and regularity of distribution. It consists essentially in the combination of a syphon retaining the water which may accompany the air into the conduits with an automatic regulator for controlling the pressing of air in the conduits in accordance with the resistance in the circuit; it also combines an apparatus for heating the compressed air before it passes into the motor, so as to increase the efficiency of the motive fluid.

MOTORS.—Messrs. H. Rogers and E. J. Curtin have patented an improved construction of high-speed, single-acting, high-pressure, or compound, or triple expansion engine. For compound the high and low-pressure cylinders are so arranged that there are two diametrically opposite low-pressure cylinders, the pistons of which are connected rigidly to a central loop in which works a crank on the engine-shaft, while the high-pressure cylinders have their pistons connected by rods to the same or different cranks on the engine-shaft, the supply of steam to the high-pressure cylinders being regulated by a disc valve, while the passage of the steam to the low-pressure cylinders is effected through parts governed by the pistons of the high-pressure cylinders.

FORGING METALS.—Mr. M. Gledhill has patented a novel method and machine, whereby metals can be forged either hot or cold. For this purpose rollers are used by and between which the metal ingot is rotated and moved endwise while subjected to the required pressure. The machine has a strong bed, upon which are bearings for the mandrel or bar being worked; these bearings are adjustable in all directions. Three rollers are employed, which are supported in bearings in suitable standards secured upon the bed. These rollers are arranged at equal distances apart, in such a manner that the tube being operated upon extends centrally between them. The rollers, or one of them, must have the bearings adjustable radially in the standard, so that they can be made to approach or recede from the centre of the space between them, and thereby caused to exert greater or less pressure upon the metal.

ANNOUNCEMENTS.

BOURNEMOUTH SOCIETY OF NATURAL SCIENCE.—This Society invite contributions on the following: (1) The fertilisation of the Coniferæ; (2) The fertilisation of the Ericaceæ; (3) The common forms of fresh-water Algæ found in the district; (4) The common forms of microscopic life; (5) The constancy or variation in form of pollen grains in a natural order, *i.e.*, how far is the shape of a pollen grain characteristic of an order; (6) The micro-fungi attacking plants; (7) Micro-section cutting; (8) Household waste in the things we throw away; (9) A process for softening water, the best adapted for domestic use; (10) Mimicry in nature; (11) The relation of insects to flowers; (12) Common forms of marine zoology found in this district; (13) Variation in insects; (14) Larvæ breeding, noting the effect of different kinds of food and degrees of light upon colour of the perfect insects, manner and times of feeding, sleeping, moulting, and putating, etc.; (15) Gall collecting, and Cynips breedings; (16) Indoor and window entomology, including two-winged flies, beetles, moths, parasites, bees, etc.; (17) Notes on the botanical geography of the district, on the rate of coast denudation, and the effect of the S.W. winds on the currents and tides.

DIARY FOR NEXT WEEK.

Monday, *Dec.* 3.—Royal Institution, Albemarle Street, at 5 p.m.—*General Monthly Meeting.*
Society of Chemical Industry, Chemical Society's Rooms, Burlington House, at 8 p.m.—*The Analytical Examination of Water for Technical Purposes*, by Mr. A. H. Allen.
Victoria Institute, 7, Adelphi Terrace, Strand, W.C., at 8 p.m.
Society of Arts, John Street, Adelphi, at 8 p.m.—*Light and Colour*, by Captain W. de W. Abney, C.B., F.R.S.
Society of Engineers, Westminster Town Hall, at 7.30 p.m.—*High Pressure Steam and Steam Engine Efficiency*, by Mr. W. Worby Beaumont, M.Inst.C.E.

Tuesday, *Dec.* 4.—Society of Biblical Archæology, 9, Conduit Street, Hanover Square, W., at 9 p.m.
Zoological Society of London, 3, Hanover Square.—*On the Mammals obtained by Mr. C. M. Woodford during his second expedition to the Solomon Islands*, by Mr. Oldfield Thomas, F.Z.S.—*On certain Points in the Structure of Clitellio (Claparede)*, by Mr. Frank E. Beddard, F.Z.S.—*On the Distribution and Morphology of the Supernumerary Phalanges in the Anura*, by Prof. G. B. Howes and Mr. A. M. Davies.—*On the Natural History of Christmas Island, Indian Ocean*, by Mr. J. J. Lister, F.Z.S.
Institution of Civil Engineers, George Street, Westminster, at 8 p.m.—*The Influence of Chemical Composition on the Strength of Bessemer-Steel Tires*, by J. Oliver Ar F.C.S.

Wednesday, *Dec.* 5.—Entomological Society, 11, Chandos St Cavendish Square, W., at 7 p. *Monograph of the Genera Conne Tinægeria, Wlk., with Eretruscera, Z* Lord Walsingham, F.R.S.—*Incidente servations in Pedigree Moth Breedi* Mr. Frederic Merrifield.—*Descriptio variety of Ornithoplera Brookiana*, b Rev. Dr. F. A. Walker, F.L.S.—*M graph of British Braconidæ, Part* by the Rev. T. A. Marshall, M.A.-*New Species of Lepidoptera from Kruk* by J. H. Leech, B.A., F.L.S.
Civil and Mechanical Engineers' So Westminster Palace Hotel, at 7 p. *Presidential Address.*
Society of Arts, John St., Adelphi, at 8 —*The Graphophone*, by Mr. H. Edm

Thursday, *Dec.* 6.—Chemical Society, Burlington Hou 8 p.m.

Saturday, *Dec.* 8.—Physical Society, Normal School of Sc South Kensington, at 3 p.m.—*On Facts connected with Systems of Sci Units of Measurement*, by Mr. T Blakesley.

CONTENTS.

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

Dr. A. S. Hudson (see page 509 of this magazine) cites the case of a herd of five cows to which salt was given every Sunday, the cows always appearing at the gate on that day for the customary dole, and infers therefrom that they counted the days between, as they were far from a house, and there were no differences shown between the doings of Sunday and working days.

Another and more probable explanation may, I think, be found in the ordinary physiological law of periodical recurrence of appetite. Artisans who dine punctually at 1 p.m. have an internal timekeeper that indicates the approach of that hour. Bricklayers, etc., whose dinner-hour is at mid-day are similarly warned one hour earlier, and those who dine in the evening have stomachs that are correspondingly educated. Ladies who indulge freely in five o'clock tea complain of a craving for that popular stimulant when the hour arrives.

A farmer friend, who is very successful in stock-rearing, tells me that one of the secrets of his success is punctuality in feeding those that are stalled for market. Immediately the feeding-time arrives the animals begin to "fidget," and if the feeding is delayed only a quarter of an hour they lose weight by the "dissipation of energy" due to such fretfulness.

The desire for salt is very strong among cattle that feed in hilly countries, and its supply is necessary for the maintenance of their health. In Norway this desire is utilised as the means of collecting the goats and cows for milking, especially at the "sæters," or upper pastures, where the requirement is strongest. The girl in charge of the sæter goes to the milking-place, dips her fingers in her pocket filled with salt, and the animals already assembled there, crowd around her to take their "licks." I have seen quite a pyramid of struggling goats concealing the girl altogether by climbing on each others' backs. Punctuality is observed in this both by the cattle and the milkmaid.

On pages 342 and 343 is an article on "Domesticity of Animals," in which three classes are enumerated, the third being that in which the animal is not merely the chattel, but the companion and friend of its owner; as the dog, cat, mungus, the parrot, and a few song-birds.

The writer proceeds to say that "it is a curious fact that no ruminant animal can be admitted into this class; pet lambs, kids, fawns, etc., always grow vicious as they reach maturity, and have to be consigned to the butcher."

This is usually true, but not unexceptionally so. A remarkable exception occurred some years ago in the case of a lamb that for some reason was spared by a butcher in Jermyn Street. My acquaintance with the animal commenced when it was full grown. It was then in the habit of following the butcher's man through the streets like a dog, like a well-trained dog, as it kept close to the man's heels. It was well known throughout the neighbourhood. I am sorry to add that its habits otherwise were not exemplary. I have seen it devour very eagerly a raw mutton chop, and suspect that this perverted appetite was the fundamental source of its devotion to the man in blue clothing. If a piece of beef or mutton and a handful of grass were placed side by side this docile creature ate the flesh first.

The case is instructive, and available for vegetarians as a reply to the argument for flesh-feeding, based on the supposed "natural" appetite of civilised man for flesh, as it shows how greatly the natural vegetarian appetite may be perverted. On the other hand, it seriously damages the vegetarian's assertion that flesh-feeding provokes ferocity, and that pure vegetable diet promotes the virtues of gentleness and amiability; for this cannibal was peculiarly gentle and docile, and did not, like those described by the author of the quoted article, grow vicious as it reached maturity.

My own theory of the difference pointed out by that writer is simple. Ruminant animals do not, in the ordinary course, enter into the third class of domestic animals, simply because they help themselves to their food. Those that become "the companion and friend" of man do so simply because they are fed by man with food more or less prepared by man, and in most cases directly supplied from his hand.

I have thus tamed many unlikely animals—frogs, toads, and more particularly those pretty and much-libelled legless lizards, the "slow worms." These reptiles have so far advanced in docility as to lose their ordinary timidity and come towards me for their food, in some cases to take it from my hand. Fishes may be similarly tamed.

I recently had a curious pet named "Waddle." He was the only outcome of a sitting of duck's eggs placed under a hen, and was consequently reared "by hand" in the house. Before arriving at mature drakehood he was turned out among the fowls, but treated them all with supreme contempt, while showing a dog-like love of human society. I was his especial favourite. My summer reading-seat was under a large elm, where Waddle always sat at my feet. If I walked round the garden he followed me; if I ran he stretched his wings half flying to keep up with me. He was a show bird whose performances were exhibited to all our visitors. My superior place in his affections was explained by the fact that I cultivated my own garden, and in the course of digging turned up many fat worms, that were always handed to Waddle.

When he was about two years old I purchased for him a couple of wives, pure specimens, like himself, of the white Aylesbury breed. They were brought to him in a basket, and were the first of his own species he had ever seen. Here was an experiment to test the theory of instinct resulting from inherited memory. According to this he should have fallen in love with them at first sight. He was in a pen bounded by frames of wire netting when the two ducks were introduced. His terror was so ludicrous that the witnesses of the experiment were convulsed with laughter. At first he rushed into the sleeping-place, and when the ducks followed him came out and flew over the hurdles as though the invaders were duck-eating vultures or other birds of prey that "inherited memory" had rendered terrible by instinct.

My lizard pets—the misnamed "slow worms" or "blind worms"—were very interesting. I had several, and they varied considerably. One of them was remarkably docile, its ordinary habits quite changed, habits that appear to be little understood even by good naturalists.

They are burrowing animals, residing in tunnels made in soft soil. They feed on slugs and earthworms, slugs preferred, are neither slow nor blind, but, on the contrary, are remarkably keen sighted and vivacious. Mine were kept in a disused aquarium half filled with soil. At first they vanished at the approach of footsteps, but I trained them by placing slugs at the mouths of their tunnels. Presently they lurked in these with head protruded, which was withdrawn on my approach. Gradually they ceased to fear me, and to regard me as a purveyor of slugs. My best pupil came out and licked my finger, which had been anointed with slug-slime in order to secure his affections. Ultimately it submitted to handling, and would coil round my finger and lick it with as near an approach to affection as such an animal could manifest.

All were short-lived—one till two years—and all died in the same manner. They were found lying on the surface with lack-lustre eyes and languid movement. My theory of their popular names is that the foolish rustics who persecute them as poisonous reptiles only see them when in this moribund condition, and imagine such to be their ordinary state—a very shallow conclusion, seeing that if it were so their extermination would have been consummated long ago. They only survive the stupid persecution to which they are subjected by virtue of their nimbleness. I strongly recommend their cultivation in gardens and greenhouses for keeping down the numbers of mischievous slugs.

THE VIADUCT OF GARABIT.

We give an account of the great viaduct of Garabit, with illustrations for which we are indebted to the courtesy of our contemporary *La Nature*. We shall describe how the great central arch has been put in its place, and what system was adopted for raising this enormous mass.

The central arch of the viaduct constructed by M. Eiffel is of 165 metres span, and rests on two great piers with six stages, the metal portion being more than 60

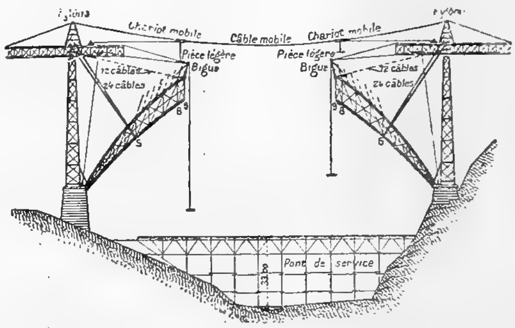

Fig. 1.—Method of Erecting the Arch.

metres in height; the total weight of the arch and its piling is about 1,165 tons.

The piers were first built, and then the ribs of the arch were put together on raised embankments. The next step was to hoist these ribs so that one end should rest on each pier, and the other end be in the position required for the arch. Each of these ribs thus placed was secured firmly by means of 28 cables of steel wire, moored to the abutments of the viaduct.

This being done, two scaffolds were erected which formed centerings which followed exactly the curve of

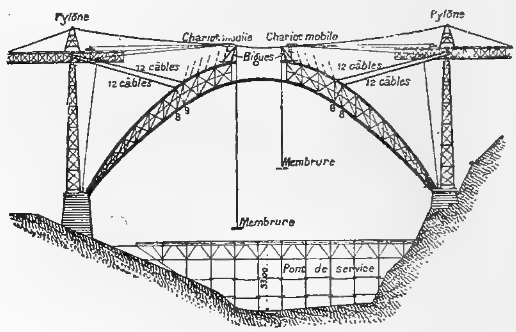

Fig. 2.—Last Phase in the Erection of the Arch.

the under-side, or intrados, of the arch. Upon these centerings were placed the various metal parts required for the cross girders and framing, and they were put together while the ribs were vertical, and afterwards lowered to the angle required by means of twenty steel cables. Afterwards the building of the arch with the ribs inclined was proceeded with according to the system previously adopted by M. Eiffel for the Douro Bridge. Step by step the new parts were attached to those already fixed, care being taken to rig up a new set of cables when the weight became considerable.

By means of the cables it was possible to raise or lower the parts of the arch which were being erected at any stage of the proceeding. The cables were controlled by hydraulic presses, and collectively formed an apparatus capable of moving masses of over 400 tons by a series of successive efforts never exceeding 15 tons.

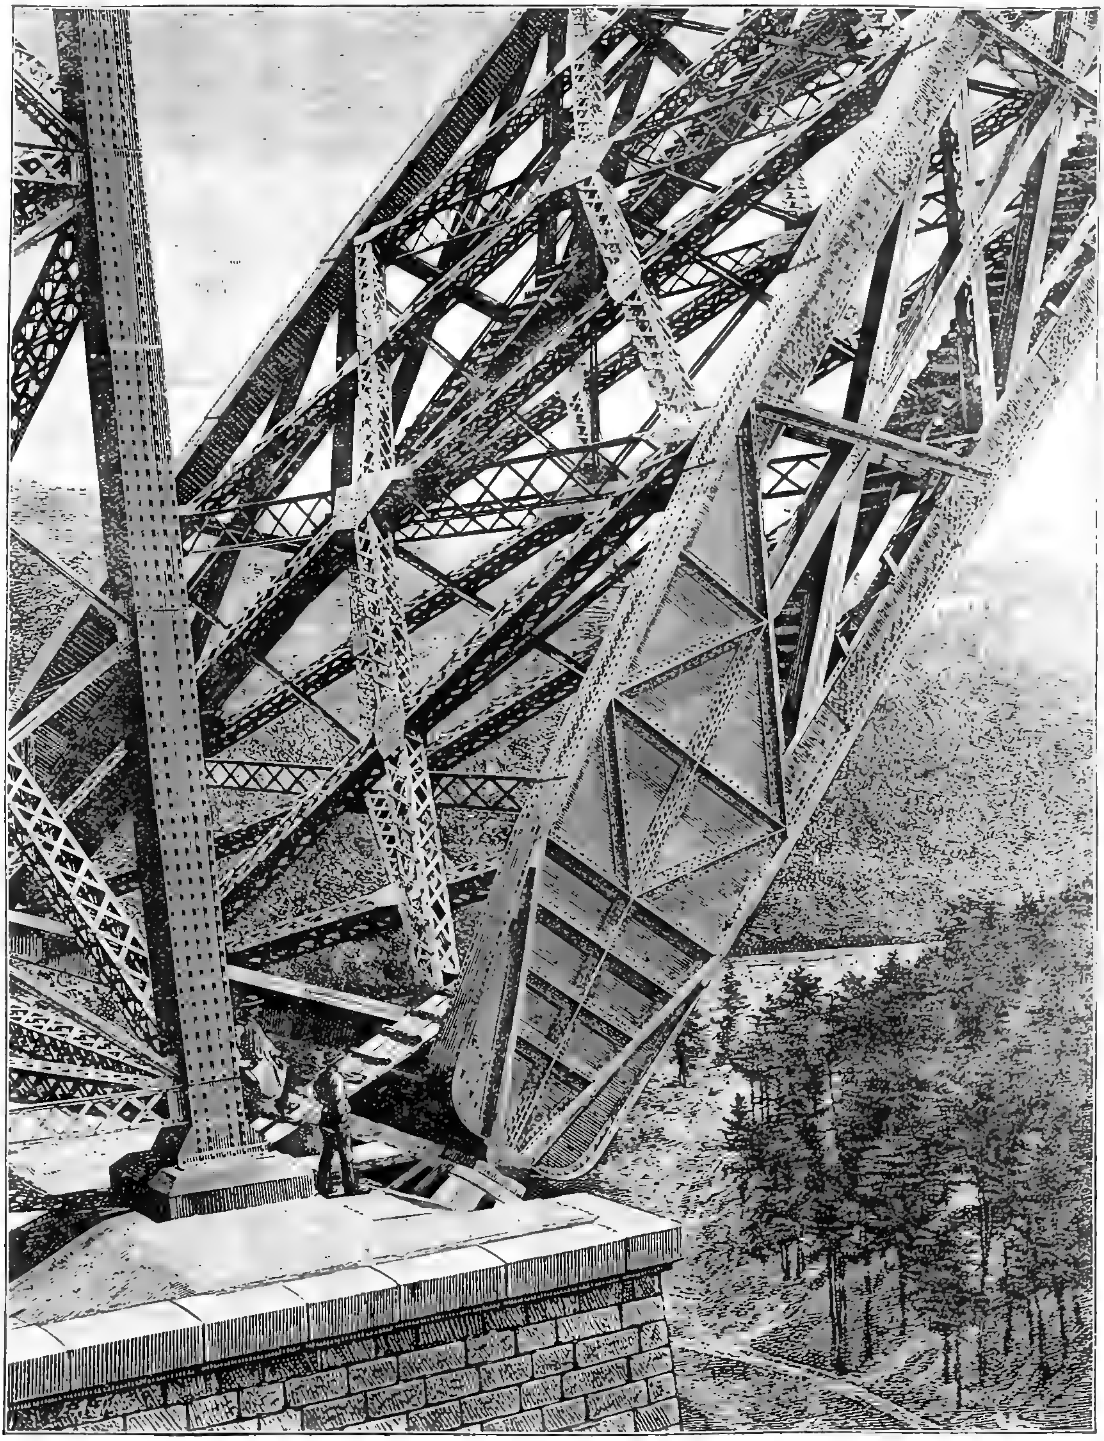

Fig. 3.—Spring of the Arch.

The completion of the intrados, or underside, of the arch was effected on April 20th, 1884, and all the cables were immediately slackened in case a fall of temperature should produce excessive strains either in the cables or in the arch itself. On April 25th a little lattice-work and a few other parts not yet in position at the crown of the arch were fixed, and the next day all was ready for introducing the key of the extrados, or upper side, of the arch. The hoisting of this key-piece was begun at 3 p.m., and at 7 p.m. it was in its place. With a few blows from a hammer it gradually assumed its right place, and the numerous holes for the two joints were perfectly true. The operation thus succeeded with a precision which might almost be regarded as mathematical, considering the magnitude of the work and the conditions under which the erection had to be performed.

We have only to mention the trials which took place in April last, before the viaduct was opened for traffic. These trials were of two kinds: in the one the loads remained stationary, and in the other they were rolling. The trial loads consisted of a locomotive of 75 tons, drawing trucks of 15 tons each, and the results obtained show the exceeding firmness of the work. The arch, loaded over its entire length with a train of 22 trucks, weighing 405 tons, showed a deflection of only 8 millimetres. The same train, placed upon one of the half-lengths of the arch, caused a deflection of only 4 millimetres at the crown, and finally, under the action of the rolling load the deflection was only 12 millimetres.

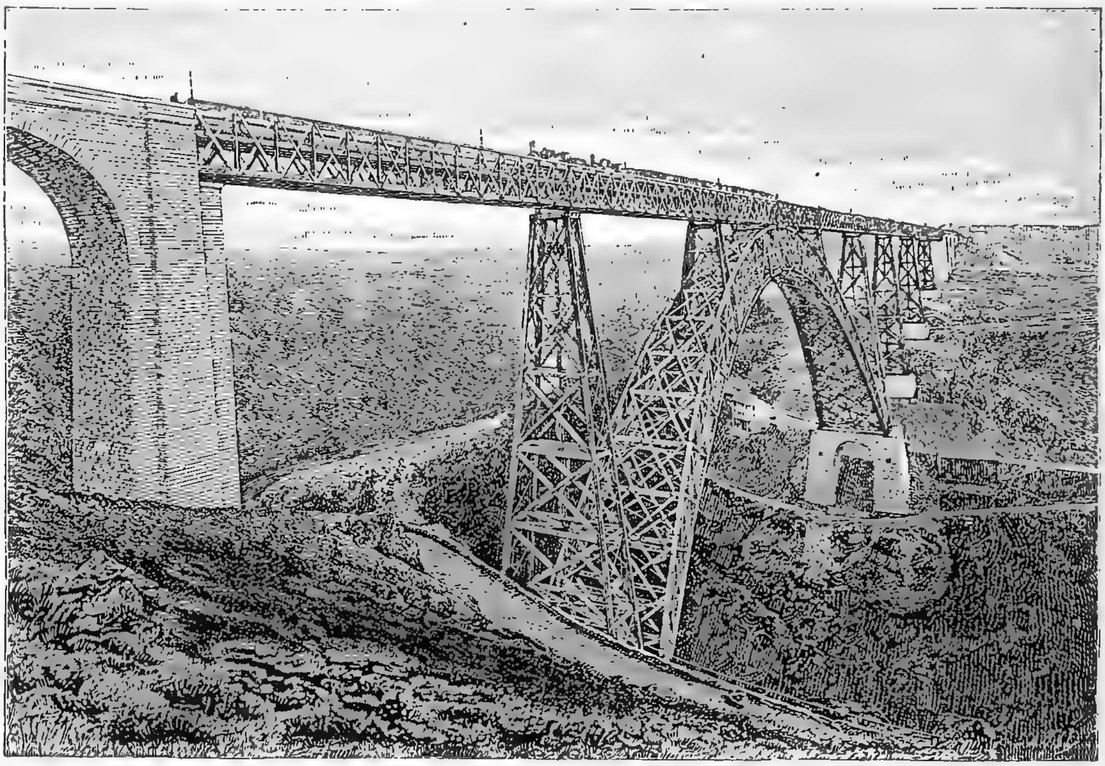

FIG. 4.—GENERAL VIEW OF THE VIADUCT OF GARABIT.

SOME RECENTLY DISCOVERED FORMS OF MICROSCOPIC CRUSTACEA.

ALTHOUGH it may with perfect truth be said that there is nothing new under the sun, it is no less true that there are many things which have hitherto escaped the ken of our senses both in the organic and inorganic worlds.

Even were it not so, and everything above and below the earth were known and tabulated, the zoologist, botanist, and geologist would still find endless occupation in studying the life history, histology, and composition of this multitudinous variety of life and matter spread out before us.

One has only to take up the study of any special branch, and he will first be astounded at his own ignorance, and then, as he perseveres and obtains some grasp of the labours of previous workers in his line of research, he will before long come to see that the air, earth, and sea have not yet yielded up all their storehouse of treasures, and that there is still room for original investigation in every branch of natural history.

In our own time a remarkable stimulus has been given to the study of biology, especially through the life and works of that greatest of naturalists, Charles Darwin; and with such a brilliant example before us of quiet, patient investigation, extending over so many fields of nature, we may well be encouraged to persevere in the study of any one special subject. The choice will depend upon the particular taste or environment of the individual.

To those of us who reside near the sea board, great opportunities are ready at hand—stones and rocks at low water being sure to furnish material from all the divisions of invertebrate life; and the possession of a boat and dredge will ensure the capture of forms unaffected by tides.

It is proposed in this paper briefly to describe and illustrate several species of minute marine crustacea which Mr. Isaac C. Thompson, F.L.S., has recently discovered, taken principally by means of the tow-net in the waters about our west coast.

They all belong to the *Copepoda*, an order of the *Entomostraca*, of the great class *Crustacea*, the *Copepoda* being probably the oldest and most degenerate members of the class.

They are not at all confined to salt water, many species being common in our ponds and lakes, of which the cyclops is perhaps the most familiar example. Indeed, it would be difficult to find a pool that does not contain it, and it is not an uncommon inmate of caraffes in country, and perhaps even in town, hotels. A copepoda is a somewhat pear-shaped animal, composed of from sixteen to twenty somites or segments, having two pairs of antennæ, known as anterior and posterior, three pairs of prehensile and masticatory or suctional mouth-organs, and five pairs of swimming feet. The carapace, or shell-covering, falls loosely over the limbs, the terminal portion of the animal being the abdomen, which is composed of from three to five segments. Attached to the latter

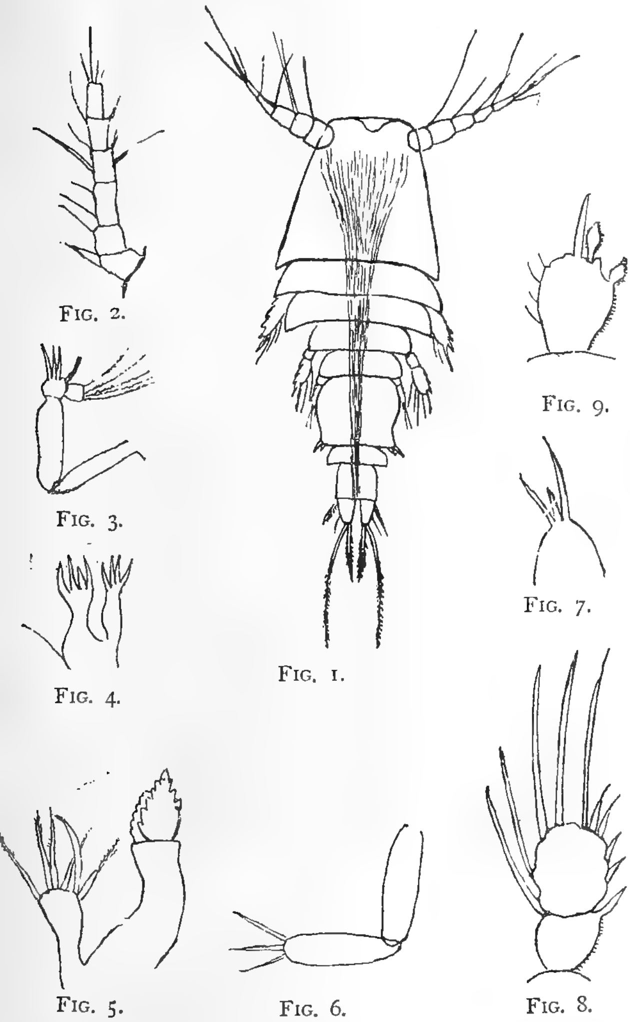

PLATE I.

CYCLOPS PUFFINI, I.C.T. (FIGS. 1-9).

Fig. 1. *Cyclops Puffini*, I.C.T., female, × 150 diams.

the female often carries external sacs containing ova; the larvæ are immature when hatched, and go through several metamorphoses before arriving at the adult form.

The eyes in most species are situated in the frontal portion of the body, and generally appear as though one only; they are connected with the brain by nerves, and are imbedded in a mass of pigment.

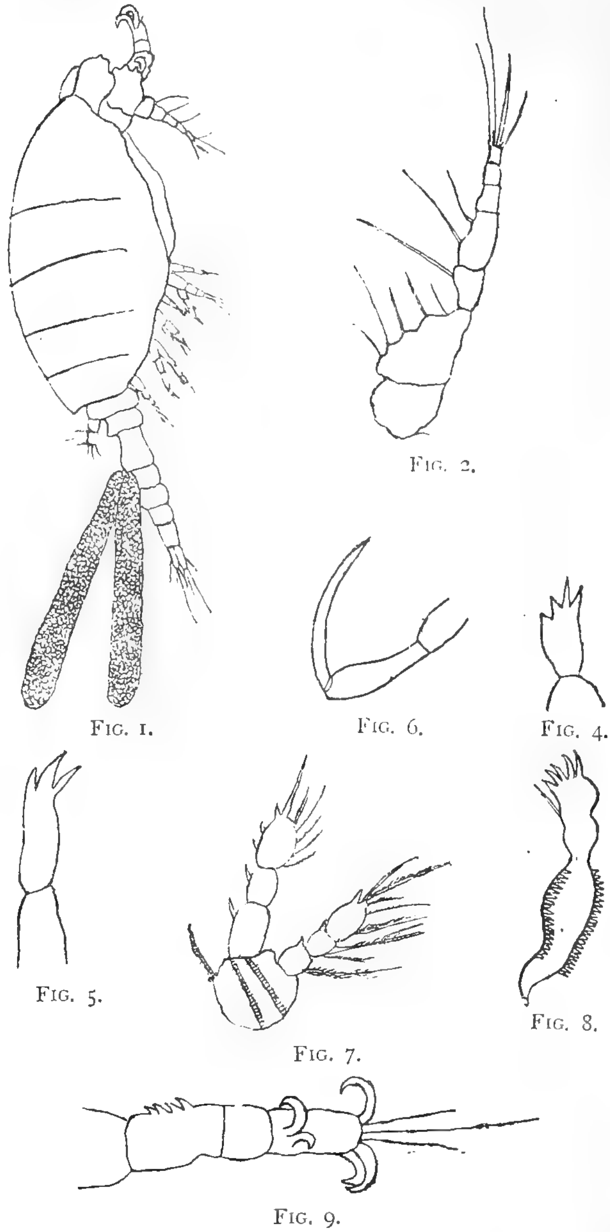

PLATE II.

LICHOMOLGUS SABELLÆ, I.C.T. (FIGS. 1-8.)

Fig. 1. *Lichomolgus Sabellæ*, I.C.T., female, × 150 diams.
Fig. 2. Anterior antenna of do. 250 „
Fig. 3. Posterior antenna of do. 250 „
Fig. 4. Anterior footjaw of do. 400 „
Fig. 5. Posterior footjaw of do. 400 „
Fig. 6. Posterior footjaw of male 400 „
Fig. 7. One of fourth pair of swimming feet 400 „
Fig. 8. One of fifth pair of do. 400 „

The anterior antennæ are used vigorously by the animal in propelling itself through the water; it is probable that they also contain organs of smell, as is known to be the case with ants and other insects. Copepoda abound everywhere in the ocean. In size they range from $\frac{1}{30}$ in. to nearly half an inch in length in one northern species, which is said to be the chief food of the Arctic whale, and gives a distinct red colour to the waters where it abounds.

They are very easily captured by means of a tow-net, a long, very fine muslin bag, with a round metal hoop about a foot in diameter, and narrowing in a length of about five feet to nearly a point. Attached to a long cord, the tow-net is pulled along from a boat, skimming the surface and occasionally being allowed to fall a few feet or more below. In about ten or fifteen minutes it is taken out, and the inside end floated into a wide-mouthed jar of clear water, which, on being held up to the light, will probably be found to contain minute creatures of brilliant colours darting vigorously about in all directions.

These are mainly copepoda, and it is a little remarkable that so comparatively small attention should have been given by naturalists to a class which forms by far the largest proportion of the life of our seas and oceans, and which are of the greatest service to mankind, for they are truly the scavengers of our lakes and seas, devouring refuse matter that would otherwise lead to pollution, and by turning the seeds of decay and death into vigorous life, again forming rich food for fishes and higher crustaceans, which, in their turn, furnish an illimitable quantity of food for man.

There are few more interesting or beautiful objects as seen under the microscope, and their variety gives scope for endless examination and careful study. They are very easily preserved in glycerine, or in a mixture of glycerine, alcohol, and water, and if put into such a solution soon after capture will retain their colours for a very long period, if not indefinitely. As microscopic slides they may without any further preparation be permanently mounted in glycerine jelly, and viewed with objectives varying from the one inch to the one-eighth inch power.

Cyclops Puffini, I.C.T. (Plate I.)—This elegant little species was first found near Puffin Island, at the mouth of the Menai Straits, being taken by a tow-net from the steamer *Gamecock* during the excursion of the British Association from Manchester last year. It is specially interesting to science as being the first species of the genus Cyclops ever found in salt water, thus forming a connecting-link between marine and fresh-water species. It is one-twentieth of an inch long. The anterior antennæ (fig. 2) are short, being six-jointed, and clothed with long whip-like setæ or hairs. The posterior antennæ (fig. 3) are terminated by several spines and plumose setæ. The mandible, or masticatory jaw (fig. 4), is divided at the apex into long sharp slender spinose teeth. The maxilla (fig. 5) is furnished with several plumose spines, the termination of the palp having a deeply serrated edge. Two of the swimming feet are represented in figs. 8 and 9. The abdomen (fig. 1) is three-jointed in both sexes, being terminated by caudal segments, with long plumose hairs at ends.

This Copepod was named after the Island, Puffin, around which it has been taken on several occasions during the late summer. A biological station has been recently opened upon this charming island, under the directorship of Professor Herdman, of Liverpool University College, and is being largely availed of by students and naturalists. Its situation for biological purposes is all that can be desired. It contains sleeping accommodation for six, and is fitted up with microscopes and all the other paraphernalia for biological investigation. The resident curator furnishes weekly returns of the work done, also particulars as to weather and other meteorological observations.

Lichomolgus Sabellæ, I.C.T. (plate ii.)—This striking Copepod was first taken at Beaumaris, North Wales, about a year ago, being found adherent to the tentacles of the sandworm Sabella, hence its name. It is somewhat strange that this species should not have been previously recorded, as numbers of specimens of the worm examined were all found to be similarly infected. It is of a greyish-brown colour. Both sexes were found on a single worm, the male being one-tenth of an inch long and the female one-fifteenth of an inch, the latter the most plentiful, and at once distinguished by its long, narrow ovisacs. The body is ovate, and the first segment nearly half the length of the cephalothorax. The rostrum is short and beak-like. The anterior antennæ (fig. 2) are alike in both sexes, composed of seven joints, the two basal joints large and strong and about equal in length to the other five; their edges are roundly serrated and curled over, with several setæ. The third joint has three long setæ on inner margin, and the terminal joint has several long setæ at apex. The posterior antenna (fig. 3) are also alike in both sexes, and have four joints; the second joint has four teeth placed longitudinally; the terminal joint has several hooked claws both at side and at apex, the latter having also several long setæ. The mandible is strongly toothed, the terminal portion having three spines. The maxilla has a long process terminated by a blunt spine, and bearing on each side a row of sharp teeth similar to those of the mandible; the other extremity has five digital spines.

The anterior footjaw (fig. 4) is two-jointed, the second joint terminated by four short spines. The posterior footjaw is also two-jointed; that of the male (fig. 6) being terminated by a long falciform claw, similar to that of *L. fucicolus*, Brady, and that of the female (fig. 5) is elongated and terminated by three claw-like spines. The swimming feet of the first four pairs are two-branched (fig. 7), each branch being three-jointed, and bearing several spines and plumose setæ. The fifth feet (fig. 8) in both sexes are composed of one short straight joint terminated by two spines. The abdomen is five-jointed in each sex; the first joint nearly equal in length to the remaining four, and much broader, especially in the male. The caudal segments are parallel, and about three times as long as broad, and are each terminated by four setæ, in addition to a small seta about the middle of the outer edge. The species can be easily recognised by its remarkable antennæ. Even after being preserved in alcohol, the crustaceans were tenaciously attached by their strong, broad-set antennæ to the tentacles of the sabella, some force being required to remove them without injury. It has within the last month been found on the same worm at Puffin Island.

(To be continued.)

Manchester Scientific Students' Association.—At a meeting held on November 20th Mr. Henry Hyde read a paper on "Comparative Respiration in Animals," illustrated with diagrams.

Edinburgh Geological Society.—At the anniversary meeting, held on November 22nd, Mr. Ralph Richardson, vice-president, delivered an address dealing with Darwin's geological work.

General Notes.

New Locality for "Boghead."—According to M. Martin, a genuine specimen of the Boghead mineral has been found in Eastern Siberia, in the Stanovoi mountains. The quantity of the find is not mentioned.

Leprosy in Russia.—According to the *Medical Press*, leprosy is becoming more prevalent in Russia, as several *foci* of infection have appeared in distinct parts of the empire.

Diamonds in Borneo.—It seems, according to *Cosmos*, that diamonds of the first water are being mined in Borneo. The locality is not stated, but it seems to be in that portion of the island under Dutch sovereignty.

The Polar Flattening of Neptune.—M. Tisserand, in a memoir presented to the Academy of Sciences, shows that the polar flattening of Nepture may be deduced from the movements of his satellite. The disc of the planet subtending only three seconds, a direct observation has not hitherto been possible.

A Probable Expression of Chemical Affinity as Mechanical Attraction.—Professor J. W. Langley of the Michigan University, suggests that chemical affinity may produce a direct attraction acting in right lines for greater distances than the radius of a molecule, and having a selective character.

The Height of Waves.—*Cosmos* mentions that waves off Cape Horn have been estimated at from fifteen to twenty yards in height, reckoning from the level of the sea. The height from the bottom of the trough to the crest of such a wave would, therefore, be from thirty to forty yards. These estimates, of course, lack precision.

Royal Institution.—The next course of Christmas Lectures adapted to a juvenile auditory will be given by Professor Dewar, F.R.S., the subject being "Clouds and Cloudland." They will begin on December 27. During the recess the staircases leading from the gallery of the theatre have been considerably altered in order to facilitate more speedy egress.

Geology of London.—Professor H. G. Seeley, F.R.S., is about to deliver a course of lectures on the practical study of the geology of the country round London. This course is given at the request of students of the London Geological Field Class, and information concerning them may be obtained from Mr. William Dunn, 21, King William Street, Strand, W.C.

Purification of Minerals by Electricity.—Quartz, china clays, and other minerals are often found unfit for use in pottery, glass-making, and other chemical arts, on account of the presence of oxide of iron. When such minerals exist in or are reduced to the state of powder, the iron can be removed by bringing them in contact with a series of powerful electro-magnets.

Magnetic Perturbations.—M. André (*Ciel et Terre*) remarks that from France to Tierra del Fuego magnetic perturbations are a general phenomenon, absolutely simultaneous over the whole earth, and taking place in all parts at the same moment. He attaches these perturbations to a cause not residing in the interior of the earth, but external, and to be sought for in the sun.

Detection of Strychnine.—Mr. Lovett communicates to the *Journal of Physiology* some observations on the "topography" of the action of strychnine. By experiments on that "martyr of science," the frog, he has found the greater part of the poison taken is to be found in the spinal cord, which contains more than the brain, liver, and muscles put together. Hence in chemico-legal investigations the spinal cord should be analysed in all cases where strychnine is suspected.

Human Diet in Prehistoric Ages.—M. Piette (*Comptes Rendus*) concludes, from his prolonged researches in the bone-caverns of the Pyrenees, that the so-called "Magdalean" age, which forms part of the Mesolithic epoch, was much more prolonged than it has been generally supposed. At its outset a great number of horses were eaten as food, but towards the end this custom seems to have disappeared, and to have been succeeded by the consumption of reindeer and other *Cervidæ*.

The Pasteur Institute.—The subscriptions for founding and endowing this institution reached the sum of 2,586,000 francs. There exist in the world twenty such establishments—seven in Russia, five in Italy, one in Austria, one in Spain, one at Bucharest, one at Rio de Janeiro, one at Havana, one at Buenos Ayres. Two more are in course of organisation—one at Chicago, and one in Malta. Such is the trouble man has to take to defend himself against "his most faithful friend the dog."

The Crops in Belgium.—According to *Ciel et Terre*, the crops for the last season have been almost universally deficient in Brabant. The yield of wheat and rye has been bad; barley is less universally defective, but the yield is below an average both in grain and straw. Oats have not been much injured, as it has also happened with peas, beans, and buckwheat. Colza and flax are bad. The yield of hay has been deficient, and it has been gathered in bad weather. Potatoes are attacked by disease, and the sugar-beet has produced more leaves than roots.

What is a Billion?—When this term was first devised by the Italian arithmeticians of the fourteenth century it was intended to mean the square of a million, or a million millions. In this sense the term is still used in Italy, Germany, and Britain. But in France men of business and schoolmasters have taken to give the name "billion" to a thousand millions, though astronomers and mathematicians retain the original notation. The United States have followed suit, either, as *Science* puts it, in order to be like the French or to be unlike the English, and we have thus a pretty piece of confusion.

Decomposition of Carbonic Acid Leaves under the Influence of Light.—Th. W. Engelmann (*Archives Néerlandaises*) has made a quantitative examination of the absorbent power of leaves of different colours, whereby it appears that chlorophyll consists of at least three different colouring matters. Yellow leaves of *Sambucus niger* decompose carbonic acid, though less energetically than green leaves. Another group of coloured leaves contains not chromophyll but cellular juice of a red colour. An influence of this colouration upon vitality could not be traced. The chlorophyll of such leaves is of the ordinary kind. The rays absorbable by chlorophyll pass nearly unaffected through the red cellular sap.

The Earthquake in Liguria.—M. Issel has communicated to the Academy of Sciences a full account of the damage occasioned in Liguria by the earthquake of 1887. The area shaken on February 23rd differs little from that agitated on February 23rd, 1818, September 9th, 1828, and May 26th, 1831. The number of persons killed in the province of Porto Maurizio was 597, and in that of Genoa 38. The wounded in the former were 474, and in the latter 81. The damage done to houses, etc., in the districts of Porto Maurizio and San Remo is estimated at more than thirteen million francs, and in the province of Genoa 2,281,000 francs.

The Ancient Greek Alchemists.—Professor Berthelot has just laid before the Academy of Sciences the completion of the publication of these treatises, accompanied by translation. The fifth part of the work is the most interesting, containing not mystical reveries and imaginings, but positive processes and definite results. It comprises a series of memoirs on tempering and colouring metals, especially bronze and iron, the moulding of bronze, the gilding of iron, the colouration of imitation precious stones, the treatment of pearls, the manufacture of potash from wood-ashes, that of beer and soap. Most of these tracts seem to be drawn from a great Byzantine manual of industrial chemistry, compiled in the 8th or 9th century. But some of the portions date back to an earlier epoch.

A New Proof of the Earth's Rotundity.—It is now some years since M. Ch. Dufour pointed out, from theoretical considerations, that, since the surface of water in large bulk is really spherical, with a curvature corresponding to that of the earth, the image of the sun reflected from it must really have an elliptical form. In 1886, Signor Ricco commenced some still uncompleted observations on the solar reflection from the marine horizon, as seen from the Palermo observatory; he has found the obliquity of the sun's image very marked in clear and calm weather. M. C. Wolf has applied the same principle to the distortion of star images; this, with the results just announced by M. F. A. Torel for the eccentricity of the solar image after reflection from the Lake of Geneva, shows that it is no longer simply theory, but a new direct experimental proof, that the earth is round.

Electric Storms.—Professor Müller, of the Russian Lyceum of Tashkend, describes (*La Nature*) a storm which took place in and near that town on July 29th, and lasted for three hours. Amidst dense clouds, which quite obscured the daylight, the lightnings crossed each other without interruption, and the thunder roared, but there fell all the time not a drop of rain. The air, however, was sensibly cooled and purified. On the next day a friend of Professor Müller was walking along the flanks of the wooded mountains near Vladikavkas, at about six p.m., when he heard a dull sound which gradually increased. He stopped, and saw below him a group of fire-balls which were moving slowly in the direction of the valley. He distinguished clearly three such balls; that in the centre, apparently of two feet in diameter, was yellow with golden reflections. At its sides there were two others of a splendid purple colour. The phenomenon lasted for three minutes.

Interesting Discovery.—Lieutenant D. Bruun, of the Danish army, having had a moss dug out in Finderup, in Jutland, has made some interesting discoveries. In the moss were found trunks of oak, beech, and fir trees, from 6 to 30 inches in diameter. The branches had in some cases been cut off, but the bark remained. By the side of one of the oak trunks two earthen vessels were discovered, and near another a third shaped like an urn. In the latter lay a sandal cut from a piece of leather, with flaps, and leather straps for tying to the ankle, the length of the sandal being 7 inches. It seemed as if the trunks of trees had been placed in a certain position for some purpose or another. About 20 feet farther to the south, and at the same depth, viz., 6 feet, a yoke of oak was found, $5\frac{1}{8}$ feet long and 3 inches thick, being fairly cylindrically cut out in the centre. At each end were holes, in one of which remained a strap of leather. Other implements of oak were also found, evidently used for carrying. Some of them seemed part of a wheel. Close to the yoke another earthen urn was discovered, which, like the three referred to, was surrounded with sprigs of heather and bramble. Formerly some horns of bullocks and the skeleton of a man in a fur coating were found in the moss. The various objects are now in the Copenhagen Museum, and are said to date from the early iron age.

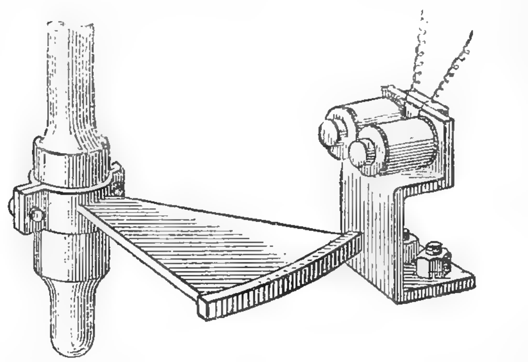
The Public Health.—The Registrar-General's return for the week ending November 24th shows that the deaths registered during that period in 28 great towns of England and Wales corresponded to an annual rate of 18·2 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The six healthiest places were Derby, Hull, Leicester, Birmingham, Wolverhampton, and Sheffield. In London 2,722 births and 1,409 deaths were registered. Allowance made for increase of population, the births exceeded by 12, while the deaths were 370 below, the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had been 19·7, 18·5, and 19.7 in the preceding three weeks, fell last week to 17·2. During the first eight weeks of the current quarter the death-rate averaged 18·9 per 1,000, and was 1·0 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,409 deaths included 133 from measles, 20 from scarlet fever, 41 from diphtheria, 19 from whooping-cough, one from typhus, 15 from enteric fever, 1 from an ill-defined form of continued fever, 18 from diarrhœa and dysentery, and not one from small-pox or cholera; thus, 248 deaths were referred to these diseases, being 27 above the corrected average weekly number. In Greater London 3,536 births and 1,756 deaths were registered, corresponding to annual rates of 33·3 and 10·6 per 1,000 of the estimated population. In the Outer Ring 29 deaths from measles, 6 from diphtheria, 4 from whooping-cough, 3 from "fever," and 3 from scarlet fever were registered. Fifteen fatal cases of measles occurred in West Ham, 4 in Tottenham, and 2 in Sunbury sub-districts; 2 deaths from diphtheria were recorded in Godstone, and 2 from whooping-cough in Tottenham sub-districts.

RECENT ASTRONOMICAL WORK AT THE LICK OBSERVATORY.

THE Lick Observatory was transferred to the Regents of the University of California on June 1st, 1888, and has, therefore, been in active operation as a State institution for about four months, and much of this time has been devoted by the astronomers to studying the instruments under their charge, and determining the constants necessary for future work, the great telescope naturally claiming the largest share of attention; but many observations of important phenomena have been made, and the objects of greatest interest in the sky have been carefully examined with a view to the discovery of new features, as well as for the purpose of testing the performance of the lens. The sun has not yet been observed with the great telescope, but it is doubtful whether any advantage can be gained here in the study of his surface by the use of a large instrument. The seeing on Mt. Hamilton is usually poor in the daytime, owing probably to the heated air of the surrounding valleys, which is rapidly cooled at night by radiation or shut in by the fogs which then pour in from the ocean.

Mercury and Venus have been seen in the daytime only, and, therefore, under the same disadvantageous circumstances. There are, however, days of good seeing, when the features of these planets can be profitably studied. The moon is a most beautiful and interesting object with the great telescope. It was photographed throughout an entire lunation in August, and the pictures then obtained are a distinct advance on all previous work in this direction. The diameter of the lunar image on the negatives is five and a quarter inches, and with the plates used the exposure required was a little less than half a second. Observations were made with the various instruments during the total lunar eclipse of July 22nd, and will be published in the memoirs of the National Academy of Sciences. Mars had become too low in the west after the transfer of the Observatory to be well seen. Numerous drawings were, nevertheless, made by Professor Holden, Mr. Schaeberle, and Mr. Keller, and published in the *Astronomical Journal*. The principal canals of Schiaparelli were seen, not as double, but as single, ill-defined lines; and the continent of Libya, which, according to M. Perrotin, had been submerged or did not exist during April and May, appears on the drawings in its usual shape and position. The micrometer observations of the satellites made by myself when the planet was in opposition have been published in the *Astronomical Journal*. The satellites, which appear to have been seen with great difficulty elsewhere, were bright and easy objects with the 36-inch equatorial—a fact which affords gratifying testimony as to the instrument, and the excellence of the atmospheric conditions. Phobos was seen on July 18th, when its brightness was only 0·22 of that at mean opposition, and one-eighth of that at the time of discovery by Professor Hall. From the ease with which this satellite was seen in close proximity to the planet, it seems to me probable that we can observe eclipses during favourable oppositions, and determine the mean motions of the satellites with greater accuracy than is obtainable by micrometer observations.

Jupiter was frequently examined on fine nights in June and July. His surface showed a wealth of delicate detail which would have required a much longer time to record satisfactorily than it was possible to give. A number of observations were made of curious appearances presented by the shadows of satellites in transit. The satellites themselves appear as large and well-defined discs. Saturn has not been observed since the telescope was first mounted in January. It was then a splendid object, all the wonderful details of the system shining with a brilliancy and distinctness probably never before equalled. The outlines of the rings were sharp and clear, and a fine, dark line was seen close to the outer edge of the outer ring, with a dark shading extending inward toward the great black division. The gauze ring was very conspicuous. Neptune has been observed by Professor Holden and Mr. Schaeberle, and (with its satellite) has been photographed several times. Many double stars have been discovered and measured by Mr. Burnham with the 36-inch and 12-inch equatorials. Perhaps the most interesting of this class of objects discovered with the aid of the large telescope is the star ρῦ (Gamma) γ Cassiopeæ, which is found to have a minute companion distant 2·2″, in position angle 256°. It has been frequently observed lately with the 12-inch equatorial. Difficult stars, previously known, have also been measured by Mr. Burnham. The planetary nebulæ have been studied by Professor Holden and Mr. Schaeberle, who have observed in several of these objects curious helical forms, which do not appear in earlier



ELECTRIC CONTROL OF THE CLOCK OF THE GREAT TELESCOPE.

drawings with smaller instruments. The ring nebula in Lyra is a wonderful object in the great telescope. The central star, discovered by Von Hahn, is very conspicuous, and four other stars of exceeding minuteness appear within the limits of the inner ellipse, while a star, almost as bright as the one in the centre, is seen exactly at the proceeding extremity of the major axis of the ring. Many other small stars not so critically situated, and therefore less interesting, are seen in proximity to the nebula. These minute stars are beyond the range of all but the most powerful telescopes, although it may be noted that there is a class of observers with very small telescopes prepared to immediately "verify" all discoveries made by powerful instruments, even when, as has sometimes been the case, the supposed discoveries are afterward found to be purely fictitious. There is no way of disproving that a difficult object can be seen by such an observer with an apparently inadequate instrument, or of showing that excess of zeal is made to take the place of sufficient optical power. Mere size, it is true, unaccompanied by other qualities, counts for but little, and the greater part of astronomical work has been done by skilled observers with instruments of moderate dimensions. To many persons the cost and difficulty of construction of great telescopes seems out of proportion to the optical advantage gained, but the same thing is seen in other departments of astronomy, as well as outside of the science. A sextant, with which the places of the stars can be determined to within a fraction of a minute of arc, costs less than a hundred dollars, while thousands must be expended if fractions of seconds are to be taken into account, the error of position in either case being beyond detection with the unassisted eye. The 12-inch telescope has been used by Mr. Barnard for the observation of comets and nebulæ. It has been found by him to be capable of giving photographic images of exquisite sharpness, and in this capacity forms an important addition to the outfit of the Observatory. Twenty-five new nebulæ have been discovered by Mr. Barnard with this telescope, and a comet (comet *e*, 1888) was discovered by the same observer with the 4-inch comet seeker, on September 2nd. It is probable that the 12-inch telescope will be fitted with a new driving clock, in order to better fit it for photographic work. No change has been made in the dome and hydraulic elevating floor of the large telescope. The convenience, and indeed necessity, of the elevating floor is every day more apparent. The rapid motion of the eye end of the telescope (a foot in eight minutes for an equatorial star) would alone make the use of an observing ladder proportioned to the size of the instrument, extremely troublesome. The pier, when finally placed in exact position, will probably be filled with brick and sand. The driving clock of the large telescope was provided by the makers with an electric control for keeping its rate in exact coincidence with that of a standard astronomical clock. The vertical shaft of the governor rotates in one second, and has near the bottom a small projecting pin. A stud on the armature lever of an electro-magnet is struck by the pin as the governor shaft rotates, when a current is passing through the magnet, but when the current is broken once a second by a standard clock, the stud is withdrawn at the proper instant to allow the pin to pass. There is also an ingenious and beautifully constructed attachment for breaking the circuit in case the standard clock should, either by accident or design, omit one or more seconds in a minute. The driving clock is adjusted to run a little fast, and is continually checked by the control, the governor being allowed to rotate by turning on a friction collar. It was found, however, that the impact of the pin on the governor shaft against the stud of the armature caused a shock which was transmitted to the telescope, and produced a disturbance of the image fatal to photographic work. The control was therefore removed, and another which Mr. Keller devised for the purpose of giving a perfectly smooth motion, was substituted for it. The new control answers its purpose so well, and is of such extreme simplicity, that we shall give a description of it here, as it can be applied to any clockwork having a shaft which rotates in an integral part of a second. A soft iron sector, subtending an angle of 36°, and having a radius of six inches, is clamped to the vertical axis of the governor, and rotates in a horizontal plane. The sector passes very close to the poles of an electro-magnet (part of the old control) which is mounted on a slightly elastic standard of steel. At every second a strong current is sent through the coils of this magnet, by means of a standard clock, the circuit being closed, as in the case of the old control, by the relay points of the chronograph attached to the driving clock. The driving clock is set so as to run a little too fast, and when the governor is started the sector gradually gains upon the click of the chronograph until it reaches the magnet of the control, when the friction produced by the attraction of the latter prevents any further acceleration, and the governor will rotate in exactly one second by the standard clock, as long as the control is in operation.

The elasticity of the support on which the electro-magnet is mounted plays an important part in the proper working of the control. When the sector passes at the exact instant of the passage of the current, the magnet springs in toward the sector, and comes into actual contact with it, very greatly increasing the friction, while the passage of the sector at any other instant meets with no resistance, the magnet being slightly withdrawn by its support. The current used [illegible] ntrol is obtained from the battery of twen[illegible] employed during the daytime in transmitting time signals to San Jose. As the signals are not sent at night, the battery is then connected with the control by turning a switch. With this control no shock is communicated to the telescope; and the image of a star is steady. Since, however, changes of refraction and slight irregularities in the clockwork produced small displacements of the image in a telescope, it has always been necessary in photographing with long exposures to keep the telescope pointed by hand, correcting any displacement which may occur by the slow motions of the instrument. It was found impracticable to move the immense mass of the Lick telescope with the quickness and delicacy required in this operation, and after various experiments, Mr. Schaeberle suggested that the photographic plate should be mounted upon double slides, one moving in right ascension, and the other in declination, and should be kept upon a star by means of a diagonal microscope attached to the plate. A rough experimental model was constructed on this plan by the observatory machinist, and performed so satisfactorily that a plate holder of more accurate workmanship will be made on the same principle. The public receptions on Saturday evenings interfere greatly with these experiments, as all apparatus must then be removed to fit the telescope for visual observation. Probably few visitors are aware of the hindrance to astronomical work caused by their entertainment, although, as a duty to the public the sacrifice is always cheerfully made. Many fine nights are to be expected during the months of October and November, but after that, fog and rain will almost put an end to observation until the succeeding spring.

Wolverhampton Literary and Scientific Society.—On November 20th Mr. Harold B. Dixon, F.R.S., delivered a lecture on "The Nature of Explosions," before this society. Mr. Dixon demonstrated the different kinds of explosion produced by gases, gunpowder, and gun-cotton. He referred to the difference in the mechanical means by which the oxygen and the combustible body come together, and said that explosions, according to two distinguished French chemists, could be divided into three parts—the ordinary combustion, the intermediate period of vibration, and the period of detonation. Reference was made to the measurements of the explosions of gases, and the conclusions arrived at under this head, together with illustrations of the amount of pressure produced in instantaneous explosions.

Natural History.

GROUSE.

HARDLY any wild birds are so familiar as the grouse, and no others equal them in economic value. These are surely good reasons for a glance at their natural history, which will be found to lead to questions of some theoretic interest.

Four species of grouse occur in the British Islands. Two belong to the genus *Tetrao* of modern systematists, and two to *Lagopus*. The red grouse (*L. Scoticus*) inhabits Scotland, North England, Wales, and Ireland; the ptarmigan (*L. alpinus*) is found in Scotland only; the black cock (*T. tetrix*), whose female is the grey hen, occurs in parts of England, Wales, and Scotland; while

BLACK COCK (*Lagopus tetrix*).

the capercaillie (*T. urogallus*), formerly native to Scotland and Ireland, after becoming completely extinct in both countries, was reintroduced some fifty years ago from Sweden to Taymouth, where it continues to flourish and gain ground. Scotland, it will be observed, enjoys all four of these valuable birds, England possesses two, and Ireland one.

Three of the species found here have a considerable foreign range in northern or Alpine regions, but the red grouse, alone among birds, is peculiar to our islands. Quite recently its range has been artificially extended by Oscar Dickson, who has succeeded in establishing a colony at Gottenburg, in Sweden, but the ultimate result of this experiment is still to be waited for.

Our rude English nomenclature ignores all natural affinity, and even etymology. *Grouse*, in some old writings spelt *grice*, is perhaps "brown" (Fr. *gris*). *Ptarmigan* is believed to be the Gaelic *tarmachan*, and was formerly written *termagant*. The initial *p* is entirely superfluous, having been added, like the *n* in *newt*, the *s* of *scratch*, and the *d* of *thunder*, in the days when every man spelt as he thought emphasis required. A convenient English phraseology would be attained if we could use the descriptive epithets of red, snow, heath, and wood grouse, to denote the red grouse, the ptarmigan, the black cock, and the capercaillie respectively, but the innovation is perhaps too bold to be entertained.

The most obvious peculiarity of the grouse is the feathered feet, which distinguish them from their nearest allies the partridges, and if we consider native species only, this is a sufficient mark. Grouse are rough-footed, gallinaceous birds. Of internal peculiarities, the most curious is the enormous length of the cæca of the large intestine. If we examine the beginning of the large intestine of a pigeon, we find a pair of little sacs about a quarter-inch long; in the fowl they are about four inches long, and dilated at the ends; in the red grouse each is a yard long, and its inter- surface is greatly extended by eight longitudinal folds. These appendages are filled with a sort of chyme, extracted from the food by the aid of the digestive juices, and their relative size appears to bear some relation to the nutritive value of the food. Where a given bulk of the ordinary food of the species yields a small amount of nourishment, as is the case with the heather-buds upon which the grouse feeds, the cæca are, as we have seen, of enormous length.

Grouse of the genus *Lagopus* usually change their plumage towards winter. The mottled brown of summer gives place to grey, and this to snowy white. As spring comes on the birds resume the summer plumage, which is also their wedding dress. In the ptarmigan this change is effected by a triple moult, which is not only unusual in its frequency, but also unusually complete. In other birds the second moult, where it occurs at all, is partial, a small proportion of the feathers being affected, or some part only of each feather being discarded. In the ptarmigan, however, the change is extensive, and concerns nearly all the feathers except the quills of the wing and tail, which are changed only at long intervals. Few adaptations are more familiar or more striking than this seasonal change, which brings about in regular succession a protective resemblance to the brown heather, to the thinly strewn snow, and lastly to the dense snow of a northern mountain. The only *Lagopus* which undergoes no corresponding change is our own red grouse, a species which would be rendered fatally conspicuous by turning white in winter.

Those of us who remember the days when the "Origin of Species" appeared will recollect how much was said about that time of the one bird peculiar to the British Isles. Owen, in the British Association Address for 1858 (which appeared a few weeks after Darwin and Wallace's preliminary papers), made this fact the text of an interesting though inconclusive discussion, which is now of some historical interest. It marks that change in scientific thought which for the first time forbade men to entertain seriously any such explanation as that the red grouse had been called into existence by a special creative act in and for the British Isles alone. Various writers have referred to a supposed former Continental range of the red grouse, for which bones found in caves and similar remains have been adduced as proof. We are very sceptical as to such identifications, for to distinguish the bones of our native species from those of the Continental willow-grouse would baffle the acutest anatomist. The history of the genus *Lagopus*, so far as it can be unravelled without light from fossil remains, may be conjecturally restored somewhat as follows: The common ancestor probably resembled in many respects grouse of the genus *Tetrao*, particularly in not turning white before winter. Our red grouse, by reason of its southern habitat, alone preserves this presumed ancestral peculiarity, and is so far the best surviving representative of the hypothetical common ancestor. Other forms, more or less northerly in range, have developed in a marked degree the seasonal change of plumage. Of these the willow-grouse is most nearly related to our own red grouse, while the ptarmigan, and the closely allied species which inhabit Spitzbergen and Arctic America, are more specialised forms, in which the winter changes are extraordinarily marked.

The combats for the possession of the females for which the game-cock is so notorious are exemplified in a yet more amusing form by the love-fights of the black cock and the capercaillie. The cocks assemble at well-known spots, where during weeks together they display their charms before the assembled females. The black cock struts, and dances, and beats his wings, and turns round and round in an excitement which at length becomes perfectly frantic. So absorbed are the birds that one after another may be shot, or even caught by the hand, without disturbing the others. When these antics are over the birds begin to fight, and eye-witnesses tell us that the snow may be seen all bloody on the battle-fields of the capercaillie, and that the black cocks make the feathers fly in all directions. In our Scottish pine-woods the excitement seldom reaches such a pitch, perhaps because crowds of birds cannot easily be gathered together, but the capercaillie, or cock of the woods, may often be found perched on the top of a high tree, and defying the universe by means of ludicrous noises and gestures, while the awe-struck females wait in silence the result of the engagement which usually ensues.

Abstracts of Papers, Lectures, etc.

THE INSTITUTION OF CIVIL ENGINEERS.

At the meeting on Tuesday, the 27th of November, the President, Sir George B. Bruce, being in the chair, a paper on "The Witham New-Outfall Channel and Improvement Works" was read by Mr. J. Evelyn Williams, M. Inst. C.E.

The author stated that in 1878 he was instructed, by the Witham General Commissioners, to report upon the improvement of the river Witham. He then found the Outfall, or tidal portion of the river, most unfavourable, both for drainage and for navigation. A tide which rose 21 ft. in Clayhole, in the estuary of the Wash, only rose 12 ft. 6 ins. at Boston. The lower reach of the channel, between Hobhole Sluice and the estuary, was not only shallow and circuitous, but untrained and broken through a mass of shifting sands. The flood-waters rushing seaward cut frequent and successive "steeps," from 10 to 12 ft. in height, which kept tumbling into the channel and choking it up; the channel thus became distorted, and sometimes shifted a mile from east to west in a few weeks. The flood-tide, from the estuary, swept over these shifting sands, and flowed like a rapid wave up the river to Boston, carrying a large quantity of sand in suspension. This was deposited during slack-tide in the upper reach of the outfall, where in dry seasons, during the absence of the fresh-water scour, the deposit reached the level of 11 ft. 6 ins. above the sills of the Grand Sluice in Boston, and rendered the flow of neap-tides insensible at the sluice. Ultimately it was decided to make a new outfall, and this paper consists of a detailed description of the work, but it is too technical for our columns.

PHYSICAL SOCIETY.

On November 24th, Professor Reinold, President, in the chair, Captain Abney read a paper "On the Measurement of the Luminosity of Coloured Surfaces," which was illustrated by experiments. In a communication to the Royal Society General Festing and the author have described a method of comparing the intensity of the light of different parts of the spectrum, reflected by various pigments, with that reflected from white; and luminosity curves have been constructed, the areas of which give comparative measures of the total luminosities. This method of comparison is accurate, but requires considerable time, and the author has devised a more rapid process. The coloured surface whose luminosity is to be compared with white is placed beside a white patch within a dark box. A direct beam of light passes through an aperture in the box, and a black rod casts a shadow on the coloured patch; another beam from the same source is reflected at an angle, and forms a shadow of the same rod on the white patch, the junction of the two shadows coinciding with that of the two surfaces to be compared. In the path of the direct beam is placed a rotating disc with angular openings, adjustable whilst rotating by a simple lever, and by this means the white patch can be made to appear too light and too dark in rapid succession. By gradually diminishing the range of oscillation of the lever, a position of equal luminosities can be found. The coloured surface is now replaced by a white one, and the adjustment again made; and from the angular apertures required in the two cases the relative luminosities are determined.

Comparisons made in this way (the numbers relating to which are given in the paper) with emerald-green, vermilion, French ultramarine, etc., gave results in close agreement with those deduced from the luminosity curves obtained by the spectrum method.

In reply to questions, Captain Abney said the spectrum method was the more accurate, and could be relied on to 1 per cent. The new method gave results within 2 per cent., showing that the eye is very sensitive to small changes of luminosity when such changes take place in rapid succession.

Professor Rücker made a communication "On the Suppressed Dimensions of Physical Quantities."

Professor Carey Foster, after discussing the effects of defining specific heat as a ratio, or as a quantity of heat on the dimensions of temperature, pointed out that as quantity of heat = temperature × entropy, the dimensions of temperature would be determinate if those of entropy were found.

Professor S. P. Thompson considered part of the difficulties of dimensional equation arose from the fact that no distinction was made between *scalar* and *vector* quantities.

ZOOLOGICAL SOCIETY OF LONDON.

At the meeting held on November 20th, Professor Flower, C.B, LL.D., F.R.S., President, in the chair, the Secretary read a report on the additions that had been made to the Society's Menagerie during the months of June, July, August, September, and October, 1888, and called attention to the acquisition of three specimens of Pallas's Sand-Grouse (*Syrrhaptes paradoxus*), captured out of the many flocks of this Asiatic bird that have lately visited the British Islands. A letter was read from Professor J. B. Steere, C.M.Z.S., giving a preliminary account of the "*Tamaron*," a Bovine animal found in the Island of Mindoro, Philippines, which he believed to be allied to the Anoa of Celebes. Mr. Edgar Thurston, C.M.Z.S., exhibited and made remarks upon a collection of corals from the Gulf of Manar, Madras Presidency. Mr. H. Seebohm exhibited and made remarks on a specimen of a new species of pheasant (*Phasianus tarimensis*), obtained by General Prejevalsky at Lob Nor, Central Asia. Mr. H. Seebohm also exhibited a specimen of a species of plover new to the British Islands (*Vanellus gregarius*), which had been shot in Lancashire about 25 years ago, and had been previously supposed to be a cream-coloured courser. Mr. J. W. Hulke, F.R.S., F.Z.S., read a paper on the "Skeletal Anatomy of the Mesosuchian Crocodiles, based on fossil remains from the clays near Peterborough, in the collection of A. Leids, Esq., of Eyebury." The author remarked that within the primary divisions of the order the definition of species had, as Strauch had remarked twenty years ago in his excellent "Synopsis of Extant Crocodiles," ever been one of the more difficult tasks of the systematic herpetologist. This he attributed largely to the mutability of the characters, chiefly external, employed; but principally to the inadequacy of the osteological material then available for the purpose. This latter want was at the present time scarcely less than when Strauch wrote, yet an exact and comprehensive acquaintance with the anatomy of the Mesosuchia must constitute the only secure and enduring basis of classification. In treating of extinct forms the difficulty was much increased. The collection of Mr. Leids contained a large series of crocodilian remains from the Oxford Clay in admirable preservation, which illustrated many anatomical details not to be learned from the skeletons embedded in slabs of rock contained in public museums. The author described a selection of bones from Mr. Leids's collection illustrative of the two chief families into which Messrs. Deslongchamps (père et fils) had divided the Teleosauria. The skeletal differences of the Teleosauria proper, and Metriorhynchi, and those existing between both these and the Eusuchian skeleton were pointed out; and the morphology of certain bones was discussed. Mr. Oldfield Thomas, F.Z.S., read a paper on a "Collection of Small Mammals obtained by Mr. William Taylor in Duval County, South Texas." The collection contained examples of one new species and one new geographical variety, besides adding no less than six species to the National Collection of Mammalia. A communication was read from M. L. Taczanowski, C.M.Z.S., containing a "supplementary list of the birds collected in Corea by Mr. Jean Kalinowski."

EDINBURGH ROYAL PHYSICAL SOCIETY.

At the meeting on November 21st, Dr. Sims Woodhead, F.R.S.E., Vice-President, in the chair, the Secretary, Dr. Traquair, F.R.S., submitted a paper "On the Structure of *Pterichthys* and its Allies," comparing it with the genera of *Asterolepis* and *Borthriolepis*. After remarking that some geologists have denied that *Pterichthys* was a fish, he went on by the aid of numerous specimens and casts to describe the more salient structural arrangement. Regarding the curious shield on the top of the head, he was inclined to believe it to have been a guard for the eyes, which, by an arrangement of muscles, could be raised or lowered at will. In a second paper "On *Homosteus*, Asmuss (Hugh Miller's *Asterolepis* of Sromness)," Dr. Traquair agreed with the Continental authorities that it must be classed as a *Pterichthyan* fish, and exhibited a beautiful cast of an exceedingly fine specimen. Mr. Harvie-Brown submitted a paper "On the Seal in Fresh Water," in which the occurrence of the seal in Loch Awe, first noticed in the Old Statistical Account, 1793, was traced down to the present time. It had been supposed at one time that the seal had made its way up the rapid river Awe in pursuit of salmon, but the opinion now held pointed to their presence in the loch as being due to physical changes. In the course of a discussion which followed, it was pointed out that Dr. John Murray's recent discovery of organisms in the locks of the west coast, which are not found anywhere else within the 100-fathom line, went far to support the theory of geological changes imprisoning animals in what might be considered quite unsuitable localities, but to which they had adapted themselves. In this way it was quite possible that the seals of Loch Awe had lived there from generation to generation. The physical features of the surrounding district were also remarked upon as showing evidence of late geological changes. Mr. George Brook, F.L.S., read a short note on a "roller" lately shot in Mull by Mr.

McLean, of Lochbuey, and business was concluded by the exhibition of a skeleton of the Great Auk (*Alca impennis*) by the Secretary.

GLASGOW NATURAL HISTORY SOCIETY.

On November 13th Professor Cossar Ewart delivered a lecture, under the auspices of this Society, on the Electric Organs of Fishes.

Professor Cossar Ewart said there were few if any structures in the whole realm of nature which, in addition to perplexing and puzzling the naturalist, had attracted more general attention than the electric organs of fishes. Aristotle seemed to have pondered long the peculiar force by which the electric ray numbed the fishes that came within its reach, and Darwin, after long and careful consideration, came to the conclusion that the electric organs offered a special difficulty to his theory of natural selection. And although, as the result of numerous investigations, a considerable increase had recently been made to our knowledge of these organs, it was still impossible to account for their origin, in some cases to offer an opinion as to their function, or even to say whether they were progressive structures or mere useless vestiges. Proceeding, the lecturer showed how the torpedo and other electric fishes fascinated the Greeks and to a less extent the Romans, and how they held their ground during the dark ages. One of the most noteworthy facts about electric organs, he went on to say, was that they were only found among fishes, and that although there were hundreds of different kinds of fishes there were practically only three kinds that were known to have electric batteries sufficiently powerful to be of any evident use. These were malapterurus of the Nile and other African rivers, the gymnotus of South America, and the torpedo found at times in our own waters and in considerable numbers in the Mediterranean and the Atlantic. Of the others in which electric organs were known to exist were the once sacred oxyrhynchus of the Nile, and the skates and rays which abound round the coast of Scotland. The malapterurus was a quaint-looking fish, with a fatty dorsal fin like the salmon, and six long barbules around the snout. It was said sometimes to reach a length of four feet. In this fish the electric battery was in the form of a continuous subcutaneous jacket or tunic, which invested the whole body, with the exception of the head and fins. It consisted of a countless number of minute cells from which electricity was thrown off at will. The gymnotus was a soft-skinned, sluggish creature, with small, stupid-looking eyes flattened back, and long ventral fin. It sometimes reached a length of six feet, and as the electric batteries occupied nearly two-thirds of the entire fish, one could easily understand how much it was dreaded by the natives of the Orinoco region, and how ordinary fishes gave the electric eel a wide berth. The gymnotus had four batteries—two large and two small—on each side of the body, supplied by about 200 pairs of nerves. The batteries were so powerful that a shock from a large, active fish was strong enough to strike down a man and numb away his consciousness for several hours. The torpedo was of special interest, because we were beginning to understand all the steps through which its organ had passed during its long and gradual evolution. Some of the species attained a great size. There was one, the giant torpedo, over four feet in length, which when cast ashore at Cape Cod, was said often by its unexpected shocks to strike down the unwary fishermen when they attacked it with their harpoons and boathooks. The shock of the common British torpedo was sufficiently strong to kill a duck, and when the organ was connected with a telephone the discharges first produced a croaking sound, but as the fish got excited each discharge was accompanied by a pronounced groan. The electricity discharged from the torpedo's batteries behaved like ordinary electricity, rendering the needle magnetic and emitting sparks, and it might even be used in charging a Leyden jar. But it should be specially noted that the living battery of fishes differed from the ordinary batteries. A Leyden jar or a voltaic pile had no influence on the electricity it contained, while the electricity of the torpedo was entirely under the control of its will, the torpedo refusing to give a shock at one time, but readily discharging its batteries at another. What was perhaps still more remarkable, there were two large lobes in the brain of the torpedo which regulated the production, storage, and discharge of the electricity. These electric lobes were composed of numerous giant nerve cells, from which numerous nerve fibres extended to pass direct to the batteries. When the electric lobes were destroyed or the nerves passing from them were divided the torpedo was rendered as helpless as an engine without steam. The lecturer then proceeded to describe the structure of the electric organ of the torpedo. He stated that the battery consisted of an enormous number of columns or prisms—in the ordinary torpedo from 400 to 500, in the American about 1,000, making in the two batteries 2,000 columns for storing electricity. In each of the 500 columns there were about 600 electric plates, so that in the ordinary torpedo there might be about 300,000 electric plates altogether, and in the giant torpedo some 500,000. These plates were supplied with an enormous number of nerve fibres, so fine and dividing more and more that with the highest power of the microscope it was impossible to trace them. Each of these tissues was connected with the electric lobes in the brain, and when cut across were seen to be made up of a large number of nerve cells. The lecturer described in detail the structure of the electric plate, and went on to say that the electric organs claimed special attention, not only because of their remarkable structure and still more remarkable properties, but because their very existence was a mystery. Mr. Darwin found the electric organs a special difficulty to his theory of natural selection for two reasons —he was able neither to understand their individual nor their ancestral history. That the electric organs had been gradually built up as the torpedo and electric eel became more and more specialised, Darwin had no doubt; but he was unable to account for their origin by his law of natural selection. And before proceeding he emphasised the difference between evolution and natural selection. We spoke of the fact of evolution, but the theory of natural selection, for while all naturalists now agreed that animals and plants had been evolved, there was still some diversity of opinion as to the method by which the evolution had been effected. In reference to any plant or animal it would be said by most naturalists that it was slowly evolved out of a mass originally shapeless of growing protoplasm by means of natural selection operating on fortuitous variations. As to the guiding hand, science must be absolutely speechless. In asking science to tell us what was the cause of causation, we were asking her to cross an impassable channel, to pass from the domain of fact to that of belief, a feat which if essayed must inevitably end in failure. Returning from this digression, Professor Cossar Ewart went on to remark that when, thirty years ago, the "Origin of Species" was launched on its wonder-working career nothing was known of the ancestral history of the torpedo. Now the position was altered, and he was able to tell them not only what the torpedo's organs had been derived from, but also to trace every step in their life history. To redeem his pledge, he went on to direct attention to the so-called "pseudo electric" organs of skate. He pointed out that fifty years ago no one ever suspected that the skate was possessed of electric batteries, and that until a few months ago naturalists would probably have expressed surprise had it been suggested that there was considerable diversity in the form and structure of the electrical apparatus of the various members of the skate family. The discovery of the existence of the electric organ of the skate was due to Dr. Stark, of Edinburgh, who read a paper on the subject before the Royal Society of Edinburgh in 1844, but having been labelled by naturalists "pseudo-electric," it had been until quite recently neglected alike by physiologists and naturalists. But the skate's organ was coming to the front again on account of the light it threw on the development of the powerful battery of the torpedo. The discharges from the skate's batteries, though weak, and as far as had been ascertained useless, behaved exactly like the discharges from the torpedo. The skate did not keep its electric battery at each side of the gill like the torpedo, but carefully tucked away in the tail. He described at length the structure of the electric organ of the skate. Instead of consisting of a series of plates, it consisted of a series of discs or cones fitted into each other like thimbles, and forming a long electric spindle. Each disc consisted of several distinct layers. The first layer, into which all the nerve-fibres pass, was not unlike the electric plate of the torpedo. Altogether, in the electric organ of the skate there might be 25,000 discs, or 50,000 in the two electric spindles. In other skates, instead of the discs, there were numberless cups, each cup having led into it numerous nerve-fibres. He further showed that in other instances the electric organ was composed of muscular cups; and in the young of the skate the process of development of the muscular tissue into the electrical organ was traced. In the same way, he said, the electric organ of the torpedo, notwithstanding its extreme complexity and remarkable powers, had been formed out of ordinary muscular fibres. For some inscrutable reason, the fibres of certain muscles concerned in moving the jaws of the ancestral torpedoes became more and more modified generation after generation, until they entirely lost their original function, and were so profoundly altered in structure that it was no longer possible to recognise in them the remotest resemblance to muscular tissues. But though he had been able to show that the torpedo's electric organs had been thus evolved, he had to admit that he only dealt with one of the difficulties—he had said nothing of the manner in which the transformation had been effected.

ROYAL GEOGRAPHICAL SOCIETY.

At the meeting held on November 26th, Mr. J. Thomson read a paper on "A Journey to the Atlas Mountains," before a large audience. General Sir B. Walker, K.C.B., presided.

Mr. Thomson, in the course of his paper, said that the idea of visiting Southern Morocco and the Atlas Mountains first dawned upon him in 1885. At that time he was engaged in a mission to the Central Soudan, and the infant civilisation he there found flourishing made him desirous of studying its parent resources. Until recent years Leo Africanus, a Moorish traveller, remained the sole authority on the subject of Southern and Central Morocco and the Atlas Mountains. The first really serious attempt to follow in the footsteps of Leo was made in 1871 by Sir Joseph Hooker and his companion, Mr. Ball, who brought back with them vast stores of botanical information; but much then still remained to be accomplished. Accompanied by a young friend, Mr. Harold Crichton-Browne, Mr. Thomson said he left England in March, 1888. Arrived at Casablanca, he secured the services of a Moorish soldier, and thus scantily attended they rode overland through the provinces of Shawia, Dukalla, and Abdar to Mogador. As far as the river Tensift the country traversed might be described as a gently undulating, upraised sea-bed, forming a low plateau or broad step, nowhere rising above 500 feet in elevation, and composed in great part of tertiary shell sands. It was a supremely monotonous country, chiefly distinguished by the complete absence of trees and the scarcity of the population—the result of Moorish misgovernment. The travellers passed from areas ablaze with a gorgeous carpet of flowers to tracts of bush and palmetto, or traversed rich plains of black loam, covered with splendid crops of barley and peas, alternating with fields left waste and desolate. Only one stream, the Um-er Rbia, found its way through this region from the mountains. With their arrival at Tensift all this disappeared. Here commenced the area of Argan forest, that peculiar and useful oil tree which found sustenance where the more water-loving olive could not live. They obtained their first view of the Atlas mountains on leaving the plain of Akermut, near Jebel Hadid. With their arrival at Mogador, with its gleaming whitewashed houses, they commenced operations for an excursion to the Atlas, and on the 7th of May they left Mogador with a little party of five men. As travelling in Morocco was a new experience, and the Moorish character an unknown quantity, he judged it best not to plunge straight into the interior until he had satisfied himself to some extent on these points. For that purpose he went by a circuitous route to Saffi through Shiedma. It was well that he did so, for the few days devoted to that trip revealed a state of things among his men which almost reduced him to the verge of despair. Their laziness, insolence, gluttony, and deceit were quite a revelation, and he speedily saw that the first essential to successful progress was the settlement of the question who was to be master. Arrived at Saffi they directed their steps to the city of Morocco. The route led over the raised sea-bed of Abda, till, reaching the second step of the plateau, they left Abda behind and entered the province of Beled-el-Hummel, or the "Red Country," so called from the colour of its soils, the result of the denudation of the red and purple cretaceous shales, which here were largely developed. After passing the small salt lake called Zima, on the fourth march, they left behind them the hills of Rahamna and entered the great plain of Morocco, the dried-up bed of some ancient lake. Here for the first time the Atlas range burst upon the traveller in all its massive grandeur as it rose abruptly from the plain and passed by successive irregular terraces into one or two prominent snow-clad elevations, though in the main presenting an even sky-line. At their arrival at the city of Marakish the real difficulties of the trip commenced, as they were on the threshold of untrodden paths. The base of the mountains was reached at the small ruinous town of Sidi Rehal, where an interesting geological feature attracted their attention in the occurrence of a continuous boss or dyke of basalt, which, as investigation showed, extended from Demnat to the Wady Nypes. Words failed him to describe the charming valley in the centre of which the little town of Demnat stood. Irrigation channels spread themselves in a perfect network over the entire valley, everywhere spreading fertility. In their first excursion from Demnat they were led up this picturesque valley, and some miles above the town, where the first narrowing valley seemed to end, they discovered the wonderful natural bridge aqueduct of Iminifiri. On reaching this strange natural phenomenon they saw what appeared to be the mouth of an enormous cave, as its name denoted, from which rushed the Wadi Demnat in a boisterous torrent. On entering they found themselves under a magnificent arch hung with stalactites, with walls presenting all the aspect of clustered pillars. Pushing their way in, they soon discovered that it was no cave, but nothing more than an arch, springing at a height of over 100 ft. from one side of a mountain gorge to another. The rocks around Iminifiri had an added interest in being clad in masses of the gum euphorbium. Above Iminifiri they crossed a valley broken by numerous hills which ended in sharply tilted limestone peaks, rising abruptly into mountain masses 6,000 ft. or 7,000 ft. high. The most prominent of those peaks they ascended, and discovered the ruins of a so-called Christian church, which, in his opinion, belonged to a pre-Christian era. But the goal of their trip was Tasimet, a place south-west of Demnat. That proved to be a lovely and picturesque spot cradled among mountain heights. Around were magnificent groves of walnuts and pine woods crowning various rocks and heights. It was an occasion of no small anxiety when the day arrived for leaving Demnat, and starting for the point selected for the first serious attempt to cross the mountains. Before starting they secured the services of a Jewish interpreter, who made them perfectly independent of the services of their men. It was only when they were well into the mountains that the situation dawned upon the latter, and then their faces were a sight to see. In a short time they reached the glens of the Lar and the Lemulha cut through purple shales, the bright colours modified by patches of bush or grass. Passing through the village and market of Enzel, they struck the Wad Gadat, up whose rugged glen their way lay into the heart of the mountains. Along this track there were no villages, and the sides of the glen were well clothed with callitris and juniper and at places an evergreen oak. Further up the glen, which soon became a gorge, lay the picturesque district of Zarktan. There the Gadat divided and spread itself in radiating tributaries on the northern face of the central range. From Zarktan the road to Glauwa zigzagged up a high, narrow ridge which soon brought them to the foot of the Atlas crest. Far below on their right ran the Gadat, the gorge of the Asif Adrar-'n-Iri flanked then on the left, while the bright-hued ridge they stood on led to the entrance of the gorge, which ended in the pass across the mountains. Struggling up the gorge of the Adrar-'n-Iri, over rugged, angular blocks for some time, they arrived at the district of Tetuta, where the gorge expanded and ended in the very heart of the Atlas range. A more desolate prospect could never be seen, irresistibly reminding them of Aden. Hardly a tree or bush was to be seen, only a little grass on the small, irrigated terraces. The next day a sharp climb of an hour brought them to the top of the pass, the Tizi-n-Teluet, at the height of nearly 9,000 ft. A view of magnificent extent spread itself out before them. Southward the eye roamed far into the hazy distance over the basin of the Draa, and northwards scanned the glen of Gadat, the plain of Marakish, and rested on the mountains of Bahamna and Srarna. As far as the eye could reach there was only a slightly broken plateau region 7,000 ft. to 8,000 ft. in altitude, without a conspicuous feature to catch the eye. Even in colour it was mournful and monotonous in the extreme; a deadly gray which spoke of friable shale and general barrenness, unrelieved by green forest or bush. The one refreshing feature of this disappointing landscape was the little valley of Teluet, which lay 3,000 ft. below them, resembling the dried-up, grass-grown bed of a mountain lake, which, indeed, it might have been. On either side of the pass the moun ains rose 2,000 ft. above, like the rugged pillars of a gate. In the valley of the Teluet the Kaid of Glauwa had his castle, where they were hospitably entertained for some days. Being foiled in their attempt to proceed west along the southern aspect of the main axis, they recrossed the Tizi-n-Teluet and passed down the glen of the Gadat, reaching the Kasbah of Misfiwa in two big marches, and in a single march of fourteen hours they went straight from Misfiwa to the Kasbah of Gurguri, arriving early the next day at Amsmiz. From that point they again went into the mountains, their object being to reach the small mountain province of Gindafy, and their route lay up the Amsmiz. At midday they succeeded in reaching the top of the Tizi-Nemiri at an elevation of 9,600 ft. On crossing the Tizi-Nemiri Mr. Thomson said he had seen a very conspicuous snow-clad peak to the west, and a great desire to ascend it had taken possession of him, as it was evidently the highest point between Wady Nyfis and the Atlantic. Leaving his friend—who was at that time ill—behind, and taking only three men and a soldier guide, he went west to the Wady Nyfis, and reached Marossa on the same day. From Marossa he turned east, skirting the base of the main axis to Eduz, and then started for the district of Ogdinit at the foot of the peak. Even the most faithful of his three men were in a terrible fright at having to venture into a more than semi-independent district. But he was not to be turned from his purpose, and succeeded in reaching his destination. He was, however, at the time placed in a most critical situation, the ascent of the peak developing into a race in which he was chased by the natives and had more than one narrow escape of being shot. It took him some time to recover sufficiently to take any observations, but when he was able the prospect displayed sufficiently repaid him. From that vantage point, 12,500 ft. above the sea, he could see 10,000 ft. below him the river Sous in glittering reaches, winding seaward through the grove and field mottled valley, gathering within its banks a score of streams from the mountains. The chief attraction, however, was the sight of the massive elevation of the Anti-Atlas, whose table-like top formed an almost straight line on the horizon. East, west, and north a bewildering assemblage of snow-streaked peaks, sharp barren ridges, gorges, and glens rocky and desolate above, grove fringed and terraced below, met the eye, making description almost impossible. Mr. Thomson then described a short stay they had at the city of Marakish, and went on to speak of the ascent of the Tizi Likumpt at a height of 12,500 ft. Here, rather to their surprise, they found a branch of the Mrika river, penetrating into and running parallel to the central axis. On the 9th of September they started on a hazardous trip up the valley of the Imintanut, which was a very narrow gorge, caused by the occurrence of an almost vertical bed of compact limestone. They then passed into another glen, that of the Wady Msira; crossing that depression, they rose rapidly for half an hour, and at an elevation of only 4,500 ft. they found themselves at the top of the pass that led into a tributary of the Sous. The impression that was acquired at the end of that pass or watershed was that they were skirting the end of the Atlas as a range, and that westward lay only a broad plateau, cut off geologically and topographically from the range to the east. They then travelled through Bibawan to Tarudant, and traced out the tail of the Atlas range, and remarked the manner in which the cretaceous sandstones were thrown on the flank of the range, though comparatively undisturbed away from the immediate line of upheaval. The lecturer then said that, after returning to Casablanca, a despatch asking him to go to the relief of Emin Pasha brought him home, or he had intended to do a little more exploring. In conclusion, Mr. Thomson gave some of the practical results of his trip. They had ascended and crossed the Atlas chain in no fewer than six different places besides making various subsidiary trips into the lower ranges. A large series of barometric and boiling-point observations had been taken which would assist in forming a more accurate idea of the general elevation of the range. Several glens had been explored and the head-waters of some important streams had been mapped out. New and important light had been thrown upon the geological structure of the mountains. A small collection of plants from the higher altitudes had been made, and finally a series of photographs (which were exhibited) of the mountains, the inhabitants, and their houses had been obtained. He had reached an altitude in the mountains 1,300 ft. or 1,500 ft. higher than any other traveller.

ROYAL STATISTICAL SOCIETY.

The first ordinary meeting of the present session was held at the Royal School of Mines, in Jermyn Street, on the 20th ult. The President, Dr. T. Graham Balfour, F.R.S., Honorary Physician to her Majesty the Queen, occupied the chair.

Before delivering his inaugural address, the President congratulated the Society upon its continued prosperity and numerical strength, and referred in terms of regret to the losses the Society had sustained by deaths since the anniversary meeting in June last, especially mentioning the services rendered to the Society in the past by Mr. Frederick Purdy and the Rev. E. Wyat-Edgell. He also urged on the Fellows generally, and the younger ones especially, the importance of forwarding the objects of the Society.

The President then proceeded to show how errors may arise in the use of figures under certain conditions, and some of the benefits to be derived from statistics when correctly and carefully employed. In illustration, reference was made to the assumption that town life leads to physical degeneration, as argued in an article on the "Health and Physique of our City Populations," in the *Nineteenth Century* of July, 1881, recently reprinted in "Prosperity and Pauperism," edited by the Earl of Meath. Other subjects and instances were also mentioned, showing how easy it is to arrive at erroneous conclusions from a comparison of two periods without regard to the important principle of similarity of the conditions.

Dundee Naturalists' Society.—At the meeting on November 21st a paper on "The Origin of Coral Reefs" was read by Mr. Alexander P. Stevenson. After drawing attention to a large collection of corals from the Biological Museum of the College which had been kindly lent by Professor D'Arcy Thompson, Mr. Stevenson pointed out that these coral masses were composed of the skeletons of myriad organisms which had lived in tropical seas, and secreted the limestone of which the skeletons were built up from the lime present in the ocean water. The reefs were not built up by the corals in the sense in which we generally understand building. The builders were unconscious, and showed neither toil nor skill, but, dying, left their skeletons to form a basis on which other generations could repeat the same process of growth and decay, and by the fusing together of the innumerable skeletons, the "bricks" were formed of which the reefs were the aggregates. The coral was shown not to be the "insect" of which one frequently hears, but a near relation of the sea anemone, which lived in colonies, and had the power of secreting a skeleton in its tissues. A description of the coral polyp was given, and illustrated by beautiful models and blackboard sketches. It was shown that the fact of the organisms only being able to live in water where the temperature never fell below 60 degrees practically limited the reef-building corals to the region of the tropics. The difficulty involved in explaining the origin of coal reefs, more especially those annular rings of coral with a lagoon of smooth water in the inside, and on the outside the surging breakers of the fathomless ocean, and which were known as "atolls," was shown to consist in the fact that the corals could not exist at a greater depth than twenty fathoms, while outside these reefs the soundings revealed enormous depths. How, then, had they risen from the deep-sea bottom? The various theories suggested by early naturalists were touched upon, and the views of Darwin, Agassiz, Le Conte, Semper, John Murray of the *Challenger*, and Dr. Guppy explained at length the weakness or strength of each being pointed out. The conclusion reached was that of honest Sir Roger de Coverley, "that a good deal might be said on both sides."

Geological Society of Glasgow.—At the meeting held on November 19th, Mr. Dugald Bell, vice-president, in the chair, the following gentlemen were elected to fill the vacant offices in the council:—As Vice-President, Mr. Forsyth Sommerville: as members of Council, Messrs. William Armour, C.E., William Jolly, F.G.S., R. J. Steele and James S. M'Lennan. Mr. John Young, F.C.S., exhibited specimens and sections, under the society's microscope, of a variety of Ormund stone (a volcanic tuff), enclosing pearl-sinter or pearlite, from Corrieburn, Campsie. In the sections it was seen that the interspaces between the fragments of erupted rock had been penetrated at an after period by a fluid aqueous magma, probably in a heated condition, and which held in solution several mineral elements, such as silica, alumina, lime, and iron. The last three of these appear to have been the first to gather together in the form of small spherical balls, more or less polygonal in outline in section, with a faintly radiated crystalline structure These spheres are seen to have been afterwards enveloped in the silica of the magma, as they have a glistening pearly grey coating, resembling that known as pearl-sinter or pearlite, which has been found in volcanic tuffs from various parts of the world, although apparently not previously recorded from Scottish volcanic rocks of carboniferous age.

Liverpool Science Students' Association.—At the meeting on November 16th, a short but interesting paper on "Instinct in Plants" was read by Mr. R. H. Day. A paper on "The Philosophy of Cross-fertilisation," a subject of great interest to botanists, was read by Mr. J. W. Baylis. The wonderful variety of flowers in form, colour, and odour was graphically pourtrayed, evidencing that they were factors in the production of cross-fertilisation, which consisted in the fertilisation of the ovaries of flowers by pollen from other flowers of the same species, effected through the agency of the wind or insects. The conveyance of pollen is essential in the great majority of plants, the sexes in some cases being borne on separate flowers, and even when the male and female organs are united in an individual, self-fertilisation is made difficult or impossible by various causes, such as the relative positions of the organs and the different periods at which they arrive at maturity. The curious contrivances and modifications that flowers, especially orchids, possessed for the furtherance of cross-fertilisation, and the inter-dependence of flowers and insects in the struggle for existence, were alluded to at considerable length. In closing, the essayist referred to the researches in this direction of the late Charles Darwin, and said the theory of natural selection was alone adequate to explain the phenomena. An interesting discussion followed, many members taking part, after which Mr. W. Read exhibited in the lantern some interesting slides illustrative of the coal measures of the Wigan coal field.

St. John's Natural Science Society.—At the meeting of this Society on November 27th, a lecture was delivered by Mr. J. W. Slater, F.E.S., on "Nature's Sanitary Service." The lecture was illustrated with specimens of the insects most active in removing putrescent or morbid matter.

Falmouth Naturalists' Society.—At the meeting held on November 26th, the Rev. A. R. Egar (President) in the chair, the Rev. J. A. Leakey gave a lecture on "The Antiquities of St. Gerrans."

FLINTS.*

PROFESSOR J. W. JUDD said he must commence by apologizing for slightly altering the order in which he treated the subject that he had to bring before them, owing to some alterations necessary in the microscope-lantern not being completed. He would, therefore, that evening proceed to speak of the modes of occurrence of flints, leaving the microscopic treatment of flints for the next lecture, when he hoped to be provided with the necessary apparatus. In the remarks he had addressed to them in previous lectures he had endeavoured to point out what could be found out concerning flints by means of experiments. Experiments, as they would have perceived, were simply ways of observing how Nature acted, but in experiments they, as it were, laid a trap for Nature. They determined the conditions themselves under which Nature should act, and then watched the process she followed. But the geologist was often quite unable to follow out that mode of inquiry by experiment. Often it was not possible for him to lay down conditions under which Nature should act. He could only take advantage of the circumstances, and observe what took place under various conditions. Then they spoke of that mode of inquiry as "observation." They would see that "observation" and "experiment" agreed in the fact that in both cases they were observing the action of Nature, but in experiment they themselves determined the conditions under which Nature acted, whereas in ordinary observations they were obliged to take advantage of any opportunities that were afforded them of seeing how Nature worked. The object of experiments and observations was to obtain a number of facts upon which they could reason, and the reasoning which they founded upon these facts and observations was called inductive reasoning. When they had obtained a sufficient number of facts and observations they might form a theory—it might be but a working theory —to account for the facts that they had observed, and they might then proceed to try that theory by other facts, and if it held, to extend and elaborate the theory; or if they found that the theory would not hold good, to give it up. That was the process which was continually carried on in scientific work, and he was going to ask them that night to inquire what "observation" taught them concerning flints, what facts they were able to learn from certain flints which would enable them to make scientific inductions concerning the mode of origin of those flints.

They would inquire what was the mode and occurrence of flints; in other words, where did they come from? Now every Londoner knew that there were two sources from which flints were obtained. Sometimes flints were observed having a beautiful outside coating with a grey or black interior, which was exhibited on fracture. They were all familiar with ordinary white flints with black interior as being employed so commonly in rockeries, and sometimes very ingeniously at railway stations, to pick out the names of the railway stations in large letters. They were all familiar with those large flints; very irregular they were in form; and generally those large flints were obtained from the chalk. They were got out of the chalk beds and were brought to the places where they were used in the way he had described, and in many other ways. But they were equally familiar with another kind of occurrence of flints. They saw flints which had not that black or grey colour, and which have not white coatings outside. The flints may be black or grey, but they were not unfrequently brownish, or reddish, or yellowish in colour, and they were very different in appearance, and they were without irregular and fantastic forms that they were acquainted with in the flints from chalk beds. These flints had various forms. Sometimes they were almost perfectly angular; at other times the edges were worn off and rounded. They were spoken of as subangular flints. In other cases a mass had been worn into a perfectly rounded form, a form called a pebble. Between those several forms they found every possible gradation. They might find flints which were evidently produced by fracture and fracture only. The edges were perfectly sharp and well defined. They might find others in which the process of wearing down had gone on but a little way, and the flint was thus sub-angular; and others in

* Third Lecture to Working Men at the Royal School of Mines.

which there was so much worn away that it was converted into the peculiar rounded form of the pebble; those pebbles were nothing but water-worn flints. Here was a case where they were obliged to fall back upon observation. Nobody could watch for himself the actual wearing of the actual flints and pebbles, but by examining all those cases they might convince themselves that without doubt the flint-pebbles were merely angular flints that had been worn and rounded. In that way they arrived at the conclusion that those sub-angular and rounded flints, which occurred in the gravels beneath and around London in such great abundance—that those flints were nothing but flints from the chalk which had undergone this process of rounding and rolling by the action of the water. It was true that their colours were very different in many cases from the colours of ordinary black and grey flints, but, as he had pointed out to them, the colour depended upon the very minute quantities of foreign substances in it. He had shown them how small a quantity of gold would alter the colour of a great mass of water, and it was equally true that a minute quantity of iron combined with oxygen would alter the colour of a great mass of flint; and so far as the chemist was able to find out, there was very little difference indeed between those flints which were converted into a brown or red tint and those which retained their original black or grey colour. If any doubt existed as to these pebbles having come originally from the chalk, it would be dissipated by the fact that they often found shells and fossils, to which he would have to refer, in the middle of those rounded pebbles; and in all cases the shells and other fossils found in the gravel flints were the same as those found in the chalk flints, so that, after examining a great number of cases of that kind, they could not doubt for a moment that the flints which were found in gravels had been once flints imbedded in chalk. That being the case, then, they might dismiss the question of the gravel flints. These were once imbedded in chalk. They had merely been washed out and left behind on account of their hardness, while the chalk had been washed out and dissolved, and the flints had been gradually rolled into rounded forms, passing through the condition of sub-angular flints into the condition of pebbles.

Let them, then, go to the chalk itself, the original source of the flints, and inquire how the flints occurred in the chalk. They were all familiar with the chalk which appeared at so many points around London, points which they must all have visited. They had, no doubt, all seen the chalk pits on the downs, and in these days of easy transit probably all must have seen the chalk-cliffs in the Isle of Wight or along the south coast of England, where there were beds of chalk with layers of flint lying in them. They must all be familiar appearances of those chalk strata. Now, if they went to the chalk downs or to the chalk cliffs, and examined either the openings in the chalk or saw the cliff where the chalk strata were exposed, they would be able to observe the way in which the flints occurred. All who had visited the chalk cliff or bed must have noticed that sometimes chalk flints occurred, scattered in the most wonderful manner through the chalk. The flints were found lying, without any apparent order, in the midst of the chalk. They might pick away the chalk and suddenly come upon a little nodule, often very irregular. Sometimes it was perfectly rounded, like a bullet, but frequently it was a very irregular mass, lying quite isolated in the chalk. But besides these scattered flints, and much more abundant than them, were bands of flints, and all who had made a journey to Brighton or by any of the lines that run out of London, if they had looked out of the window, must have noticed how regularly those bands run for considerable distances. The layers or beds of chalk were marked out conspicuously by those bands of flint. Now he wanted to call their attention, in the first instance, to the fact that there were three varieties of these bands of flint. He might mention in passing that these bands of flint were very irregularly distributed. On the average the flint bands generally occurred some three or four feet apart, but sometimes two bands were seen quite close together. At other times a thickness of six, eight, and ten feet and more of chalk existed without flints. Now, these bands of flint were of two kinds. Most commonly they consisted of nodules, very irregular masses, exceedingly fantastic in form and outline, but arranged in tolerably continuous lines side by side. In the second place there was, though much more rarely, another kind of flint bands—what were known as tabular flints. These tabular flint bands were more or less continual for a very considerable distance. Very frequently when those bands were broken they could be seen to be not single bands, but double, consisting of two layers meeting along an irregular line in the middle. There was another fact to which he must call attention, and that was that sometimes these tabular bands give off layers or other tabular masses, more or less at right angles, and sometimes running obliquely from them, and the position in the chalk was that those tabular bands generally lay along cracks which were known as the jointing of the chalk, along which the rock split up with tolerable ease. So there was a tolerably clear distinction between those two kinds of flint bands, the nodular and the tabular.

Those were the chief varieties of flint that would be observed in the neighbourhood of London or in any part of the south of England that they were likely to visit. Either the flints were scattered through the chalk, taking very irregular form, or else they occurred as bands, the bands being sometimes nodular and sometimes tabular in character. Now, if they were to travel as far as Norfolk or the north of Ireland they would find flints occurring in still another manner. In addition to the bands and the scattered flint bands being sometimes tabular and sometimes nodular, more frequently nodular, they sometimes found flints of gigantic dimensions and of very curious form. A specimen exhibited was like a pot; sometimes it was closed at the bottom, and sometimes it was open throughout, and if they were fortunate to see them in a bed, as at Horstead, in Norfolk, they might find them arranged in a very singular manner. These flints were found to make vertical series. One flint seems to fit in the top of another somewhat irregularly, and another time they found a long series of these gigantic flints arranged vertically. These had received a very curious name, and the origin of the name was still more curious. He believed the name originated in this way: The celebrated geologist Dr. Buckland was making a tour in the north of Ireland, and he had as guide an Irishman who conducted him to places he wished to visit, and on his way the doctor picked up a great number of interesting things, and the Irishman, with natural curiosity, asked the names. The doctor gave some of those wonderful compounds of Greek and Latin which at first sight seemed so uncouth, and whatever the doctor picked up he had a wonderful name for it. At last the doctor came upon a thing he had never seen before—one of those gigantic flints—and then it was his turn to ask a question: "Why, Paddy, what do you call that?" Paddy saw his opportunity, and was equal to the occasion. "That, sir," said he, after a moment's consideration—"that, sir, is a Paramoudra." The doctor wrote it down in his note-book, and from that day to this they had been paramoudras. Unfortunately, the name sounds very much like a Greek name, and many persons had puzzled themselves about the Greek derivation of this name. He believed, however, it was only fair to mention that Gaelic scholars, people who were acquainted with all the niceties of the Irish language, assert that "paramoudra" is an Irish word signifying "big stone;" whether the Irishman fell back upon his Gaelic or invented a word on the spot I do not know, but ever since it had retained the name of paramoudra. Now, these gigantic paramoudras, or pot-stones, were very curious and enigmatical things. They would see presently that there were many remains of sponges in the chalk, and the nearest thing they could compare with these paramoudras were some gigantic sponges which were found in the sea, and which were known as Neptune's cup. It was suggested that as the mud which formed the chalk was gradually being accumulated at the bottom of the sea those sponges got on to it, and they gradually formed the paramoudra. The explanation was, perhaps, not a very good one, but at present they were not able to offer any other. The occurrence of these paramoudras was a very singular circumstance indeed. As he had mentioned, they did not occur near London, but only in Norfolk and North Ireland.

Now to return to more ordinary flints, with which they were likely to make frequent acquaintance, he would point out the fact that flints were often, when broken, found to be hollow. Every one who had looked at flints must have noticed the circumstance that if you broke some flints across you would find they were hollow in the middle; and every one must have noticed the fact that flints were sometimes partly black and partly white. Very frequently when flints were broken open they found an outside layer of white, and a great mass of the flint was black, and inside again the mass was white. He must remind them that that difference between black and white flint was a difference of very slight importance. They had already seen that if an ordinary black flint was ground to powder the powder was perfectly white, and there were many similar illustrations to the same effect that might be brought before them, such as a lava known as obsidian, and a piece of the same lava blown up into a froth by the gas which escaped from the mass. It was perfectly white and regular. They had seen how the green water of the sea, when lashed into foam, made a perfectly white foam; and the colour of that mass was due to the mode of aggregation of the water, and not to any change in the liquid itself. When the mass was blown into bubbles it became white. He must not enter into the physical cause of that appearance, which was due, as those who had thought anything about physical questions were aware, to the fact that instead of the light being reflected from one surface it was reflected from a great number of surfaces—from every film of glass or liquid which was formed when the mass was blown up into bubbles. When they came to study the microscopical characters of flint they would see why black flint in parts passed into white flint; but for the present it was only necessary to point out to them that black flint and white flint were varieties of the same substance, and if they analysed them they would find both to consist of silica, and nothing but silica. If they took an ordinary white flint and washed from the outside very carefully, all the adhering chalk, which they could do more readily with a little vinegar or other acid to dissolve the chalk outside, the flint would present a very striking appearance. If examined with a lens, it would be found to be covered with unmistakable marks of little shells. On the other hand, if they took one of the hollow cavities and examined the white material of the central part, they would find the white powder consisted of a number of curious little shells, many of which were of great beauty. A well-known geologist, Dr. Hinde, once found one of these paramoudra in Norfolk, and from it he obtained a whole museum of specimens. Carefully washing them out and examining them under a microscope, he found thousands and tens of thousands of forms, many of which he examined with great care and described, showing what a wonderful diversity of forms existed in the centre of these hollow flints. This white powder in many cases was not a shapeless mass—a mass of particles having no individuality; but if it be examined carefully with the microscope, it would be found that it consisted of little shells. There was only one point he would call attention to about these shells, and that was that though they consisted of silica or flint now, whatever they did once, if they were treated with vinegar or any acid they were not dissolved like ordinary shells would be, but they remained; they were, in fact, converted into silica. They would see they were once shells consisting of carbonate of lime, but now they consisted of silica.

He would point out one or two other facts that they must all have noticed about hollow flints. Sometimes hollow flints have their insides lined with beautiful little crystals, and if they had a lens—and he would advise them all to have a lens and use it—they would find that these little sparkling crystals were quartz crystals just like those beautiful quartz crystals to which he called attention in a previous lecture, only very minute. They were like quartz crystals, set very closely together with their points directed towards the central hollow of the flint. In other cases when a flint was broken open the hollow was found filled with a substance forming curious rounded nodular masses, and it was a substance to which mineralogists gave the name of chalcedony. He would have to refer to that chalcedony on a future occasion; but he would call their attention to the fact that sometimes they were found filling the hollow of the flint, sometimes crystals, sometimes the substance known as chalcedony.

He must also mention a fact you may have observed for yourselves, that sometimes flints have not a uniform colour and texture, but exhibit a curious arrangement of dark and light portions ranged in definite bands. Sometimes they might, in examining a flint, see that those banded portions, as they were called, had been formed after the other portions. They might see that there had been a hollow place in the flint, and that there had been a succession of layers of flint laid down, the layers having different tints, and filling up those hollow places. When such flints were worn into pebbles, they often found that the separate layers yielded very unequally to the process of wearing away by the weather. Some of the bands stood out in relief, while others were worn into curves. They might even find banded flints which were often mistaken for true fossils. Now he must refer them to the fact that flints sometimes possessed some other curious characteristics. There was a bed at Charlton, North Woolwich, where it looked as if there were flints; if one picked away the chalk the flint tumbled into a large number of little pieces. This showed that, through some upheaval, probably, the flint had been smashed to pieces, but the chalk had held every portion in its place, and they did not see that the flint was smashed up until they removed the surrounding chalk. The fact was that the beds had been subjected to great movements, and during the movements the crushing operations had taken place, but the flints had not been able to fall to pieces, on account of the surrounding chalk. Sometimes one came across a still more curious circumstance—a flint had been sometimes broken up into pieces, and fragments had been more or less displaced, but after the displacement the flint had been cemented together again, and so perfectly mended, that if one tried to break it it would break anywhere except along the original fracture—just as it was said that if a man's arm was broken, if he had an accident again it would not break again in the same place. So with fractured flints. It was evident that a remarkable process of fracture and mending had gone on in the flints.

He must next call attention to the fact that flints not unfrequently contained fossils, that was, remains of animals and plants that had once lived, and a very great number of fossils had been found in flints. Those fossils sometimes occurred in one way, and sometimes in another. Sometimes the fossil was a wonderful replacement of the original shell; sometimes they got what looked exactly like an ordinary shell, which they knew to consist of calcic carbonate, and when they examined them carefully, instead of consisting of calcic carbonate which dissolved easily in vinegar or other acid, they found it consisted of the totally different substance, silica. That those shells such as oysters and other well-known forms of shell were once formed of the substance calcic carbonate there could not be the slightest doubt. The whole of the original substance of the shell had been dissolved away, particle by particle, and another particle of silica had been put in the place of the several particles of calcic carbonate, that is chalk matter, until the whole mass had been converted into silica or flint. But at other times it was evident that the process of making the fossil had gone on in a totally different way. Some fossils exhibited were evidently remains of shells of sea urchins, but if they examined them they found that the shell had not been preserved, that they had a cast or impression of the inside and another cast of the outside, and the place where the shell itself was, was now perfectly hollow, as in cases such as exhibited. So that when they got a perfect fossil they had the cast lying in the midst of the flint, and the space occupied by the original shell had been completely dissolved away. In a specimen exhibited they got the outside shell perfectly impressed on the flint. Inside the shell every little hole and marking most perfectly preserved an exact impression such as one would be able to take with sealing-wax or plaster of Paris in the midst of the shell. Then in another case exhibited they had an external cast and an internal cast. He would have to refer more particularly to these casts, and the way in which they originated in a future lecture. Sometimes they found that the shell, like one produced, resembling the great pinnæ that lived at the present day, had been worn away, but while the shell was living, sponges, which made their home in shells, had burrowed into the substance of the shell. These burrows had been filled by white chalk mud, which filled the fossil originally. Now a curious thing had occurred. This chalk had been converted into flint, but the substance of the shell was removed, and thus perfect casts were obtained of those wonderful burrows. They would find subjects of infinite interest and variety in the study of those curious fossils which occurred in flint, especially if, as he hoped to be able to point out, they could reason as to why in some cases they got a cast, and in other cases got the actual replacement of the shell.

He must now ask them to direct their attention from the flints to the chalk in which the flints occurred. That chalk —as they were all aware now the subject had been so frequently explained—had a most wonderful resemblance to the white mud which was found occurring at the bottom of the Atlantic, and which was brought home by the *Challenger.* This mass contained a quantity of sticky material known as globigerina ooze, which covered a large portion of the bottom of the Atlantic. It was not quite so white as chalk, but in other respects it resembled somewhat grey chalk reduced to powder. If they placed some fragments of chalk which had been washed carefully and some of the globigerina ooze under a microscope, it would be seen that they presented a most wonderful resemblance. What he had now to call their attention to was that, if they examined this Atlantic ooze and chalk much more carefully, they would find that Atlantic ooze contained objects which were not found in the chalk. If they dissolved away with a little vinegar or other acid, the chalk would have very little left. If they took Atlantic ooze, and with a little vinegar or other acid dissolved away the shells, which were composed of calcic carbonate, they would in most cases find left behind a great number of minute objects, and if they were examined they would be found to be very interesting objects indeed. A careful examination would show that they were composed of silica —that kind which was called colloidal silica, and when they came to look at their forms it would be seen that they were very definite structures indeed. They were skeletons of curious organisms, some of which were plants and some animals. The plant formations were very minute forms indeed. Drawings of the very beautiful forms known as the diatomaceæ, which had skeletons composed of colloidal silica. Every little plant was simply a little cell, and consisted of a membrane containing a liquid, but each of those little cells had the power of secreting a skeleton which was of very curious form. It consisted of three portions like a box. First there were two discs, which were sometimes round and sometimes had very curious shapes as represented in other figures, and between them there was a double girdle so that the two parts fitted into one another. These skeletons were so excessively minute that they could only make out the forms and marking with a very high power microscope—a power of $\frac{1}{4}$ inch or $\frac{1}{8}$th inch or even higher power. If they examined them with such high powers it would be found they were covered with most beautiful patterns and markings, something like specimens shown in a diagram, which, however, represented only a few of the infinite variety of those exquisite forms of vegetable life. In addition to the plants there were skeletons of minute animals. Those larger organisms were skeletons of animals known as radiolarians. There was a wonderful diversity of beautiful forms represented in a diagram exhibited, but they were only a very small selection indeed out of the thousands of wonderful forms that were known and had been described by microscopists. Last of all they would find a number of rods and plates, often assuming very curious forms, and these they would recognise as being portions of the skeleton of curious sponges—of which specimens were on the table—sponges which had skeletons composed entirely of colloidal silica built up into rods and plates in the most complex patterns, as represented in diagrams produced. Now, they found none or scarcely any such objects as those in chalk when it was dissolved in acid, but in the globigerina ooze they would find them.

He must call their attention for a moment to the chemical composition of the different rocks forming the chalk series. He had already pointed out to them the way in which chemical analysis was carried on, and he had with him some results which had been obtained by analysing some different kinds of chalk, and beds which lay below the chalk in the South of England and elsewhere. Many of those present might have noticed the fact that flints were confined to one portion of the chalk. In the upper part a great thickness of chalk with flints was found, whereas in a lower part there was no chalk flint, and that difference was accompanied by other differences. Chalk which contained flint was of a beautiful white colour, and chalk which did not contain flint was more or less of a grey tint. Many of them could recognise in their visits to the seaside that the upper part of a cliff contained flints and the lower part none. If they examined the chalk they would find that the chalk with the flints consisted entirely of the pure substance calcic carbonate, and there was only a very little silica, but if they took a mass of the lower chalk they would find the quantity of carbonate of lime was somewhat less, but the quantity of silica was much greater. The suggestion offered itself at once that in the upper chalk the silica had been separated out to make the flints, while in the lower chalk the silica remained distributed through the chalk. Now that was the first suggestion which struck one, and they would presently inquire whether they were able to verify that working hypothesis. If they examined the other beds below the chalk they would find that many of them contained a considerable quantity of silica, and they also contained sand and other substances that could be washed out of them, but into that subject he must not at present enter further.

Now let them ask two questions that would be of great use to them in their future inquiries: Were there any rocks besides flint which consisted of silica and silica only? All substances known as sand and sandstone, and the very hardened variety known as quartzite consisted almost entirely of silica, but they differed from flint in the fact that while flints appeared to have a very uniform texture, when examined by a lens or microscope, the sand or sandstone, or quartzite, would be seen to be made up of little fragments, these little fragments being derived from granite and other rocks which contained the substance silica, so they might put aside sandstone and quartzite as having but little analogy with flint except that they consisted of silica, but their silica had evidently been derived from the breaking up of other rocks. But there were other substances which presented much closer analogies with flint. First of all he must call their attention to the fact that in some parts of the world they found hot springs which rose from the ground: the great hot springs which occurred in Iceland, known as geysers, and also in Yellowstone Park, North America, and in New Zealand—these springs coming from the ground boiling hot and rising into the air to a great height, and making great eruptions. But this hot water contained in solution large quantities of silica, and when the hot water cooled down the silica was deposited. The silica left sometimes formed basin-shaped hollows, sometimes masses like cones known as geyser cones, and at other times it formed curious sorts of cups forming most wonderful natural bathing places like the White and Pink terraces which were unfortunately destroyed in the great eruption of Tarawera in 1886. Now, the silica had evidently been held in solution by the water, and as the water had cooled, that substance had been left behind, building up beautiful and wonderful structures. Just as they dissolved silica in alkali, and then made it separate from the liquid by adding acid, so they had in those cases the like action of the hot waters containing various acids. These acting upon the lavas of the districts, they got silicate of soda and of potash in solution, the silica being left behind in a colloidal form. Now he must call their attention to another class of substance which presented some analogy to flint. They not unfrequently found deposited a mass of materials entirely composed of the skeletons of different organisms which had skeletons made up of the substance silica. Many years ago Sir Joseph Hooker found out that at the bottom of the Antarctic Ocean there was a mass of white mud entirely made up, or almost entirely made up, of the remains of beautiful plants—the skeleton of the wonderful diatomaceæ, hundreds of varieties being present in countless millions; and the observations of Hooker had been confirmed by the explorations of the *Challenger* and other vessels. In other parts of the ocean, however, they found a great mass of rock, entirely made up of the remains of the diatoms. There were skeletons composed of colloidal silica which were much larger than those of the diatoms, and sometimes they found masses entirely made up of the remains of sponges and radiolarians. In various parts of the country where lakes had been drained or filled up they also found masses of white material which were also found when examined under the microscope to be made up of these minute plants, skeletons of diatomaceæ. This substance, which was used for making dynamite on account of its great absorbing power, was composed entirely of these excessively minute skeletons of this curious plant, the diatoms. In other places they found great masses of rock, as in North America, especially in the Island of Barbadoes, made up of radiolarians, and in other places they found deposits crowded with fragments of the curious siliceous sponges. He thought they were now in a position to profit by the investigation that they would be able to make by aid of the microscope, as to the actual structure of flints, and from the study of the microscopic structure of flints he hoped they would be able to draw some inferences as to the probable mode of origin of the flints. It had been necessary to bring those general facts before them in order that they might reason upon the facts that they would observe by the aid of the microscope.

RECENT INVENTIONS.

The following list has been compiled especially for the SCIENTIFIC NEWS *by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents, of* 323, *High Holborn, London, W.C.; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester; and* 6, *Lord Street, Liverpool.*

TELEPHONIC APPARATUS.—Messrs. G. L. Anders, J. S. Sawrey, and H. Collet have patented improvements in telephonic apparatus. By this invention a support for a telephone is combined with an automatic switch. A horse-shoe receives the edge of the mouthpiece of the telephone which is cut to a suitable shape to slide into the horse-shoe. The telephone when placed on the base and within the horse-shoe presses down one or more contact springs or switches by the weight of the telephone, thus being automatic and reliable.

BRIDGES.—E. W. Ives has patented an improved bridge. It consists in placing trussed triangular girders, parallel to each other, encased with iron to float them, across the waterway at such a height and with such openings as to allow small craft to pass through the bridge when placed on its bearings in position to carry traffic. To move the bridge for the passage of large vessels, it is lifted or lowered from its bearings by moveable pontoons, after which the bridge is connected by locking bolts to radial arms working freely on a vertical post.

ELECTRICAL FUSES.—Mr. W. E. Hayne has patented a safety fuse for electrical circuits. A short piece of fusible material is placed in the circuit, the fuse being acted upon by springs which exert a pulling or pushing force upon it. When the strength of the current is in excess, the fusible material becomes plastic and is broken by the spring force, the circuit being thus broken. The breaking of the fuse is utilised to bring into circuit, automatically, a second fuse to take the place of the one broken, so that the circuit may be again completed without loss of time.

DISTANCE RECORDER.—Mr. R. M. Lowne has patented means for indicating the distance run by cycles or velocipedes. The object is to obviate the disadvantages of ordinary automatic indicators, and to provide one that will revolve with the crank of the cycle, and notwithstanding the machine being geared up, such as in safety machines, it will register the distance travelled at any speed correctly. This automatic indicator is of a very flat construction, its thickness not much exceeding the thickness of the cycle crank, and attached to this indicator is a strong clip of gun metal with projecting lugs and a screw to firmly grip the cycle crank.

ELECTRIC REGULATORS.—Mr. N. Benardos has patented an improvement in electric regulators. The object is to regulate currents by introducing electric resistances in the circuit. A metal cylindrical tube is provided, having an internal lining of insulating material. It is charged with a mass of granulated carbonaceous material which can be more or less compressed by screwing up metallic end plates, the screwed stems of which pass through end covers of insulating material and engage in forked brackets fixed on an insulating base. The brackets can be electrically connected by inserting metallic plugs between them. The whole set of resistances may be enclosed in a casing.

HELIOGRAPH.—Mr. J. L. Watkins has patented a heliograph. The invention consists entirely in the arrangement for operating and deflecting the signalling mirror. The movement is obtained by a continuation of the axle of the signalling mirror working within a hollow bearing, fitted into a slide rest fixed on the side of the U frame, carrying the mirror frame. The regulating slide is fitted on a solid block with an endless traversing screw fixed in bearings at each end with a suitable knob to turn the screw by. The desired length of stroke is accomplished by a milled-headed screw fixed on the slide, and the tension of the spring is regulated by an eyebolt and travelling set nut.

ELECTROLYSING CHLORIDES.—Mr. W. Spiker has patented a method of electrolysing chlorides, bromides, and iodides. This method consists essentially as follows: The suppression of the polarisation of the chlorine is obtained by the introduction of slaked lime into the anode compartment, which is separated from the cathode compartment by a diaphragm of porous clay. By this way the chlorates are obtained, and by an analogous method the bromates and iodates are obtained. The polarisation of the hydrogen is suppressed by a continuous current of steam or air, or both, blown over the surface of the cathode. A current of the same is passed into the anode and cathode compartments in such a way that an intense motion of the electrolyte is obtained.

STEAM ENGINES.—Mr. D. Purves has patented an invention relating to the construction of cylinders of steam engines. In applying it to a double pressure steam cylinder the outer cylinder terminates at each end in a cylindrical steam chest having internal ports, the steam supply pipe being branched so that the chests form practically the ends of the pipe. The cylinder between these ends is recessed, leaving a cylindrical space between the outer cylinder and the inner lining, which forms the piston cylinder and slide valve, which is caused to travel over the steam ports of the chests. These are similar to those employed in ordinary slide valves, the inner cylinder having ports corresponding with those in the chests, and when it is suitably moved they open into the cylindrical space between the cylinders and thence to the exhaust.

ELECTRICAL PROPULSION.—Mr. F. Wynne has patented an apparatus to be employed in applying electricity to propel vehicles. In order that the armature of each contact maker may act in a stronger and more certain manner than heretofore, it is caused to be polarised, when its attracting core of magnetic material is polarised. This is effected by winding the armature with a solenoid that may be in electrical connection with the solenoid that polarises its attracting core, and with the auxiliary electric conductor which is electrically connected with the latter solenoid, and is placed in connection with the main conductor by a contact maker in rear. Flexible connecting wires are used to permit movement of the armature. The coil surrounding the armature is provided with an exposed contact placed in electrical connection with the main conductor when the contact maker is closed. This connection is effected by a contact strip carried by the adjacent end of a forward auxiliary conductor.

ANNOUNCEMENTS.

ROYAL INSTITUTION.—The following are the lecture arrangements before Easter:—Professor Dewar, six lectures (adapted to a juvenile auditory) on Clouds and Cloudland; Professor G. J. Romanes, twelve lectures constituting the second part of a course on Before and After Darwin (The Evidences of Organic Evolution and the Theory of Natural Selection); Professor J. W. Judd, four lectures on The Metamorphoses of Minerals; Dr. Sidney Martin, four lectures on the Poisonous Action of Albuminoid Bodies, including those formed in Digestion; Professor J. H. Middleton, four lectures on Houses and their Decoration, from the Classical to the Mediæval Period; Professor Ernst Pauer, four lectures on The Characters of the Great Composers and the Characteristics of their Works (with illustrations on the pianoforte); and eight lectures by the Right Hon. Lord Rayleigh on Experimental Optics (Polarisation, the Wave Theory). The Friday evening meetings will begin on January 25th, when a discourse will be given by Professor G. H. Darwin; succeeding discourses will probably be given by Professor W. C. McIntosh, Sir William Thomson, Professor A. W. Rucker, Mr. Harold Crichton Browne, Professor Oliver Lodge, Professor Archibald Geikie, the Rev. Alfred Ainger, the Right Hon. Lord Rayleigh, and other gentlemen.

SELECTED BOOKS.

Elementary Commercial Geography. A Sketch of the Commodities and Countries of the World. By H. R. Mill, F.R.S.E., Lecturer on Commercial Geography in the Heriot Watt College, Edinburgh. London: C. J. Clay and Sons. Price 1s.

On the Senses, Instincts, and Intelligence of Animals. With Special Reference to Insects. By Sir John Lubbock, Bart., M.P. With 100 illustrations. London: Kegan Paul, Trench, and Co. Price 5s.

DIARY FOR NEXT WEEK.

Monday, Dec. 10.—Society of Engineers, 9, Victoria Chambers, Westminster, at 7.30 p.m. — *Annual General Meeting.*
Society of Arts, John Street, Adelphi, Cantor Lecture, at 8 p.m.—*Light and Colour*, by Captain W. de W. Abney, C.B., F.R.S.

Tuesday, Dec. 11.—Institution of Civil Engineers, 25, George Street, Westminster, at 8 p.m.—*The Influence of Chemical Composition on the Strength of Bessemer Steel Tires*, by J. Oliver Arnold, F.C.S.

Wednesday, Dec. 12.—Society of Engineers, Guildhall Tavern, Gresham Street, at 6 30 p.m.—*Annual Dinner.* St. James's Hall, at 8.30 p.m. —*Lecture on Architecture*, by Messrs. G. A. T. Middleton and Cecil Orr.
Society of Arts, John Street, Adelphi, at 8 p.m.—*Explosives*, by Mr. W. H. Deering, F.C.S.

Thursday, Dec. 13.—Society of Telegraph Engineers and Electricians, 25, Great George Street, Westminster, at 8 p.m.—*Annual General Meeting.*
London Mathematical Society at 8 p.m.—*A Method of Transformation, with the aid of Congruences of a Particular Type*, by J. Brill.—*The Equilibrium of a Thin Elastic Spherical Bowl*, by A. E. H. Love.

Friday, Dec. 14.—Institution of Civil Engineers, 25, George Street, Westminster. Students' Meeting, at 7.30 p.m.—*The 26-Knot Spanish Torpedo Boat, Ariete*, by Mr. Julian King-Salter, Stud. Inst. C.E.

METEOROLOGICAL RETURNS

for the ten weeks ending on Monday, Nov. 26th, 1888. Specially prepared for SCIENTIFIC NEWS from official reports.

	Mean Temperature.	Rainfall.	Duration of Sunshine.
Scotland, East	45·8 degs., being 2·1 degs. above average.	7·0 ins., being 0·4 ins. below average.	139 hrs., being 50 hrs. below average
England, N.E.	47·1 ,, ,, 0·6 ,, ,, ,,	4·3 ,, ,, 2·2 ,, ,, ,,	162 ,, ,, 11 ,, ,, ,,
England, East	47·7 ,, ,, 0·4 ,, below ,,	4·3 ,, ,, 2·1 ,, ,, ,,	220 ,, ,, 7 ,, above ,,
Midlands ...	47·0 ,, ,, 0·1 ,, ,, ,,	5·6 ,, ,, 1·2 ,, ,, ,,	181 ,, ,, 14 ,, below ,,
England, South	49·5 ,, ,, 0·5 ,, above ,,	6·6 ,, ,, 0·4 ,, ,, ,,	210 ,, ,, 6 ,, above ,,
Scotland, West	47·4 ,, ,, 0·9 ,, ,, ,,	10·5 ,, ,, 0·8 ,, ,, ,,	143 ,, ,, 30 ,, below ,,
England, N.W.	48·1 ,, ,, 0·2 ,, below ,,	7·6 ,, ,, 1·5 ,, ,, ,,	166 ,, ,, 5 ,, ,, ,,

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

A great deal of ingenuity has been expended on theories that have struggled with the question of the origin of petroleum. To those who, like myself, have been engaged in the manufacture of petroleum, have produced it in tons and hundreds of tons, all this learned discussion appears very crooked and far-fetched. We know that if certain kinds of coal are enclosed in any kind of surrounding, such as an iron, or clay, or brick retort, and if this is heated moderately and *slowly*, the slower and more moderately the better, we obtain liquid hydrocarbons not merely similar to the petroleum of the natural springs, but actually the same; that we obtain gases and vapours identical with those that escape from such springs, and we find left behind in our retorts a material identical in chemical composition with anthracite. Its mechanical structure is not quite the same; it is more porous; but if this porous coke be subjected to such pressure as that to which anthracite certainly has been subjected it becomes anthracite.

The simple inference, therefore, is that certain beds of bituminous coal have been heated moderately and slowly, and thus their volatile constituents have been driven from them, as from that in our retorts, and that the non-volatile coke has been left behind, as in our retorts, and this having been subjected to the pressure of the superincumbent strata, has acquired the form of compressed coke, or anthracite.

In controversion of this very simple view, we are told that petroleum is not found associated with coal, but that the springs occur in Silurian, Devonian, Cretaceous, and other non-coal-bearing regions. This presents no difficulty to the oil-maker, who is accustomed to attach pipes to his retorts, and carry the oil vapour to condensers, and the liquid oil from them to considerable distances from his coke. He knows that if his retorts were porous and imbedded in other porous material the vapours would penetrate that material, and there become condensed when it reached a cooler stratum, and that after condensation the liquid would flow downwards, until it reached the limits of the porous material, and that it would there accumulate.

These are exactly the conditions under which many coal-seams have been converted into anthracite. That such conversion has taken place is proved by the fact that there are seams from which the hydro-carbons have been distilled at one end, that end being converted into complete anthracite, the other end of the same unbroken coal remaining highly bituminous, and the intermediate portions forming a gradation due to varying degrees of coking. Mr. Hull (describing the Russian coal-fields) says, "It is a most remarkable circumstance, in connection with the Donetz formation, that the same beds of coal, from being highly bituminous in the western parts of this coal-field, pass by imperceptible gradations into anthracite in the eastern parts, in a manner analogous to that of the South Wales coal-field in our own country."

We know how water-springs are formed, and we are justified in supposing that petroleum springs are similarly formed. As a striking and typical example of a water-spring, I will take that of the celebrated St. Winifred's Well, which has given its name to Holywell, in Flintshire. Here, at a place that is otherwise not more watery than the country generally, a stream of water flows upwards from the ground, pouring forth the enormous quantity of 21 tons, or 4,700 gallons, per minute, equal to a daily supply of 6,768,000 gallons. This forms a small river that runs down to the estuary of the Dee. Why does the water issue there? The answer is very simple. The porous carboniferous strata and the millstone grit of the neighbourhood both slope downwards towards Holywell; there they terminate in a fault which presents to them a wall of compact limestone, and thus the underground flow is suddenly arrested; but its sources being much higher than the place of sudden arrest it, rises to the surface there, and then overflows. Before doing this some of the water has travelled many miles underground.

If water can thus flow through the coal-measure rocks and the millstone grit below them in Flintshire, why should not the liquid distillate from heated coal do the same in these identical rocks at other places? and why should it not accumulate when it meets a barrier of impervious limestone? As a matter of fact, the richest oil-wells like the richest water-springs, do actually occur where porous strata encounter compact rocks, usually limestone rocks.

A little reflection will show that the demand of those who say that if petroleum was formed from coal it should be found associated with it is one that asks for a physical impossibility. All who have had to do with coal-mining know, to their cost, that the rocks both above and immediately below ordinary coal-seams are freely permeable by liquids, as their pumping machinery and pit-tubbing proves, and therefore any liquid hydro-carbon that may have been formed in heated carboniferous strata in times far distant must have percolated far away from the seat of its origin, must have travelled as far as the porous rocks extend, even though that be hundreds or even thousands of miles distant. This would especially occur where the coal-bearing strata were covered with compact rocks of later formation, not permitting surface water to reach them, and such has been the case and is the case with those deeper coal-bearing strata that by reason of their depth must be heated.

Reflecting a little further on these facts, we may arrive at a very consolatory economical conclusion. It is well known that there is much coal far below human reach, the chief impediment to working it being the steadily increasing heat of the earth as we proceed downwards. If I am right in the above we may not lose all that fuel; the coke may remain hopelessly buried, but the hydrocarbons distilled by the heat into vapours will force their way, in gaseous condition, through the heated rocks, very slowly, but not less surely, until they come to cooler strata, then they will condense and accumulate where their further progress is barred by compact rocks, and thus their richest constituents, the hydrocarbons, may be utilised by man as gas-wells and oil-wells, such as abound in Pennsylvania, such as pour up from the sea-bottom on the Californian coast, such as have been running to waste for thousands of years into the Caspian, and such as have formed the great paraffin-pitch deposits of Trinidad.

It should be noted that limestone rocks are specially addicted to cavern formation, owing to their solubility in water charged with carbonic acid, that in some places these caverns extend for miles as tunnels, through which subterranean rivers flow, and in which subterranean reservoirs are standing. The phenomena displayed on boring into the American oil-wells indicate the existence of similar reservoirs of oil in the limestone rocks, oil that has probably found its way there through fissures.

In reference to the theory of animal origin of petroleum, I cannot refrain from reminding its advocates that their objection to the theory above advocated, based on the non-existence of oil with coal, applies to their own theory, as the quantity of animal matter demanded vastly exceeds that of the few fossils found in the oil regions.

Besides this, it should be understood that while petroleum has the same composition as the paraffin distillates obtained by slowly heating certain kinds of coal, both crude petroleum and the solid paraffin wax it contains in solution are widely different, both in composition and properties, from the adipocere which is supposed to be the animal basis of petroleum. Adipocere is a complex soap; Chevreul found it to be composed of a large quantity, of margaric acid and a small quantity of oleic acid, combined with ammonia, potash, and lime. Fourcroy describes it as an ammoniacal soap. Petroleum contains neither of these substances, but a series of special hydrocarbons of the marsh-gas series, *i.e.*, of the products of vegetable composition. Adipocere is readily decomposed by atmospheric and other chemical agencies. Paraffin derives it name (parum affinis) from the stability due to its chemical apathy.

It is a mistake to state that no petroleum is found associated with coal. I visited a coal-mine in Shropshire, known as the "tarry pit," where it ran down the sides of the shaft and filled the "sumph" below. A publican in South Staffordshire found a gas-jet, like those of Pennsylvania, in his cellar, lighted it, and sold much beer in consequence to curious visitors. But for reasons above stated the accumulation of large quantities is impossible in such places.

ASTRONOMY IN CHINA: THE PEKIN OBSERVATORY.

VICE-ADMIRAL MOUCHEZ has just received from Pekin, for the Astronomical Museum which he has founded in connection with the Observatory of Paris a series of photographs representing the Pekin Observatory and the instruments there erected. By the courtesy of our contemporary *La Nature* we are enabled to place these curious views before our readers, and thus give them an exact idea of the present state of astronomy in the nation which has cultivated it with the greatest zeal, for the longest time, and among whom it has received the most remarkable developments.

Astronomical functions have not ceased to be held in honour in China, and the Observatory of the Celestial Empire is at present under the direction of an uncle of the Emperor, who ranks as the fifth prince of the blood, and bears the title of Chancellor.

The number of persons attached to this establishment is more considerable than that at Paris. It amounts, including students, to 196. The chief functionaries after the Chancellor are a Chinese director and a Tartar director, having the right to wear a button of a precious stone, and to bear on the chest the image of a sea-raven. Then follow two sub-directors, one Chinese and one Tartar, and two assistants entrusted with calculations. These latter, prior to the expulsion of the Jesuits, were always foreigners. Two other functionaries require to be noted. The first is the keeper of the buildings, and the second the custodian of the water-clocks, as chronometers have not been as yet introduced into the observatory, any more than have telescopes.

The calculators of the Observatory possess tables constructed or rectified by the Jesuits in the seventeenth century, which are used in their calculations, and which they keep carefully hidden. Hence, contrary to the general principles of the Chinese Government, the astronomical functions have become hereditary. But on the other hand, they are purely honorary.

The strictly scientific functions are not very difficult to execute, since in Pekin itself there are some private observatories attached to the European embassies. Besides, the missionaries have organised at Zi-ka-wei an observatory of the first rank, where all the modern methods are carried out with carefully selected instruments. This establishment is situate at 800 kilometres to the south-east of Pekin, in the neighbourhood of Shanghai. The astronomers of the Chinese Government can thus, with little trouble, carry on the conversion of the calculations.

But they have also to discharge a more delicate function, in which they cannot be assisted by European *savants*. This is to determine the lucky and unlucky days, an operation of the greatest importance in a country where a faith in astrology is universal. They have, besides, like the ancient Augurs of Rome, to consult omens, which they do in a manner showing great simplicity.

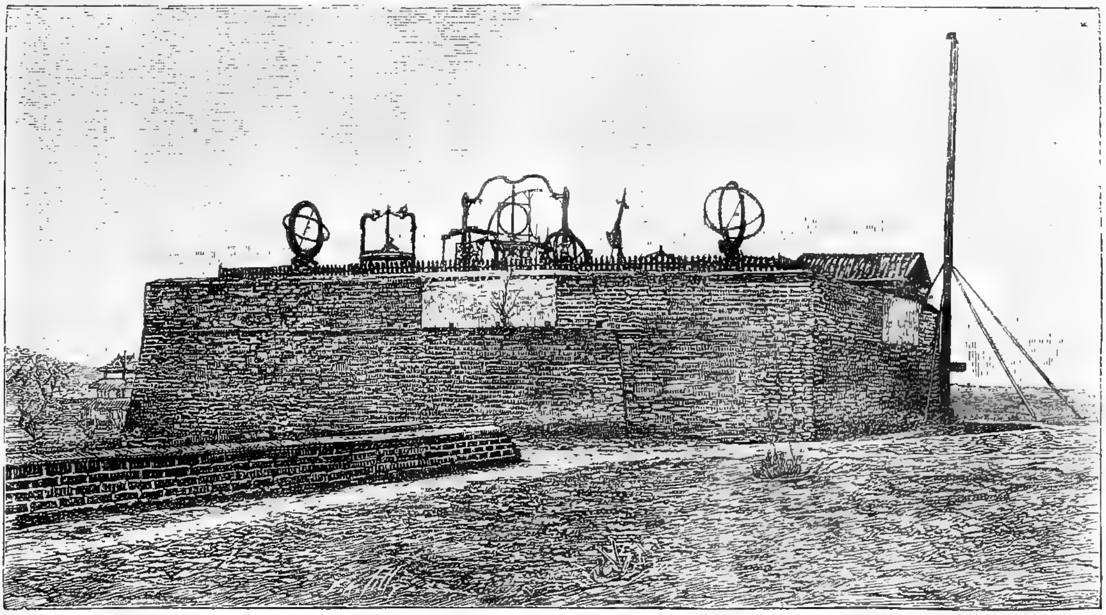

FIG. 1.—GENERAL VIEW OF THE OBSERVATORY.

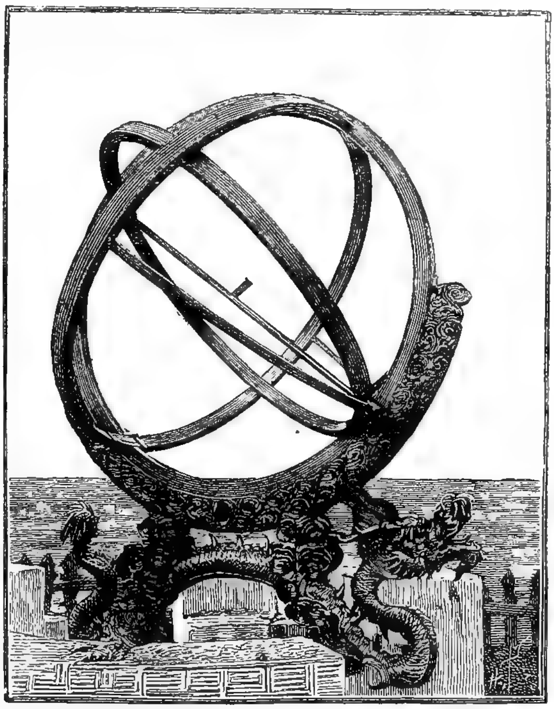

FIG. 2.—BRONZE ARMILLARY SPHERE, SUPPORTED BY DRAGON MADE IN THE SEVENTEENTH CENTURY.

The council of the Observatory of Pekin meets in full conclave on the evening of the last day of the year, and remains sitting until midnight, when the new year begins. At this moment the astronomers look from what quarter the wind blows, which they ascertain by means of sacred banners set up for the purpose. On February 14th, 1888, at the beginning of the twenty-fifth year of the seventy-sixth cycle, which is not yet completed, they ascertained that the wind was north-east, a point considered as the most favourable omen. They drew hence the conclusion that all kinds of felicity might be expected during the next twelve months.

The observatory is placed on a terrace of some yards in height, and of a square form, situated along the fortifications of Pekin. It is traversed by a tunnel, through which passes the road, and in case of need it could be utilised for the defence of the city.

Our figure No. 1 shows this terrace with the collection of instruments which the Chinese astronomers use, or are supposed to use, in their observations. The other figures show in detail the manner in which they are constructed. Fig. 2 gives an idea of the luxury and art with which some of the instruments are mounted.

Father Lecomte, who had to manage these instruments at the end of the seventeenth century, says that the workmen who executed them had been much more concerned with the perfection of the figures of dragons with flames issuing from their throats than with the accuracy of the graduations. He thinks that a quadrant of eighteen inches executed at Paris by the opticians of his time would give more useful results than the great six-foot circle executed at Pekin. The limb is divided into graduations of ten minutes, which is the limit of accuracy attainable if the graduation had been carefully executed, and if the instrument had been fitted with sights.

Father Lecomte describes the installation of a quadrant of a very careful construction, probably the one which Louis XIV. sent to the Emperor Kang-hi.

The lead which marks its vertical position weighs a pound, and hangs from the centre by means of a delicate copper wire. The index is movable and slides freely on the limb. A dragon, coiled up and surrounded with clouds, comes from every side to seize the bands of the instrument, lest they might move out of their plane. The entire body of the quadrant is in the air, traversed by the centre of an immovable axle, upon which it turns towards those parts of the heavens which are to be observed. Because its weight might cause some oscillation, or cause it to leave its perpendicular position, two shafts are placed at the sides. They are secured at the bottom by two dragons, and connected to the middle shaft by clouds which seem to descend from the air.

(To be continued.)

EXAMINATIONISM.

THE *Medical Press and Circular* writes:—It has for years been painfully evident that the effect of the examination mania on education is not productive of the good that had been anticipated. The great vice of examinations as at present conducted, is that a strain is put on one department of the memory to the quasi-exclusion of others. The acquisition of facts is an essential part of general training, but it is, after all, only a means to the end, the end being to furnish the reasoning powers with the requisite data to proceed upon. To be available, facts require to be thoroughly assimilated, so that they can be perceived at the same time. This perception is the basis of judgment and so-called experience. If the mind be over-weighted with ill-assimilated facts, the reasoning powers are unable to act to the best advantage, and become stagnant. The amount of acquired knowledge that can be utilised in a given time varies considerably in different persons. It is as with food; what will suffice to give one man an indigestion, will only make another one feel comfortable. The analogy, indeed, can be pushed a good deal further without overstraining. The same food will not suit every stomach, so success should reward, not the ingestion of the largest amount of food, but the utilisation thereof."

So far so good; but our contemporary adds, "The difficulty is of course in estimating the latter, and until the adversaries of examinations succeed in finding a means of measuring *assimilation*, the present system, with all its drawbacks, will perforce continue."

This is a somewhat lame and impotent conclusion. In some departments means of testing *assimilation* are already known. In almost every science the production of original work is proof positive that the student has assimilated the instructions given, and he ought, therefore, to be spared the superfluity of examination in that science.

There exists also a test better than examination in the case of candidates seeking to rise from a lower to a higher grade, *e.g.*, in the choice of surgeon-major or surgeon-general in the army. Let the aspirant be judged *rebus gestis*, by his practical results, by the skill and attendant success which he has already shown in the discharge of his duties. In fact, we may say that if it once becomes known that officialism is willing to admit that examinations are of very doubtful efficacy, suggestions for a better method of selection will not be lacking.

THE UTILITY OF BEES.

AS the benefits derived by man from bees are by no means fully understood, we take the opportunity of laying before our readers certain results observed on the Continent, and which have been in part published in *La Nature*. M. Eugène Jobard, editor of the Lyons paper, *Le Bien Public*, has recently published a very important work on this subject.

He does not lay the greatest weight on the direct products of the hive-bee, the honey, and the wax, although these have a considerable commercial importance, but on the part played by the bees in the fecundation of fruits, vegetables, cereals, and the natural and artificial grasses. A study of their activity in this respect enables him to declare that rational bee-keeping would revolutionise agriculture by doubling the production of vegetables and fruits.

In Saxony, he tells us, there are districts where the farmers grow nothing but seed-wheat, which they sell at a high price. All these farmers possess hives which, instead of being fixed, are installed upon little carts, and at the moment when the wheat is in flower, each farmer removes his movable hive to the midst of his wheat fields.

When the fact was mentioned one day at Velars in presence of several farmers, one of them exclaimed, "This is the reason why my finest wheat is always that which I reap near my hive."

A similar declaration was made some time after by the Mayor of Lanques, an extensive farmer of Haute Marne. He says, "As I intended, I have sown with wheat all the fields near my hive. This year, as heretofore, the grain from these fields is incontestably superior to that of all the neighbouring land. The ears are stouter, better filled, and this year again I shall select this wheat for seed.

"But further, the ears in the fields nearest to my apiary are finer and heavier than those in the rest of the district."

As to the fecundation of fruit trees, the question is proved by an assortment of facts which leave no room for doubt. For instance, the clergyman of Ninville (Haute Marne) introduced some hives in 1883 in his garden, where, during twenty years, some thirty fruit trees, in spite of his intelligent care, had borne no fruit. But after the introduction of the bees, pears and apples abounded on the trees which had hitherto been regarded as barren.

Mr. Jobard cites an observation made by Darwin, which will doubtless be familiar to many of our readers. He made very remarkable observations on the fecundation of plants by bees, which he repeated yearly, and always with the same results. Near his bee-hive he sowed colza and white clover, and when the plants were about to flower he covered some of the heads with light gauze, and thus protected them from the action of bees. When the seeds were ripe, he took both from the plants thus protected and from those which had been visited by the bees the same number of seed-heads and counted the seeds. The balance in favour of the plants fecundated by bees was on the average 50 to 60 per cent., and moreover the individual seeds were much finer than those of the covered plants.

In clover there occurred, besides, a remarkable phenomenon. The clover fecundated by the intervention of bees always grows larger than that sheltered from them. Hence Darwin drew the conclusion that this remarkable development of the plant was due to the constant suction effected by the bees in the corollæ, in which the honey is incessantly renewed. If the plant is not sufficiently emptied there occurs a congestion and an arrest of development. What confirms this observation is that of two tufts of clover flourishing together, one covered and the other open, the latter continued to grow, whilst that excluded from contact with the bees became stationary as soon as its flowers were expanded.

The neglect of apiculture, says M. Jobard, is one of the greatest errors committed by farmers, and this neglect is most general in France.

In Austria, Germany, Italy, Hungary, in Russia and the United States apiculture is encouraged in an especial manner. In Alsace-Lorraine the German Government subsidises very liberally two apicultural papers, which have been established since the annexation of the provinces.

At Vienna there is even an Apicultural Academy, under the presidency of the Emperor.

If we talk about bees to one of our great agriculturists he will reply that his time is too precious to be spent on such trifles. The eminent agriculturist who allows himself to be beaten on his own ground by foreign nations is not aware that there exist in America at least thirty financial companies, each possessing a capital of five to six millions (dollars or francs?) which they employ in—what? In spreading hives over the American territory. The Americans have been the first to act upon the discovery that bees are essential to the successful fecundation of plants. They are aware that from them alone may be obtained thousands of tons of sugar which nature has distributed so freely.

M. Jobard further informs us that with honey the strength of wines may be raised, and that wines thus treated acquire a delicacy not otherwise to be obtained.

(To be continued.)

SOME RECENTLY DISCOVERED FORMS OF MICROSCOPIC CRUSTACEA.

(*Part I., continued from p.* 574.)

Cymbasoma herdmani, I.C.T., plate iii. One specimen only of this very remarkable species was recently taken between Anglesea and Puffin Island, and it has since been recorded from Jersey.

Length 1-10th inch, the cephalothorax is nearly the same width throughout, is truncated at each end and five-jointed, the first joint being nearly equal in length to the remaining four. The anterior antennæ of male (fig. 2)

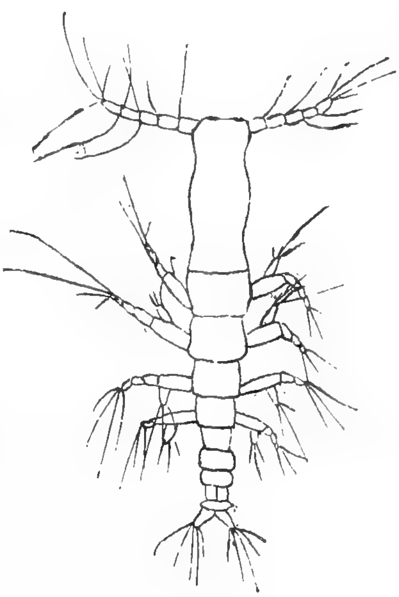

Fig. 1.

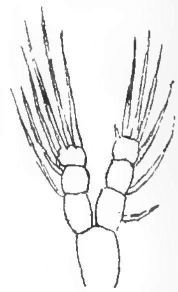

Fig. 3.

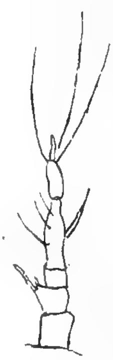

Fig. 2.

Cymbasoma Herdmani, I.C.T., figs. 1-3.

Fig. 2. Anterior antenna of do. 250
Fig. 3. One of swimming feet of do. 250

are five-jointed, strong and muscular, the fourth joint being nearly equal in length to the preceding three; there is a hinged joint between the fourth and terminal. There are several spines and setæ throughout the antennæ, the apex bearing a terminal claw. The first four pairs of swimming feet are alike in structure (fig. 3), the basal joint being very large. Both branches are three-jointed, and clothed with strong spinose setæ. The abdomen of the male is five-jointed, gradually getting smaller, the fifth being wedge-shaped laterally. The caudal segments are divergent and stumpy, a little longer than broad, each terminated by six spinose setæ.

The only hitherto known species of this genus, *C. rigidum*, Thompson,* was taken by tow-net off Teneriffe.

The total number of species of free-swimming Cope-

* Described in a paper read before Linnæan Soc., London, Lin. Jl. vol. xx., 119.

poda known to Britain amount to about one hundred and seventy. Of these about twenty-five are inhabitants of fresh water, the rest being marine, with the exception of a few species whose habitat is almost entirely brackish water.

But in addition to these are a considerable number of parasitic and semi-parasitic Copepoda. The former are found attached to fishes, annelids, various crustacea, and more especially to the compound ascidians, where they subsist on the juices of their amiable hosts, apparently causing little, if any, inconvenience to them. Many of the semi-parasitic species appear at times to leave their hosts and wander on their own account through the water, but they are comparatively rare, and usually found in tow-nettings taken after sundown or during the night.

ANIMAL GEOGRAPHY.

MOST of our readers have, doubtless, a general acquaintance with the view propounded by Dr. P. L. Sclater, and elaborated by A. R. Wallace in his great work the "Geographical Distribution of Animals." These authorities admit six main regions—the Palæarctic, the Ethiopian, the Oriental, the Australian, the Nearctic, and the Neotropical—and they base their arrangement mainly on a consideration of the mammalia, endeavouring to harmonise the boundaries thence deduced with the distribution of other animals.

Mr. J. A. Allen—not to be confounded with Mr. Grant Allen—proposes eight "realms"—the Arctic, the North Temperate, the American Tropical, the Indo-African Tropical, the South American Tropical, the African Temperate, the Australian, and the Antarctic. Other classifications, obviously of less merit, we cannot here mention.

Dr. A. Reichenow, in a recent very elaborate memoir, an abridgment of which appears in *Humboldt*, recognises in the first place an Arctic "Zone" extending from the north pole southwards to the utmost border of the forests alike in the eastern or western continents. Reichenow's Arctic Zone, therefore, includes the most northern portions of the Palæarctic and Nearctic regions of Sclater and Wallace. The whole of America, from the northern boundary of the forests southwards to Cape Horn, is characterised as the Western Zone, and corresponds to the whole of the Neotropical of Sclater and all his Nearctic region south of the forest limit. In justification of this arrangement Reichenow contends that the birds of North America have a decidedly South American character, and have had their "centre of creation or origin" in the latter continent.

In the eastern hemisphere we find greater complexity. The temperate portion of Europe-Asia extends over 180° of longitude, and its southern boundary is more or less closely connected with several parts of the globe situate in the tropics, but distinct from each other. Thus the immigration into the temperate regions has taken place, in his opinion, not from one centre, as in America, but from several. Like Allen, Reichenow concludes that the Malayan (Oriental of Sclater and Wallace) cannot be regarded as of equal value with the former, but must be combined with Africa to form a great territory, the Ethiopian-Malay region, whilst, on the other hand, Madagascar has a peculiar and independent fauna. Besides these two regions, we have in the eastern tropics only a third, that of Australia. Immigration into temperate Europe and Asia might have taken place from any of these three faunal territories. But in fact we find that the Eastern Temperate bird fauna has no relation to the Australian and the Madagascar fauna, but has a predominating Ethiopian-Malay character. Hence, ornithologically speaking, Europe and Asia must be combined with the Ethiopian-Malay regions to form the Eastern Zone, comprising accordingly the Palæarctic region of Sclater and Wallace from the northern limit of the forests, the Ethiopian and the Oriental regions as far as "Wallace's line." This zone is divided into three regions (a "region" in Reichenow's system corresponds to a "sub-region" in that of Sclater and Wallace). The Eastern Temperate region comprises Europe from the above-mentioned tree limit, North Africa to the Senegal and further east to 15° north latitude, Arabia except the southern coast, Asia from the tree limit to the Himalaya range and its eastern and western extensions, and the Japanese Islands.

The Ethiopian region includes Africa from the Senegal and the 15th degree of north latitude southwards, the south coast of Arabia, Socotra, the West African Islands, and St. Helena.

To the Malay region belong India and South China, the Sunda Islands, including Borneo and Java, Formosa, the Philippines, and the Chagos Islands.

The Madagascar and Australian faunal territories, though, of course, so far smaller, are considered equal in rank to the Western and the Eastern Zones, and are characterised as the Madagascar and the Southern Zones. The former admits of no subdivision; it includes, besides Madagascar, the Mascarenes, Comoros, and the Seychelles.

The Southern Zone resolves itself into two regions; the one of these, the Australian, includes Australia proper, Tasmania, New Guinea, the Malay Islands to the east of Wallace's line, including Celebes, Lombok, and the Moluccas, and the Polynesian Islands. The New Zealand region comprises, in addition to New Zealand, the Chatham, Auckland, Campbell, and Macquarie groups and Norfolk Island.

As the sixth and last primary division comes the Antarctic Zone, comprehending the south polar islands. These latter do not, as it might have been expected, show any connection with the nearest continents, but have a striking similarity among themselves. Thus of thirty species of birds which nest in Kerguelen's Land and South Georgia, islands far remote from each other, the half is common to both. The chief islands belonging to the Antarctic Zone are South Georgia, Prince Edward's, Crozet, Kerguelen, Macdonald's Islands, St. Paul's, and North Amsterdam.

Having thus expounded, without by any means advocating, Dr. Reichenow's system, we must point out that it differs less from that of Sclater and Wallace in the boundaries of the respective faunal territories than in the rank which it assigns them. The Australian and Oriental districts retain precisely their former boundaries, but the latter is reduced from the rank of a primary to that of a secondary division. On the contrary, Madagascar rises to the first rank.

The author, we think, scarcely pays due heed to the palæontological evidence, which is certainly less abundant in case of birds than among mammals and reptiles. By going back only, as it appears, to the close of the Glacial epoch, he is enabled to speak of the immigration of tropical forms into temperate Europe and America, and thus to introduce the notion, delusive as it seems to us, of centres of creation or origin, a theory devised in France to weaken, if possible, the evidences of evolution.

General Notes.

Cutch and Gambier.—H. Trimble, in the *American Journal of Pharmacy*, controverts the common notion that cutch and gambier are identical in composition.

Blindness in Russia.—Of the cases of blindness in Russia, which are said to be more abundant among the Finnish-Mongolian races than among those of Aryan or Semitic origin, one-eighth are due to smallpox, and one-half only to direct disease of the eye.

Rats and Electric Lighting.—M. Helbig, of Rome, writes to *La Nature* that the electric lighting in that city had been interrupted in a very curious manner. A rat, in passing over a commutator, formed a short circuit, thereon the cut-outs immediately melted.

A New Microscopical Society.—A microscopical society is in the course of organisation at Edinburgh, and it seems likely to begin operations under favourable auspices. Curiously enough, a resolution was carried declaring ladies ineligible for membership.

Prevalence of Rickets in Sheffield.—Dr. C. V. Gwynne says that few towns in the empire can compete with Sheffield in the production of rickets, and to this it is in no small extent due that the inhabitants possess the smallest physical type of any large town in the kingdom.

The Proposed Zoological Garden at Washington.—It is painful to learn from the *American Naturalist* that the proposed Government Zoological Garden at Washington has been rejected on the plea of economy. This in the case of a Government which is at a loss how to spend its surplus.

Rain in Egypt in 1888.—In the memory of man, says *La Nature*, no rain has fallen in Egypt in the month of June. This year on June 3rd the following quantities have fallen and have been duly measured: at Alexandria 0·2 millimetre, at Cairo 1·15, at Port Said 5·6, and at Suez 1·0 millimetre.

The Arrest of Civilisation in China.—Miss Adele M. Fielde (*Popular Science Monthly*) ascribes the arrest of Chinese civilisation in part to the peculiar marriage customs of that country, in virtue of which "sexual selection" is rendered inoperative, as the contracting parties have before espousal no opportunity to judge of the strength, beauty, and intelligence of their consorts.

The Survey of the Nicobar Islands.— Colonel Strahan, who has just surveyed this group, reports their total superficies as 618 square miles. The highest summit is 2,105 feet above the sea level. The scenery is said to be of indescribable beauty. Some of the rivers are navigable for boats to a considerable distance. The natives are apparently allied to the Malays; they are of a reddish-brown colour, finely developed, and have a remarkable talent for learning languages.

Colour of Lightning.—In a storm which occurred at Altona in August last, some interesting observations were made on the colour of lightning. Of the ten first flashes three were red, one greenish-red (a peculiar colour), one reddish-blue, one blue, one greenish-blue, and three doubtful. Of the ten following there were four red, of the ten next six red, and of the following ten eight red. Of the seven last, three were completely red. In the second part of the storm the number of the red flashes, according to the *Meteorolog Zeitschrift*, was still greater.

The Purity of Gold.—Dr. Cohen (*Naturwissensch Verein fur Neuvorpommern und Rügen*) discusses the arguments on behalf of the chemical theory of the deposition of gold in placers compared with those in favour of its mechanical origin. He shows that some of those urged in favour of the chemical theory are of doubtful existence. Thus it has been stated that placer gold always contains less silver than vein gold from the same region. Analyses of specimens from Buttons Creek, in the South African gold-fields, show that such is not always the case. Thus a sample of vein gold yielded 94·48 per cent. of gold, and 5·16 of silver, whilst two samples of placer gold showed respectively 91·38 and 95·02 of gold, and 6·49 and 4·60 of silver. He thinks that placer gold is mostly derived from the breaking down of gold veins, but that there is occasionally, in addition, a deposition of the metal from its solutions.

The Conditions of the Earth's Interior.—The following considerations put forward in the *American Naturalist*, by Ira Sayles, claim serious attention. It has been held by some authors, that no crust can form over a molten sphere, for, say they, when the surface cools *it is heavier than the molten mass within, and must necessarily sink; so that the centre would become solid first.* (Solid tin floats upon melted tin!) Second, ejected lavas always cool on the surface first, while yet the deeper portions are molten, and continue to flow long after a solid crust has been formed. Thus does direct observation show the falsity of their hypothesis. Third, these authors neglect the fact that the lighter materials lie like a thick blanket around the outside of the sphere, and even though they were to become frozen, they could never sink into the molten heavier matter. Cold iron will not sink in molten gold; cold silicon cannot sink in molten iron. Fourth, these lighter materials are highly non-conductive to heat, and hence husband the internal heat.

Department of Science and Art.—Mr. W. Crookes, F.R.S., has presented to the Department of Science and Art a collection of sixty-eight radiometers and similar instruments for permanent exhibition in the science galleries of the South Kensington Museum. They illustrate the steps by which Mr. Crookes was led to the construction of the radiometer, and to the production of motion and of phosphorescence by streams of electrified molecules in high vacua. Many of the instruments are of the greatest historical interest. Among them is included the first radiometer, with many others which are described in Mr. Crookes's papers in the Philosophical Transactions of the Royal Society. Others are of considerable value, as they contain collections of diamonds, rubies, etc., for the exhibition of the phenomena of phosphorescence. Nearly all are in working order, and will be of great use in illustrating lectures to students in the Normal School of Science at South Kensington. The collection will be on view in the galleries of the Museum in Queen's Gate as soon as the necessary stands and sittings are completed.

Interesting Fossil Remains.—Mr. R. Etheridge has recently examined a small collection of fossil bones found by Mr. A. S. Cotter, of Cainwarra Station, Paroo River, New South Wales, in sinking a well at Thorbindah, near that place. He states that they consist chiefly of those of the kangaroo and the large extinct diprotodon; but amongst them were two bird bones. One of these proves to be the right shank bone of a very large bird, allied to, but distinct from the emu. It exceeded the latter in stature and robustness of limb, and in Australia took the place of the gigantic extinct moas of New Zealand. The first intimation of the existence of such a bird in Australia is due to the late Rev. W. B. Clarke and Mr. Gerard Krefft, who in 1869 referred a thigh bone of a large bird found in a well sinking on the Peak Downs to the moa. This determination, however, was afterwards shown by the veteran osteologist Professor Sir Richard Owen to be only partially correct, and in naming the bone *Dromornis Australis* he showed that it represented a stuthious extinct bird, having more affinity to the emu than to the moa. Since then a left shank bone was sent to Professor Owen from Mount Gambier Ranges, South Australia, and in 1876 a large pelvis was found in the Canadian lead, near Gulgong, both of which are believed by Sir Richard to have belonged to his *Dromornis*. The late discovery is, therefore, a very welcome addition to our knowledge of the extinct Australian avifauna.

Seedlings of Sugar-cane.—The sugar-cane has been cultivated for so long a period that its native country is unknown. Bentham states that "we have no authentic record of any really wild station for the common sugar-cane." Further, according to the *Kew Bulletin* for December, the sugar-cane so rarely produces mature seeds that no one appears to have ever seen them. In botanical works the subject is often mentioned, but apparently only to restate the fact that observers in all countries "have never seen the seeds of the sugar-cane." The authorities at Kew have been working at this subject for several years. It was felt that if a sugar-cane producing ripe seeds could be found a most interesting and important line of inquiry would be opened for improving the saccharine qualities of the sugar-cane, in the same way as that so successfully adopted with regard to the beet. Hitherto the sugar-cane has been reproduced under cultivation solely by means of buds and suckers. The improvement of the cane has therefore been restricted to chance variations occurring at wide intervals, and probably escaping altogether the observation of the planter. Now all this is likely to be changed. It appears that at Barbados seedlings of sugar-canes have been successfully raised by Professor Harrison, and among these seedlings are several different kinds indicating hybridity of a definite sort, such as would be expected to arise from the crossing of different varieties. It is to be hoped this subject will be fully and clearly followed up as a definite field of investigation. In any case the possibility of improving so important and valuable a plant as the sugar-cane possesses general interest.

The Public Health.—The Registrar-General's return for the week ending December 1st shows that the deaths registered during that period in twenty-eight great towns of England and Wales corresponded to an annual rate of 17·8 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The six healthiest places were Hull, Brighton, Nottingham, Leicester, Portsmouth, and Bradford. In London 2,367 births and 1,352 deaths were registered. Allowance made for increase of population, the births were 372 and the deaths 412 below the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had been 19·7 and 17·2 in the two preceding weeks, further declined last week to 16·5. During the first nine weeks of the current quarter the death-rate averaged 18·7 per 1,000, and was 1·4 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,352 deaths included 141 from measles, 24 from scarlet fever, 34 from diphtheria, 20 from whooping cough, 11 from enteric fever, 1 from an undefined form of continued fever, 13 from diarrhœa and dysentery, 1 from cholera, and not one from small-pox or from typhus; thus 245 deaths were referred to these diseases, being 22 above the corrected average weekly number. In Greater London 3,068 births and 1,678 deaths were registered, corresponding to annual rates of 29·0 and 15·8 per 1,000 of the estimated population. In the Outer Ring 16 deaths from measles, 7 from diphtheria, and 5 from whooping-cough were registered; 7 fatal cases of measles occurred in West Ham sub-district, and two of diphtheria in Willesden and in Tottenham sub-districts.

Talking Machines.—If the improved phonograph, and its rival the graphophone, never succeed in rising to be more than toys, they will at least have afforded material for several amusing articles in which their possible uses have been discussed. In looking up a subject in the *Mechanics' Magazine* for 1839 we lighted on a letter on "Mechanical Probabilities," by Chas. Thornton Coathupe, from which we extract the following: "Musing over mechanism and mechanies, I thought of Babbage's 'calculating-machine,' and then of the embyro 'talking-instrument,' and felt that a space in mechanics was yet imperfectly explored which, if cultivated, might perchance prove of essential benefit to mankind. Perhaps here I slept, and dreamed; for having conceived our religious doctrines to be of an immutable nature, and that almost every text in our sacred Scriptures had received the fullest expositions of our ablest divines over and over again, and that little more could be advanced which had not been promulgated by voluminous edited publications, I fancied every pulpit had become a 'talking instrument,' and every sermon a steam-engine of very 'small power,' every clergyman a 'barrel' 'pricked' for its text. I thought of the saving to the agriculturists in tithes, and to the more important public in dues, fees, and other taxation, and again felt too happy. I then dreamed of schools for public instruction, in which the master's desk was a steam-engine, the master the 'barrel' 'pricked' either for grammar (English, Latin, or Greek) or for mathematics (pure or mixed). I fancied the usher the engine-man, consuming his rod in 'teasing' the fire, while the boys stood round Babbage's machine with their slates in hand, listening to the explanations from the talking barrel. I fancied I saw barrels representing professors of Oxford and of Cambridge, 'shifting' according to expediency, some branded 'multum in parvo,' intended for the elucidation of four or five branches of natural philosophy, in lieu of so many professors." Can any reader give us further information about the talking-machine referred to?

SIMPLE EXPERIMENTS IN PHYSICS.

As a means of illustration, nothing can excel projection by means of a good optical lantern. Not only can pictures and diagrams be shown clearly to a large assemblage, but apparatus of various kinds may be projected on a mammoth scale; many chemical actions may be exhibited; the phenomena of light, heat, electricity, and magnetism may be shown in various ways. In fact, there is scarcely a branch of physics that may not be illustrated in this way. The lantern is becoming

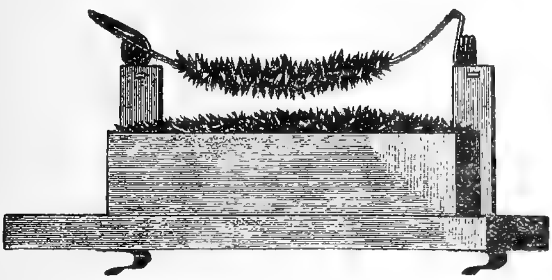

Fig. 1.—Arago's Experiment.

deservedly popular in colleges and schools and for private use. Besides being of great use for general instruction, it affords a means of rational amusement and entertainment. A poor lantern, like any other inferior piece of apparatus, is undesirable. An instrument for scientific work should have a triple condenser, a rectilinear objective, a swinging front for the vertical attachment, a calcium or electric light, polariscopic and microscopic attachments, an erecting prism, and an alum or water tank. Such an instrument may now be pur-

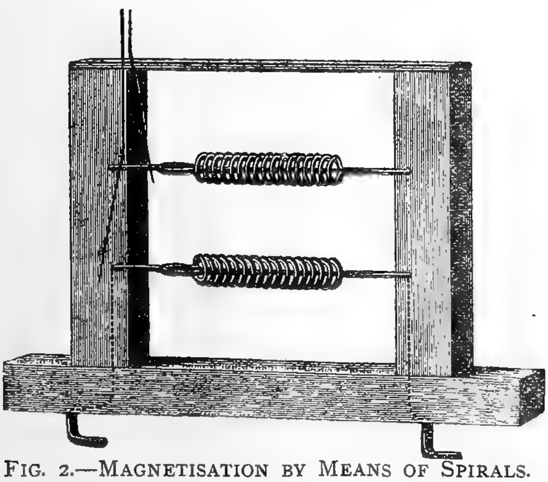

Fig. 2.—Magnetisation by Means of Spirals.

chased for a reasonable price, so that there is no economy in making one's own instrument. It will, however, be found advantageous to make attachments. A simple way of illustrating Arago's experiment, showing the magnetising effect of an electric current on soft iron, is represented in fig. 1. The lantern to which this and other pieces of the apparatus are adapted is provided with two rods, projecting from the front of the instrument and connected with binding posts, which in turn are connected with a battery of dynamo. The base of this apparatus is furnished with spring clips for engaging the conducting-rods of the lantern. To the upper ends of two posts rising from the base are attached the extremities of a copper wire, which is bent into spirals at its fixed ends. The wire is bent twice at right angles, and is curved downwardly between the arms extending from the spirals. The ends of this wire are connected with the clips. On the base below the curved part of the wire is placed a box well filled with iron filings. The box and wire are projected on the screen, an erecting prism being used. The wire is pressed down-

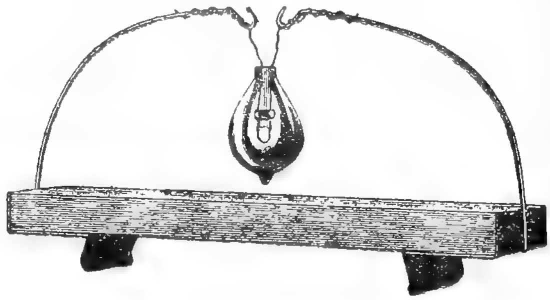

Fig. 4.—Incandescent Lamp arranged for Projection.

ward into the filings, and withdrawn before the current passes, to show that the wire, uninfluenced by the current, is not able to lift the filings. The current is sent through the wire when it is again dipped into the filings. This time it will take up a quantity of the filings, as shown in the engraving, each fragment of iron becoming a magnet, which tends to place itself at right angles to the current. When the current is interrupted the filings fall. In fig. 2 is represented a device for showing the magnetising effect of a helix, also the different

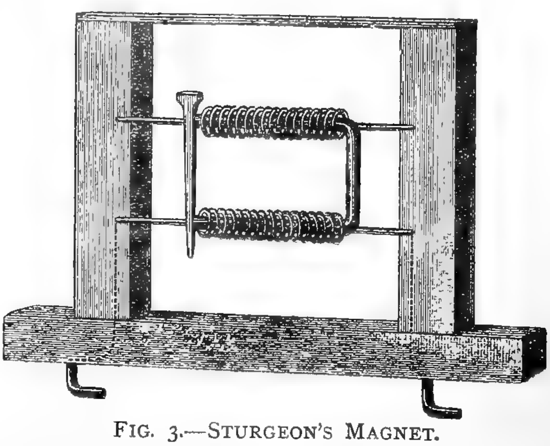

Fig. 3.—Sturgeon's Magnet.

results secured by helices wound in opposite directions. The frame is provided with metal clips for attachment to the rods of the lantern, and two helices which are oppositely wound with respect to each other are stretched across the frame. The ends of the helices are connected with the clips, so that the current passes from one clip through both helices, as indicated by dotted lines, to the other clip. The helices are provided with a coating of insulating varnish. A darning-needle is placed in each helix, and when no current is passing a magnetised cambric needle, suspended by a fine thread, is held near the ends of the needles in alternation. It is drawn toward both alike, and after a current has been sent through the helices it will be found that the darning-needles are magnetic; but owing to the opposite winding of the helices, corresponding ends will have opposite polarity, as will be shown by again presenting the suspended cambric needle to the ends of the darning-needles. It will be attracted by one, and repelled by the other. By placing a U-shaped piece of soft iron wire in the helices, as shown in fig. 3, the construction of the first electro-magnet (Sturgeon's) is clearly illustrated. In fig. 4 is shown a device for projecting the incandescent lamp. It is suspended from two conductors, and its image is thrown upon the screen with a dull light, which is just sufficient to clearly show the outline of the lamp and the black carbon filament. A current is then sent through the lamp, when the filament becomes in-

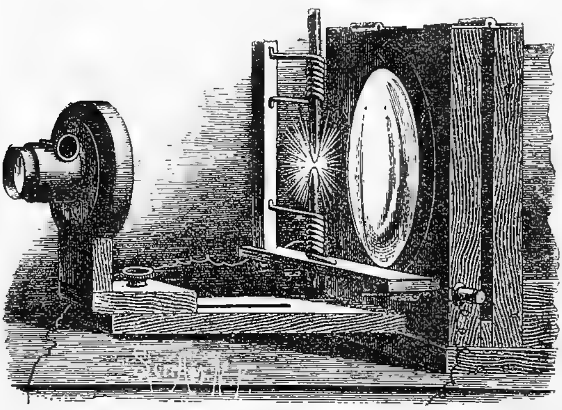

FIG. 5.—PROJECTION OF THE ARC.

candescent, and shows as a brilliant arc on the screen, while all of the parts of the lamp are distinctly visible. In fig. 5 is shown a method of projecting the electric arc, which has the advantage of showing the carbons before the arc is formed, and also of rendering them visible during the experiment. The lamp consists of two wire carbon holders attached to a wooden standard, and connected with the rods of the lantern, as in the cases before described. The carbons are projected with a dim light, showing the crater of the positive carbon and the point of the negative carbon. Then the current is turned on, the carbons are brought in contact and separated, forming the arc, the points soon become incandescent, and the arc light in full operation is seen on a large scale on the screen. These experiments are very striking when seen upon a large screen, the projection of the arc and incandescent lights being particularly interesting.—*Scientific American.*

PORCELAIN SHOT.—Under this name small white globules of porcelain are made in Munich. They are made to take the place of ordinary lead shot used for cleaning wine and medicine bottles, as porcelain is entirely free from the objection of producing lead contamination, which is often the result when ordinary shot is used. Their hardness and rough surface producing when shaken, greater friction, adapt the porcelain shot well for quickly cleaning dirty and greasy bottles, and as they are not acted upon by acids or alkalies, almost any liquid can be used.—*Rundschau; Am. Jour. Pharm.*

ANTIPYRINE IN SEA-SICKNESS.

MANY references to the properties and uses of antipyrine, a coal-tar product, and one of the recent additions to the Pharmacopœia, have been scattered through the daily and weekly journals during the last few months. It has been administered in subcutaneous injections, and recommended as a febrifuge, as well as for neuralgic headache and other ailments, but the most interesting of its numerous applications to the majority is probably its employment against sea-sickness. So many circumstantial details of its virtues in this respect have been circulated, apparently by medical men, that a considerable number of persons are by this time probably convinced that a sea voyage is henceforth deprived of its greatest terror. We even confess to have had a certain amount of this misplaced faith ourselves. It is very gratifying, therefore, to be able to give the experiences of a number of unprejudiced experimenters upon the subject.

A discussion having arisen on the question at the French Academy of Medicine, some one proposed that as the members of the French Association for the Advancement of Science were about to cross the Mediterranean to the meeting at Oran, they should test the assertions made on of behalf antipyrine and other reputed remedies for sea-sickness on their voyage. The suggestion, either from a pure love of scientific experiment or perhaps from the union of that and some small desire to escape the well-known troubles of the voyager, was evidently taken up in a commendable spirit of self-sacrifice, which we regret to say failed to receive its fitting reward. For M. Baudouin, in the *Progrès Médical,* in giving the results of this trial, describes them as deplorable, and the failure as complete, even among those passengers who, not possessing sufficient courage to await the first attacks of sickness, had taken the antipyrine two or three days before embarking. On the steamer *La Ville de Rome,* for instance, out of 300 passengers, only four sat down at the table on leaving Marseilles, although sixty persons at least had taken from one to two grammes of antipyrine in the previous two hours. Moreover, M. Rollet, one of the passengers, asserts that several of his fellow-travellers accuse antipyrine of actually causing sickness, and M. Laborde affirms that the ingestion of this remedy (?) increases very greatly the afflictions so familiar to those who are subject to sea-sickness. The condemnation of antipyrine seems complete when it is added that some of the passengers from Marseilles to Oran, who suffered severely after taking it, returned without discomfort over a sea quite as rough as it had been on the outward passage.

THE POISON OF THE MOSQUITO.—Professor Macloskie (*American Naturalist*) shows that the mosquito, in addition to septic poisons which it may transfer from one person to another, elaborates a specific poison which it instils into the tissues at every bite.

ACTION OF HYDROGEN GAS ON THE ANIMAL ECONOMY.—Hydrogen gas, according to Dr. B. W. Richardson, if inhaled by warm-blooded animals, does not act as an anæsthetic, and quickly occasions death by asphyxia. Upon cold-blooded animals its action is slower, but ultimately fatal. Insects recover even after being confined in this gas for twelve hours.

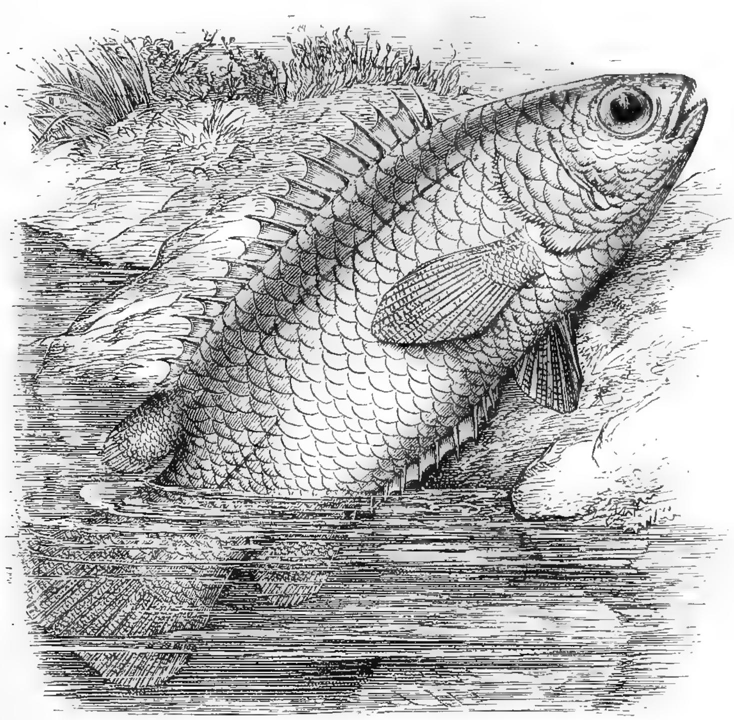
Natural History.

FISH OUT OF WATER.

THERE is remarkable variation in the period during which different fish continue to live when removed from their native element. Thus the herring, as is well known, dies almost immediately upon being lifted from the sea; whence, probably, the now proverbial phrase, "as dead as a herring." Many, as every angler knows, survive for several minutes after being brought into the air, while others, such as the carp, retain their vitality for half an hour, or in some cases even longer still. But there are yet others, again, which are able, not merely to exist for a time when removed from the water, but to leave it for hours or even days together of their own free will, in order that they may journey overland to other water at a considerable distance. And such peregrinations have even been known to take place beneath the fierce rays of an almost tropical sun.

The best known of these fishes is undoubtedly the famous Climbing Perch (*Anabas scandens*), a denizen of various Asiatic rivers, and a representative of a genus containing several species, all of which are gifted with similar powers. Inhabiting, as it so commonly does, the smaller streams, which practically cease to exist during the hotter months of the year, it frequently finds its native waters failing, and thereupon crawls ashore, works itself along by means of the alternate action of the lower fins, and starts off in search of more suitable quarters. Not uncommonly this singular fish is met with in great numbers, all journeying along together. Sir J. Emerson Tennent, for example, has published an account, supplied to him by an eye-witness, of the wanderings of quite a small host, which were passing over ground baked and cracked by the heat of the sun, and employing as much exertion in travelling fifty or sixty yards as would have carried them over half a mile at least of ordinary country.

It has been asserted by more than one writer that this fish possesses—and exercises—the power of ascending the trunks of palm-trees, in quest of any water that may have lodged at the junction of the dead leaves with the stems. But this statement appears to be wholly untrue. Of the migratory performances of the fish, however, there can be no possible doubt; and so well known is its capability of living out of water for a prolonged period, that the fishermen of the Ganges, who use it largely as food, carry it home in a dry earthen vessel, and there leave it alive, perhaps for five or six days, until required for use. And at the end of that time it is still healthy and vigorous. And many of the Indian jugglers carry a specimen or two about with them in much the same manner, as part of their stock of apparatus.



CLIMBING PERCH.

Another fish of somewhat similar habits is the Coramota, or Walking Fish (*Ophiocephalus gachua*), which is a native of Eastern India and the Indian Archipelago, and is again the representative of a somewhat numerous family. Like the climbing perch, it is quite a well-known traveller, and there is a widely-spread popular impression to the effect that it is brought down from the clouds in a storm of rain, just as has so often been reported of frogs in our own country. But the true explanation is a very simple one. As the summer advances and the smaller streams dry up, the water lies for a time in small pools here and there in their beds, and to these pools the fish resort in great numbers. As the heat increases, however, even these evaporate; and so the fish are left buried in the mud. There, however, they live quite uninjured until a few hours of tropical rain soften the baked earth and set them free. And then they proceed to wander over the neighbouring country, and appearing, as they do, immediately after the rain has ceased, give rise to the impression that they have actually been brought down by it from the clouds.

Although they can thus live interred, as it were, for a considerable time, it would seem that the presence of some slight degree of moisture is indispensable to their welfare, for it has been found that, if a cloth be laid over the mud beneath which they are lying, they shortly become stupefied and die. That, of course, is because the air-supply is cut off. But they cannot breathe air as we breathe it, for the simple reason that they possess, not lungs, but gills; and therefore oxygen, to benefit them at all, must be obtainable through the medium of water. Now the fish, seeming to be instinctively aware of this fact, is careful to bury itself at such a depth in the mud that the moisture cannot wholly disappear, no matter how thoroughly the surface may be baked and hardened. And by this moisture air is absorbed, and from it transferred to the gills. Even from a depth of more than two feet are these fish sometimes disinterred.

Eels again are great travellers, and will cross large meadows in search of more congenial quarters. But they prefer to do so by night, when the herbage is moist with dew, and seldom or never pass over a perfectly dry surface. And there are numbers of other fish which systematically leave the water in search of food, although not for periods so prolonged. Thus the Jumper Fish (*Salarias tridactylus*), resident in the seas of the Indian Archipelago, constantly springs out of the water, scrambles about over the stones and rocks lying upon the beach, and snaps up flies and various other small creatures in multitudes. And it can even climb up an almost perpendicular surface, adhering so tightly to its hold that the waves beat upon it in vain. The Shanny (*Blennius pholis*), when the tide is retreating, commonly takes up temporary quarters in some convenient crevice, and there remains for some four or five hours until the water returns. And Mr. Couch tells us that he has known a specimen to be perfectly vigorous and lively after no less than thirty hours' confinement in a dry box. And there is an extraordinary little fish known as *Anableps tetrophthalmus*, or Four Eyes (so termed by reason of the apparent division of each eye into two parts), which behaves very much like the Jumper, and seems quite indifferent as to whether it is in the water or not.

Now the power of all these fishes to remain out of water obviously depends entirely upon the structure of the gills. A fish breathes by taking in water through the mouth, and expelling it through the apertures situated upon either side of the neck, a portion of the oxygen being abstracted by the gills during its passage; not, of course, the oxygen entering into its actual composition, but that which is dissolved in it by absorption from the atmosphere. And when a fish is brought to land it dies, not because the air is actually injurious to it, but because the delicate gill-membranes become dry and collapse against one another, thus stopping the circulation. Therefore it follows that those fish whose gills retain their moisture the longest will best endure removal from the water. And in such species as those described above, a special structure is provided by which a certain amount of moisture is retained and stored up, and in such a manner that the gills can be moistened as often as required. In the Climbing Perch, for example, the pharyngeal bones which support the orifice between the mouth and the gullet are not only greatly enlarged, but are modified in such a manner as to form a most elaborate series of cells wherein water can be stored away very much as it is in the cells of a camel's stomach. And a little of this water passes to the gills whenever necessary. In the *Ophiocephali* a tolerably large cavity lies just above the gills with which it possesses direct communication; and within this cavity a considerable amount of water can be retained, and doled out from time to time in such small quantities as may be necessary. And there is a somewhat similar arrangement in the case of the eels. Thus in all these fish existence can be maintained upon land until the moisture in the reservoirs is exhausted; and that moisture, as fast as it passes to the gills, absorbs the oxygen from the air, to give it up immediately afterwards to the minute vessels with which the respiratory organs are closely studded. And so a structure is provided upon which the existence of the vast majority of individuals absolutely depends. Living under such conditions as those in which they are placed; liable, and indeed almost certain, during the months of summer, to be stranded by the subsidence of their native streams: nothing but the power of migration could save them from destruction. Therefore are they enabled for a time almost to set at nought the very laws of their being, and by a slight modification of structure to breathe through water even while living in air.

HERONS AND HERONRIES.—Mr. E. A. Fitch, F.E.S., communicates an interesting paper on this subject to the *Essex Naturalist*. The principal heronries still existing in Essex are those of Boreham, Birch, Wanstead, and St. Osyth. A heronry, however romantic it may seem, is an almost unbearable nuisance, both on account of the noise and the stench. Herons prey not only on fish, but on mice, rats, rabbits, snipe, young ducks, etc.

COLIAS EDUSA AT WOODFORD.—A male specimen of this species has been caught, according to the *Essex Naturalist*, at Woodford, in that county, as late as September 7th. In 1877 this butterfly, known as the "clouded yellow," occurred in thousands in Essex, as well as in the other eastern and southern counties. Since then, according to Mr. W. Cole, it has been very rare, though its food plants are abundant in every parish, and we have had seasons, to all appearance, as suitable as that of 1877.

A PARASITE DESTRUCTIVE TO SARDINES.—M. L. Joubin has read before the Paris Academy of Sciences an account of a parasitic crustacean, which occasions serious havoc among the sardines on the western coasts of France. The presence of this pest was first noticed by M. Moreau, in the spring of 1887. M. Joubin finds that it belongs to a genus nearly allied to the *Lerneonoma* or *Lerneascus*. It consists of a rounded head from two to three millimetres in diameter, armed with three large recurved horns, and antennæ of the shape of nippers. It has a long neck, a cylindrical thorax, and a short abdomen, followed by large ovaries. The head and a part of the neck are buried in the body of the fish, and the recurved horns prevent its extraction. The parts of the sardine which it chiefly attacks are the hinder end of the dorsal fin, the eye, the sides of the abdomen, and the root of the tail.

Nearly half the fish taken at La Nouvelle were thus infested. At Port Vendres and Banyuls not more than one in thirty or forty was attacked. At Rascoff there were none of the parasites found in July, but in October they were abundant. They occasion large abscesses, which kill the fish by exhaustion.

Swarm of Libellula Quadrimaculata.—According to the *Entomologist's Monthly Magazine*, a migratory swarm of this insect appeared off the Essex coast last summer. Mr. R. McLachlan, F.R.S., mentions that such swarms are not uncommon on the Continent, but are unexampled in this country.

The Fallow Deer.—There are two varieties of the Fallow Deer (*Cervus dura*) common in parks in this country, namely, the spotted and the black. Until recently it has always been supposed that the dark variety was introduced into England from Norway by James I. in 1602, on account of its superior hardness of constitution; but Mr. J. E. Harting now proves, in his excellent work entitled "Essays on Sport and Natural History," that a dark race of Fallow Deer existed in this country at least two centuries earlier than the date above given. This deer is a native of Southern Europe and North Africa, but the date of its introduction into this country is uncertain. It was probably never indigenous in any part of the British Isles in historic times.

The Rabbit Pest in Australia.—According to the *Queenslander*, Pasteur's remedy for this scourge is still doubtful. The rabbits which had eaten vegetables sprinkled with a culture of chicken-cholera died, but the disease did not spread to other rabbits in the same enclosure. Dr. Bancroft has studied the coccidium parasite, which lodges in the liver and is a common affection in rabbits, and he thinks that there would be neither difficulty nor danger in infecting rabbit colonies with this parasite.

Bird-work *v.* Child-work.—In England we often see rooks, starlings, and, in coast localities, gulls following the plough and picking up the grubs or maggots which the ploughshare turns up. In France, where such birds have mostly been shot down, we see the same task performed by children who have to follow the plough, each provided with a little jar for the reception of the *vers blancs*, the larvæ of the destructive cockchafer. It need scarcely be said that the work is done less perfectly and at greater cost than if it had been committed to the birds. Besides, the children ought to be at school, or at play.

Comparative Development of the Sense of Smell.—Recent experiments have shown that on the average the sense of smell is more acute in men than in women, and that they consequently can detect and recognise smaller quantities of odoriferous substances. If we compare the olfactory organs of male and female insects, we find that in a majority of cases those of the males are the more highly developed, so that a sexual difference in this sense may be traced very widely in the animal kingdom.

Fauna of Fernando de Noronha.—Mr. J. C. Braune discusses, in the *American Naturalist*, the peculiar fauna of these islands and the probable means of its introduction. The chief mammalian species present are rats and mice, which are numerous to a degree probably unequalled. There are no serpents, but there is found an *Amphisbæna*, which the Brazilians call the two-headed snake. There is also a lizard which has sometimes a forked tail. The tail of this species is long and brittle, and if a broken portion does not fall off, the fracture may heal over so as to hold it securely, whilst by its side a new tail sprouts from the injured part.

Respective Power of Vision in the Eyes.—In a number of persons whose keennesses of eyesight was tested in the Anthropometric Laboratory in Manchester, the right eye was found to have the advantage over the left.

The Pigment of Blood as a Means of Distinguishing the Interchange of Gases in Plants in the Light and in Darkness.—The production of free oxygen can be shown by means of hæmoglobine, which is converted into oxyhæmoglobine, and shows the two well-known absorption bands. If a straight thread of Spirogyra, placed in the colouring-matter of venous blood, is illuminated with a spectrum, there is formed a bright red zone of oxyhæmoglobine, which begins in the extreme red, rises as far as C, and declines from there to the green, where it disappears.

Survival of the American Bison.—It is interesting to learn that, according to Professor R. T. Hill, of the University of Texas, two herds of the American bison (commonly miscalled buffalo) still exist in Texas. The proprietors of the ranches are, according to our contemporary *Science*, doing much for their protection.

THE TEETH OF WHALES.

Part II.

Of those cetaceans which possess teeth in the strict sense of the word we have an admirable example in the cachalot, or spermaceti whale, a creature which feeds upon many of the larger fish, and no doubt finds its dental armature of considerable service in holding its active and slippery prey.

In this whale the teeth are principally situated in the lower jaw, and fit, when the mouth is closed, into conical cavities provided for them in the upper. They are large, strong, and massive, of fine quality as far as their actual substance is concerned, but not of any great hardness. So, at least, it would seem from the fact that in an adult whale they are always more or less blunted, while in an old animal the points are completely worn away. Their number is very variable. A spermaceti whale may have more than fifty teeth, or it may have less than forty, this variation being due to individual idiosyncrasy, and not to accidental loss. But the average number would seem to be forty-two, of which sixteen are situated in the upper jaw.

These latter, however, are very easily overlooked, for they project so little from the gum (scarcely more than half an inch) that only by a careful search are they likely to be detected at all. Nor do they seem of any great importance, for they are so slightly attached to the jaw-bone that, when the skull is being prepared, they almost invariably come away together with the gum in which they are imbedded.

By the natives of the South Sea Islands the teeth of this whale are, or were, held in the highest veneration, and considered as much too precious to be owned by any private individual. And more than once has one tribe actually gone to war with another in order to secure one ot these coveted trophies, that it might be dedicated to some idol deity, or take first place among the treasures of the regal dwelling.

In the black whales, two or three species ot which are recognised, the teeth are also very large and strong, averaging some nine inches in total length, of which as nearly as possible two-thirds are buried in the gum and the jaw-bone. The base of each tooth is hollowed to a distance of several inches, but its substance is, nevertheless, so dense and heavy that even a dried tooth will often weigh from sixteen to eighteen ounces.

A most remarkable modification of the dental armature we find in the narwhal, whose lower teeth are absolutely wanting, while those of the upper jaw are represented by two only. In the female animal even these two are not, as a rule, developed; without teeth she is born, and without teeth she lives and dies. But in the male, one at least, which probably represents the left upper canine, is invariably developed in a most astonishing degree, and assumes the form of a tapering, spiral rod of ivory some eight or nine feet in length; and not very uncommonly the other is developed with it. A very fine example of a two-tusked narwhal, for instance, may be seen in the museum at Hull.

But, as a general rule, one tusk only is present, the corresponding tooth remaining throughout life in a rudimentary condition. And what the function or functions of this tusk may be is still a matter of conjecture. Many theories, however, have been put forward upon the subject, most of them based upon the fact that the tip of the tusk is always smooth and polished, as though by incessant use, while the remainder is more or less encrusted, and is evidently not subjected to regular friction. Thus it has been urged that the animal employs its weapon for spearing fish, driving at them very much as a mediæval knight, his lance in rest, rode at a mounted foe. But this theory will not bear examination, and is open to two fatal objections. How, in the first place, supposing that the narwhal does so transfix its victims, is it to remove them from its spear and transfer them to its mouth? For it has no limbs available for such a purpose. Is it to be incessantly tantalised by the sight of food in close proximity to its jaw, which no efforts of its own will enable it to devour? And, moreover, if such be the duty of the tusk, why is it wanting in the female? For only in exceptional cases does she possess it.

Another theory, adopted by Fabricius, is to the effect that the tusk is employed in opening ice-holes in the huge floes which in winter cover the northern seas. But again, if this be so, why has Nature omitted to supply the organ in question to the female narwhal, whose need of air is as great as that of her mate? And how is the animal, supposing it to be capable of maintaining a perpendicular position in the water, to revolve while the boring operation is in progress? Such a feat, from its very structure, is absolutely impossible.

A third theorist suggests that the animal, when in want of food, descends to the depths of ocean, and stirs up the mud with its tusk in order to disturb any flat fish which may be lying upon it, recognising the fact that while at rest they assimilate so exactly to their surroundings that the keenest eye cannot detect them. But this theory, a somewhat fanciful one at best, is again negatived by the sexual difference already referred to.

Seeing that the tusk, broadly speaking, is a masculine appendage only, the probability is that it is employed as a weapon, not in the capture of prey, but in those combats which are frequent among male animals, more especially during the earlier part of the breeding season. We know that the male seals and walruses fight with great ferocity at that period, just as do many of the terrestrial mammals; and seals and walruses are at any rate allied to the cetaceans. And we have it, moreover, upon no less authority than that of Scoresby, the celebrated traveller and explorer, that quite large companies of male narwhals are sometimes to be seen gambolling together, crossing their long tusks, and fencing like experienced swordsmen. And it is more than likely that during the season of pairing such mimic warfare gives place to battle in grim earnest. Even if such be the case, however, it is still hard to account for the highly polished condition of the last few inches of the tusk, which part alone seems to be in constant use, and to be subjected to friction. Thus it may well be that the weapon in question has its supplementary uses, although we have as yet failed to discover them.

Although the female narwhal is not, as a rule, armed after the manner of her formidable mate, specimens ot the gentler sex are occasionally taken in which the tusk is present; and at least two cases have been recorded in which both canines, in the female animal, were similarly developed. In one of these cases the one tusk was seven feet and five inches long, and the other seven feet. Most probably females so armed are barren, their reproductive energies being diverted into other channels, and bringing about the assumption of characters ordinarily denied to them. And we have an analogous case in the crowing and spur-bearing hens which are occasionally met with, and from which eggs may be expected in vain.

Very few of the toothed cetaceans at all resemble one another in their dentition, and the number of the teeth is especially variable. Thus, in the narwhal, as we have seen, only one is usually developed. In the *Mesoplodons*, of which Sowerby's whale may be taken as a type, and also in the *Ziphii*, two rather large teeth are present, one upon either side of the lower jaw. In the pilot whale, however, there are ninety-six, evenly divided upon either side of the mouth. The porpoise possesses from eighty to one hundred and four, the dolphin from one hundred and sixty to two hundred, while the *pontoporia*, an inmate of certain South American rivers, bears off the palm with from two hundred and twelve to two hundred and twenty-two. In these last the teeth are sometimes very irregularly distributed. Thus, in the jaw of a Gangetic dolphin were found the singular number of one hundred and seventeen teeth, fifty-seven being situated upon one side of the mouth, and sixty upon the other. In apportioning teeth to the cetaceans, in fact, Nature almost seems to have laid rules aside altogether, and to have left both number and position of those organs pretty well to mere chance, alike in the species and in the individual.

Reviews.

Theoretical Mechanics. By J. Edward Taylor, M.A., London. London: Longmans, Green, and Co.

One of the few tangible advantages ot the present system of examination is, that they create a demand for manuals of elementary science. It is, however, characteristic of such text-books to find that, as in the example before us, they are "written specially to meet the requirements of" this examination, "it will be specially helpful for that," and "it will also be found sufficient for the requirements of" the other.

Several matters call for revision. We object to the ideas of absolute rest and motion in treating of the mechanics of ordinary Euclidian space. Clerk Maxwell tells us that "it is impossible for us to speak of a body being at rest or in motion except with reference, expressed or implied, to some other body." Nor is it scientific to say that "the horizontal direction is the surface that a *limited* quantity of water assumes when at rest" (the italics are the author's). As an instance of unstable equilibrium, an illustration of a cart is given, in which the centre of gravity is considerably outside the base. The cart is not in equilibrium at all. Some examples are suggestive of "blind mathematics," *e.g.*, a "cylindrical tower of the same diameter throughout is 100 feet high, and weighs five tons," etc. Of what material can the author have been thinking? If of brickwork, it would have a sectional area of about one square foot; if of cork, it would be only about 7½ square feet. One hundred and thirty tons would be near the mark for a brick chimney of this height.

Plenty of examples might be taken from ordinary engineering practice without imagining so unlikely an instance as "a rod of cast iron 100 feet long, and cross section 12 square inches, stretches 3 inches under a certain tension."

The author is not so original and interesting as Professor Perry, nor so amusing as Professor Oliver Lodge, in their admirable text-books on the same subject, but he provides numerous illustrations and examples, both worked out in full and collected at the end of the chapters.

Colour: an Elementary Treatise. By Chas. T. Whitmell, B.Sc., F.G.S., M.A. 8vo, 233 pp., 4s. Cardiff: W. Lewis, 22, Duke Street. 1888.

It would be useless to enlarge on the importance of "colour" as a subject deserving attention, since we have continual evidence of the benefits derived from it, either in the way of enjoyment obtained by seeing the beautiful variations of colour in Nature and in the artistic reproductions of them, or in the form of comfort in the agreeable effects produced by the colours introduced for the adornment of our homes, or when it is found in its many useful applications. Although some are satisfied with the mere sensations produced by colour, others, of a wisely more inquiring mind, want to know whence arise these sensations. What is colour? Why is it produced? and where does it come from? To these latter the present volnme will specially recommend itself. This treatise differs from previous treatises on the same subject in following a definite scheme of treatment. The subject-matter is divided roughly into scientific and artistic divisions. In the first of these we find the following points discussed in the order given: nature of colour, production of colour, constants of colour, mixture of colour, results of mixing colours, complementary colours, theory of colour, colour blindness, and systematic classification of colour. The second division includes description of some colours and pigments, colour combinations, small interval and gradation, colour harmonies, and finally painting and decorative art; whilst in an appendix colour photometry and some other points are treated. Many of the most valuable scientific contributions, such as the work of Lord Rayleigh (pp. 36, 60, 86, 90, 107, etc.), of Koenigs (p. 121 *et seq.*), etc., etc., are set before the reader more fully than in previous books on colour; whilst Captain Abney's and Major-General Festing's results (p. 235) appear for the first time in a book of this kind. Many descriptions of experiments are given fully, so as to allow of their being repeated by the reader. This is a great advantage, for, as the author says, "matters which may appear dry and difficult to understand in reading will be found to wear quite a new aspect when tested by experiment." In spite of the copious table of contents, we think an alphabetical index would be a useful addition.

Macaws, Cockatoos, Parakeets, and Parrots. By the late Sir T. D. Lander, Bart., F.R.S.E., and Captain Thomas Brown, F.L.S. With Chapters on Diseases and Cages, from Dr. Karl Russ. Illustrated with Forty Engravings by Joseph B. Kidd, Member of the Scottish Academy of Painting, Sculpture and Architecture. London: Dean and Son.

This little book opens with an account of the "physical characters of parrots," in which we find no little repetition, sometimes with variations. Thus we read in one paragraph that the birds only lay three or four eggs at a time, whilst on the succeeding page we are told that the number of eggs hatched at a time varies from three to six. The eggs are said, in one place, to be "equally obtuse at both ends." But then follows the information that the eggs are "of the shape of a pear, slightly flattened at the broad end." The anecdote that "Scaliger saw one that performed the dance of the Savoyards, at the same time that it repeated their song," occurs twice, on page 17 and again at page 31. Such blemishes should be eliminated in the very probable case of a second edition.

It seems to us that the authors form much too low an estimate of the intelligence of parrots. It is easy to say, as do many writers, that their speech is "mere imitation." So is that of a young child. We have observed instances of parrots connecting their remarks with appropriate facts or events, and never uttering them under any other circumstances. Thus our own parrot, on seeing water drawn from a tap, has called out, "Water, water! Polly wants!" and has drunk eagerly on some being offered her. This speech has never been taught her, and it is never uttered on any other occasion. If any one comes into the kitchen with a basket or a parcel, she generally says, "What oo got?" Now, the bird in question is by no means exceptionally clever, and has never undergone any formal instruction. We by no means contend that parrots analyse the sentences they utter, no more than do your children. But we submit that they very frequently understand some particular phrase as a whole, and use it accordingly. We must remember that the parrot has no hereditary aptitudes to fall back upon. What would be the result if a pair of clever parrots were matched and their young brought up in human society, in a suitable climate, and under kind treatment, is an unsolved but highly interesting question.

The practical portion of this work is much better than the theoretical part. We are glad to see it formally admitted, contrary to the notion of many bird-fanciers, that parrots do drink and require a supply of water. The remarks on the diet and general treatment of parrots are valuable, and will save much misery to the birds, and disappointment to their owners.

Abstracts of Papers, Lectures, etc.

GEOLOGICAL SOCIETY.

At the meeting on November 21st, Mr. W. T. Blanford, LL.D., F.R.S., President, in the chair, W. Whitaker, Esq., B.A., F.R.S., F.G.S., who exhibited a series of specimens from the deep boring at Streatham, made some remarks upon the results obtained, of which the following is an abstract :—

After passing through 10 feet of gravel, etc., 153 of London clay, 88⅓ of Lower London Tertiaries, 623 of chalk (the least thickness in any of the deep borings in and near London), 28½ of upper greensand, and 188½ of gault, at the depth of 1081½ feet, hard limestone, mostly with rather large oolitic grains, was met with. This, with alternations of a finer character, sandy and clayey, lasted for only 38⅓ feet, being much less than the thickness of the Jurassic beds, either at Richmond or at Meux's boring. The general character of the cores showed a likeness to the forest marble, and the occurrence of *Ostrea acuminata* agreed therewith.

At the depth of 1,120 feet the tools entered a set of beds of much the same character as those that had been found beneath Jurassic beds at Richmond, and beneath gault at Kentish Town and at Crossness. The softer and more clayey components were not brought up; the harder consist of fine-grained compact sandstones, greenish-grey, sometimes with purplish mottlings or bandings, and here and there wholly of a dull reddish tint. With these there occur hard, clayey, and somewhat sandy beds, which are not calcareous, whilst most of the sandstones are. Thin veins of calcite are sometimes to be seen, and at others small concretionary calcareous nodules; but no trace of a fossil has been found.

The bedding is shown, both by the bands of colour, and by the tendency of the stone to fracture, to vary generally from about 20° to 30°.

In the absence of evidence it is hard to say what these beds are, and the possibilities of their age seem to range from Trias to Devonian. It is to be hoped that this question may be solved, as on it depends that of the possibility of the presence of coal-measures in the district; and Messrs. Docwra, the contractors of the works, have with great liberality undertaken to continue the boring-operations at their own expense for at least another week.

Details of the section will be given in a forthcoming Geological Survey Memoir, in which, moreover, the subject of the old rocks under London will be treated somewhat fully.

The President inquired how much had been accomplished during the last week.

Professor Judd had not much to add to Mr. Whitaker's statement. He noticed a great similarity in character to the rocks of the Richmond boring; but at Streatham the mesozoic beds were thinner. If an appeal was made to the scientific world, it should be done at once; it would be difficult to ask for assistance if the present character of the work was maintained.

Mr. Whitaker said that, under favourable circumstances, 30 feet a week could be accomplished. He had not much hope of a change in the character of the rocks.

The following communications were read :—

"Notes on the Remains and Affinities of five Genera of Mesozoic Reptiles." By R. Lydekker, Esq., B.A., F.G.S. This paper was divided into five sections. In the first the author described the dorsal vertebra of a small Dinosaur from the Cambridge greensand, which he regarded as probably identical with the genus *Syngonosaurus*, Seeley. Reasons were then given for regarding this form as being a member of the Scelidosauridæ, stress being laid on the absence of a costal facet on the centrum.

The second section described on axis vertebra from the Wealden of the Isle of Wight, which is evidently Dinosaurian, and may possibly belong to *Megalosaurus*.

In the third section the femur of a small Iguanodont from the Oxford clay, in the possession of A. R. Leeds, Esq., was described.

The imperfect skeleton of a Sauropterygian from the Oxford Clay near Bedford, which formed the subject of a previous communication, was redescribed. This specimen was identified with *Plesiosaurus philarchus*, Seeley, which it was proposed to refer to a new genus under the name of *Peloneustus*.

The paper concluded with a notice of the affinities of the Crocodilian genus *Geosaurus*. This form was shown to be closely allied to *Metriorhynchus*, both being characterised by the absence of dermal scutes and the presence of bony plates in the sclerotic. It was also shown that some of the species of *Cricosaurus* belong to the former genus; while there appear to be no grounds by which *Dacosaurus* (*Plesiosuchus*) can be separated from the same level.

"Notes on the Radiolaria of the London Clay." By W. H. Shrubsole, Esq., F.G.S.

Microscopical examination of the London Clay of Sheppey and elsewhere has afforded proof of the existence of a Diatomaceous zone near the base of the formation. The formation of a well for the Queenborough Cement Company in 1885 was the means of furnishing a laminated clay with glittering patches of Diatoms from a depth of 225 feet. In this were also found fairly good pyritized specimens of Radiolaria, some of which were submitted to Prof. Ernst Häckel, who found a large number of fragments of Tertiary Radiolaria, but few well-preserved specimens appertaining to the families Sphæroidea, Discoidea, and Cyrtoidea, and apparently identical with those described from the Tertiary Tripoli beds of Grotte. No new species occurred among the recognised forms.

Sketches made by Mr. A. L. Hammond were also submitted to Prof. Häckel, who stated that these forms were not identical with any known species, recent or fossil.

The Author described the following new species :— *Cornutella Hammondi*, *Spongodiscus asper*, and *Monosphæra toliapica*.

The specimens were preserved in iron-pyrites.

Some tetractinellid sponge-spicules from the washings were recognised by Professor Sollas.

The President observed that the particular advantage of a paper like the present is that it shows the value of searching. He doubted the advisability of coining new names.

Dr. Hinde asked whether the Radiolaria were uniformly pyritised; also whether the sponge-spicules had undergone a similar change.

Prof. T. Rupert Jones commented on the rarity of fossil Radiolaria. Some few have been found in the chalk. Their pyritisation would tend to their ready destruction.

The Author, in reply, said that he was not anxious to apply new names. He was doubtful whether any silica remained in the sponge-spicules or the Radiolaria, although some has been detected in the Diatoms.

"Description of a New Species of *Clupea* (*C. vectensis*) from Oligocene Strata in the Isle of Wight." By E. T. Newton, Esq., F.G.S.

A number of small fishes found by Mr. G. W. Colenutt, of Ryde, during his investigations of the Oligocene strata of the Isle of Wight, in beds belonging to the "Osborne Series," were described as belonging to a new species of *Clupea*. The specimens vary in length from twenty to nearly sixty millim. In all of them the head in much broken; but the rest of the body is beautifully preserved, showing most distinctly the vertebral column, ribs, fins, tail, and ventral spines. The single dorsal fin has its front rays about midway between the tip of the snout and the base of the tail, the ventral fins being immediately under the front of the dorsal and about midway between the pectoral and anal fins. The anal fin commences about halfway between the ventral fins and the base of the tail, occupying about two-thirds of that distance, and the tail is deeply forked. The scales are thin and in most cases much broken; while the ventral region of the body is armed with a row of strong spines. The spinal column contains about forty vertebræ, of which fourteen or fifteen are caudal. The bones of the head are mostly broken, but those of which the outline can be traced agree with the corresponding parts of the sprat.

These fishes are referred to the genus *Clupea*; but although very closely allied to the common herring and sprat, the relative positions of the dorsal and ventral fins, as well as the number of vertebræ, prevent their being placed in any known species either recent or fossil, and they are therefore regarded as a new form, and named *Clupea vectensis*.

The President was not surprised at the discovery of a *Clupea* in freshwater beds.

Mr. Whitaker had suggested that the discoverer should send the specimens to Mr. Newton, and congratulated himself upon the result. It was another case of the advantage of having good local observers.

Mr. A. Smith Woodward thought he could distinguish a series of small dorsal scutes in some specimens, and inquired as to the Author's interpretation of the appearances. Most of the Eocene Clupeoids of the United States exhibited such scutes, and formed the genus *Diplomystus*, Cope. If the British fossil proved to be of the same type, the fact would be specially interesting, for, in the Old World, *Diplomystus* had hitherto been detected only at Mt. Lebanon.

The Author thanked the speakers for their remarks. Whether or not any dorsal scutes occurred was uncertain; in some there seemed to be roughening. He thought it better to leave the specimens in the genus *Clupea*.

THE INSTITUTION OF CIVIL ENGINEERS.

At the meeting on the 4th of December, the President, Sir George B. Bruce, being in the chair, the paper read was on "The Influence of Chemical Composition on the Strength of Bessemer Steel Tires," by Mr. J. Oliver Arnold, F.C.S.

The author observed that there was a growing tendency amongst engineers to specify for tires steel possessing a high resistance to tension. This was conducive to economy in wear; but it was doubtful whether such material was not more liable to sudden fracture than a more ductile, if less durable, steel. The chemical composition necessary to obtain high-tensile strain, together with high elongation, was such as to render steel liable to molecular changes, which doubtless produced disastrous results. The author submitted the data upon which he based this conclusion. The question was rendered intricate by the fact that steel was a complex body, and that the influences of its elements upon each other, with reference to physical effect, had hitherto defied all attempts to reduce them to formulas; also by the difficulty of insuring in pieces of steel, identical in composition, a uniform and constant molecular structure.

In conclusion, the author said: It was worthy of remark that the elongation obtained on a 2-inch test-piece, marked at eight equal intervals, in order to ascertain the distribution of the elongation, showed that this was less in those parts distant from lines of fracture. The engineer held that a certain resistance to rupture under a falling weight, together with certain results obtained on the tensile testing machine, formed a criterion of the capacity of tires to meet strains when at work. This, though true in the majority of cases, had never been exhaustively proved. When the fracture of an axle or a tire led to some fatal disaster, the engineer was to some extent called before the bar of public opinion to account for the accident. In such cases, his explanation, that the breakage was due to an "original but invisible flaw," had become proverbial. An analysis and a tensile-test of the broken article had been made, and the results obtained had thrown no light on the matter. But the important question with regard to the mechanical test arose—Was the test-piece planed from the immediate vicinity of the fracture? The author had obtained data which proved that injurious molecular change might be very local. Returning to the question as to how far the tests to which tires were subjected before leaving the makers' works indicated their fitness to meet strains and vibrations, he suggested an investigation upon the following lines: At the works let tires be selected from groups, made from the same blows, each group being marked with a distinctive stamp. Let representative tires from each group be subjected to exhaustive chemical and mechanical tests. Let the exact mechanical treatment from ingot to finished wheel be faithfully recorded. When the life of one of these tires was finished, either from breakage or in the natural course, let the chemical and the mechanical tests be repeated. Such a series of tests would indicate whether the influences, encountered by a tire, were such as to bring about molecular change. They would also show the chemical composition, and the mechanical treatment, most conducive to injurious molecular rearrangement, and those most likely to retain a permanently tough molecular structure. Finally, the author referred to the hardening of steel generally, and the effects of molecular changes of steel.

SOCIETY OF ENGINEERS.

At a meeting on 3rd December, 1888, Mr. A. T. Walmisley, President, in the chair, a paper was read on "High Pressure Steam and Steam Engine Efficiency," by Mr. W. Worby Beaumont, M.Inst.C.E.

In the first part of the paper attention was again called to the misleading results of the common application of the theory of the perfect engine as a basis for an index to the comparative efficiency of actual engines, working under different conditions and with different pressures. Examples of the reasoning based upon this interpretation of the "Carnot" theorem, or this application of the "Carnot" ratio, were given as showing that it had been common to suppose that the useful limit to steam pressure would be reached at about 200 lbs. or below it. Reasons for expecting very large increase in available work as due to the increase of pressures up to at least 300 lbs. were given with figures showing the extra work available per extra unit of heat used.

In dealing with the steam engine as a heat engine, it was argued that considerations relative to the boiler as the producer of the steam and as the receiver of the hot water rejected by the engine are irrelevant; and, further, that no part of the history of the steam used should be included other than that part which begins with the admission of the steam into the cylinder and ends with its emission therefrom.

In estimating the quantity of steam required to perform a given quantity of work, the steam necessary to fill the cylinder at the pressure shown by indicator diagrams was not credited with providing any of the heat necessary for the performance of the work, excepting only the units of heat represented by the difference between the total heat of the steam at the initial and at the terminal pressures. In a non-expansive engine the whole of the heat equivalent of the work done would have, according to the paper, to be supplied in addition to that represented by the volume of steam required to fill the cylinder.

This heat was assumed to be supplied by initial condensation, and an object of the paper was to show that the performance of work alone demands sufficient heat to account (with the exception of some very small losses) for the whole of the observed initial cylinder condensation.

Proceeding on this thesis it was argued that cylinder condensation apart from this is a very small quantity in the best actual engines, and that it consists mainly in loss of heat by evaporation during exhaust, and of slight losses due to radiation and conduction, and to clearance space not filled at initial pressure by compression.

From this it was concluded—

1. That as small a portion of the cylinder capacity as possible should be subject to exhaust influences.

2. That it follows from 1 that multiple stage expansion is necessary with the high pressures that are advisable, and that high speeds of rotation ought to be attended with economy.

BELFAST NATURAL HISTORY AND PHILOSOPHICAL SOCIETY.

At a meeting held on Tuesday, Dec 4th, a lecture entitled "Soap Bubbles" was delivered by Mr. John Brown.

Professor Letts (the President) occupied the chair. The lecturer said—The record of men of science who have devoted attention to the phenomena connected with soap bubbles is a pretty large one, and includes such men as the celebrated Robert Boyle (who, in 1663, examined and tried to account for the colours of the bubble), Sir Isaac Newton, Hooke, Young, Leidenfrost, Brewster, Draper, Sir Wm. Thomson, and many others, as well as the great French physicist, Plateau, whose researches have a sadly pathetic interest, since he was in the midst of them attacked by a disease which deprived him of sight, and it was only with "that inner eye which no calamity could darken" that he continued to investigate these beautiful phenomena as their colours and forms were described to him by his two faithful friends and assistants, Duprez and Donny. The soap bubble is of interest, first, on account of the peculiarities of its own structure, its forms, its durability, and its colour; and, secondly, as an experimental tool for the investigation of other physical phenomena. The round form of a free bubble is due to the interaction of the air pressure inside it and the surface tension or elasticity of the liquid film. Both being equal all over the surface, it can be shown how no other figure could satisfy the conditions. The elasticity of the film is illustrated by hanging a bubble to a fixed wire ring and hanging to the bubble a second ring with a small weight attached. On allowing the air to escape by breaking the film inside the fixed ring the shrinking up of the film lifts the weight up to the upper ring. The colours of the bubble were for a long time a great puzzle to the early investigators, but since the discovery of the undulatory theory of light a satisfactory explanation of them has been found. They belong to a class of phenomena known as "colours of thin plates," and are caused by the "interference" of the light waves, reflected from the outer surface of the film with those reflected from the inner surface through the thickness of the film. The effect is to destroy some one colour in the light, leaving its complementary colour unbalanced, and therefore visibly tinting the otherwise white light. The matter is very clearly explained in Tyndall's charming book, "Lectures on Light." The colours are very well seen on a flat soap film attached to a ring of wire, or in a bubble partly filled by smoke, as was observed by Leidenfrost in the last century He compares the resulting effect to a brilliant star, and then he moralises quaintly, "But all this glory vanishes the moment the bubble bursts; the fetid smoke which escapes shows with what filth it was filled, and so offers us a striking picture of the gilded miseries of humanity." The well-known fact that two bubbles may be pressed together without coalescing is well illustrated by blowing one bubble inside another one hanging on a wire ring. The outer one must have either a drop of liquid or a wire ring hung to its under part, so as the thick under part of the inner one does not touch it; otherwise they will coalesce: or if the inner one be filled with coal gas it rises to the top of the outer one, which answers the same purpose. When the ring on which the outer one is fixed is very light and small the whole combination rises in the air, the inner bubble representing the bag of gas, the outer one the net, and the ring the car of the miniature balloon. As an experimental tool the bubble may be used to illustrate the diffusion of gases, a phenomenon examined and investigated by Graham, who, like other great pioneers of science, attacked the most abstruse problems with the simplest possible apparatus. It has been stated that his entire laboratory for his diffuson experiments was contained on an old tea tray, and consisted of a few glass tubes, phials, and tobacco-pipe stems, and some plaster of Paris. After all, as in the case of the astronomical telescope, it is the man at the small end that is of most importance. If an air bubble be placed in ether vapour for a few seconds, the vapour diffuses into the bubble in sufficient quantity to cause it to explode with a considerable burst of flame when taken out and applied to a light. The magnetic qualities of gases are conveniently studied when these are enclosed in bubbles. Although outside the domain of bubbles proper, one or two illustrations may be given of the beautiful geometrical forms produced by Plateau on wire frames after immersion in soap solution. A cubical frame shows an arrangement of one rectangular film in the middle joined to the corners by twelve trapezoidal films. A triangular prism gives a set of nine plane films, and a helix of wire gives a very pretty screw-shaped film. A frame consisting of three rings fixed to a centre forms a circular trough of soap films, round which bubbles may be rolled as the ball on a roulette table. The greater part of these experiments have been devised by Mr. C. V. Boys, F.R.S., of South Kensington Science Schools, and are described in a recent number of the *Philosophical Magazine*, where also he gives the ingredients of the solution used in forming the bubbles. Some are from other authors, and others have been devised specially for this evening. In conclusion, it may be asked *cui bono*—what is the good of it all? The seeker after knowledge asks no further result or reward than the pleasure of attaining definite knowledge. As the artist loves beauty, and will create beautiful forms for the mere love of his art, so the philosopher finds his keen pleasure in acquiring and setting in order new forms of knowledge. There is a keen delight in a new successful original experiment that belongs to few other enjoyments—in seeing for the first time that Nature has at length truly answered the question so often put in so many varied and doubtless imperfect forms before; a delight enhanced by the feeling that, having asked aright, we have been answered truly, for—

Nature never did betray
The heart that loved her.

ROYAL ACADEMY OF SCIENCES, AMSTERDAM.

At the meeting of the section of Physical Sciences on Saturday, 24th November, 1888, M. Hugo de Vries read a paper "On the Pangenesis of Darwin," urging that Darwin's doctrine presents a great many more data for the explanation of various phenomena on the domain of heredity than the doctrine of Weisman. The author especially demonstrated that the hypothesis of the transport of gemmules may be rejected without endangering the validity of the arguments in that hypothesis, which would connect the separate properties of any organism with some definite species of particles of living matter. He also pointed out that the theory expounded subsequently to Darwin, according to which the nucleus of the germ-cell must be the seat of heredity, is in accordance with the import of the last-mentioned hypothesis.

M. Martin demonstrated that the lower jaw found in the year 1823 when digging the canal called Zuid Willemsvaart, in the Kaberg, near Maestricht, and hitherto regarded as the remains of a so-called fossil or diluvial human being, was not found in the geological formation which harbours such remains, but in another of more recent date, so that the importance of this jaw—traced back by the author after a long and painful search in the anatomical cabinet of the Leyden University—can no longer be maintained.

M. Martin further stated that he discovered recently in a parcel of fossils collected by the mining engineer, J. A. Hooze, in Martapoera, some characteristic fossils from the chalk formation, and especially rudists; so that it is positively ascertained that in the South-Eastern parts of Borneo there exists a chalk formation, as was formerly supposed by Geinitz.

Victoria Institute.—At a meeting held on December 3rd, a lecture was delivered by the Rev. H. G. Tomkins on Biblical Ethnology, illustrated by means of a lantern with transparent photographs, which had been taken from the monuments themselves, and many of them from those discovered not more than a year ago at Bubastis and elsewhere. The photographs brought out the ethnographic distinctions between Egyptians, Assyrians, Israelites, Syrians, &c., with great clearness. The accuracy of the Egyptian sculptors may be attested by the fact that, although there are more figures of Rameses II. than of any other monarch, yet there is never any difficulty in deciding as to whom they are intended to represent. It is startling also to see on those ancient monuments, drawings and sculptures of Hebrew faces, of which we may find exact counterparts in the streets of London to-day.

Cambridge Antiquarian Society.—At the meeting on Monday, the 19th of November, Professor A. Macalister, M.D., F.R.S. (President) in the chair, the President exhibited and described a fragment of an Egyptian *Stele* belonging to Mr. Dodgson, of Ashton-under-Lyne. Professor J. H. Middleton made some remarks upon an altar-cloth from Lyng church, near Norwich, lent by the Rector, the Rev. C. Jex-Blake. Mr. Gadow made a few remarks upon an early Christian inscription found at Mertola, in Portugal, which had been kindly presented to the Society by Mr. T. M. Warden, an official of the Minade Sao Domingos, South Portugal.

Sheffield Microscopical Society.—The first of a series of "students' nights" in connection with this society was commenced on November 23rd, when Mr. W. Jenkinson explained the construction of the microscope, giving a full description and the uses of the various parts. Mr. G. A. Grierson gave a practical demonstration in botanical section cutting and mounting.

Edinburgh Association of Science and Arts.—The meeting was held on November 19th, Mr. J. M. Turnbull, President, in the chair. A paper on "The Principles of Ventilation" was read by Mr. A. D. Mackenzie. The lecturer first referred to the ventilation of buildings as not receiving the importance it deserved; it was too often an after-thought, considered only when the building was nearing completion, and therefore almost impossible to be effectually carried out. Dealing next with the proportions of the different gases necessary to support life, the lecturer said ventilation consisted largely of a process of dilution, a mixing more or less of the good air with the bad, and the reason of such a large supply of air being required was that they could not get the foul air away without more or less pollution of the new air. About 3,000 feet per hour of fresh air was estimated to be required for each individual, and that quantity was so large that it was almost impossible to provide for it in churches and halls. He was of opinion, however, that that quantity was far more than was necessary with any reasonably effective ventilation. He then stated the principles to be followed to ensure the proper ventilation of a room, and referred to the plan adopted in schools and other buildings of introducing fresh air all round the room, about six or eight feet up, and letting the foul air out at an opening near the floor, as an entirely erroneous principle, and one which ought to be condemned. It seemed to him that to secure a perfect system of ventilation the fresh air should be introduced as near the floor as possible, through as short a channel as possible, and should strike against some obstacle so as to break up the current. The obstacle should be a heating agent of some kind, as in our climate it was absolutely impossible to have effective ventilation at all seasons without means of heating the incoming air. The object of his paper was not to discuss the relative merits of the various systems, but if the principles were understood the details might be varied in any way to suit local peculiarities.

FLINTS.*

PROFESSOR JUDD said that in the previous lectures they had studied the facts which were taught them concerning flints— first by means of experiments, and they had seen that by such experiments they learned first the chemical constitution of flint, and secondly the physical properties presented by the substance; and in the second place they had tried to learn what was taught them concerning flints by observation, especially as to the mode of occurrence of this substance. That night he proposed that they should consider what the microscope taught them concerning flints. He must point out at the outset that the microscope was not, as many persons imagined, simply a toy to be played with, and that everybody who bought a microscope was of necessity a microscopist. Nobody going to a shop and buying a violin fancies he thereby becomes a violinist, even though the violin happens to be a Stradavarius, or other exceptionally good instrument. But somehow it had come to be thought that all that it is necessary for a man to be a microscopist is to buy a microscope, and if he buys a very expensive and a good one he is necessarily a very good microscopist. Such, however, was not the case. The results obtained by the aid of the microscope depend to a certain extent on the instrument, more could be done with a good instrument than with a bad one; but much more depended upon the eye that was placed behind the instrument, and still more on what happened to lie behind the eye. A good microscopist would do a great deal more with a bad microscope than a man who had not studied the use of the instrument at all would with the best instrument that was ever fashioned. That night he would only just call their attention to the nature of the instrument he was going to endeavour to employ that evening. The microscope he was now speaking of—the compound microscope, which was the form of instrument with which most of the important researches were made—consisted of a number of pieces of apparatus joined together, but he would only call attention to the essential parts. First, there were some lenses called the objective, or the object-glass, and upon the nature of those lenses the degree of magnification depended. There were objectives which would magnify only ten, or fifteen, or twenty times with the ordinary eye-piece, and others which would magnify many thousands of times. At the other end of the instrument they had another arrangement of lenses, constituting the eye-piece of the instrument. Now, attached to that particular instrument they had two other portions, which constituted the apparatus he had already spoken of as the polariscope. He had called their attention to the fact that they had two boxes, one below, and the other above the instrument, containing two transparent prisms of Iceland spar which polarised the light; and he had shown them that although there was nothing but a transparent body between the eye and the light of the microscope, yet when those prisms were turned in a particular position no light passed through unless a crystallised substance was placed upon the stage of the microscope, in which case they got coloured light, which varied with the nature of the crystallised substance used. Now, having called those facts to their remembrance, he would point out that they had a microscope arranged in a somewhat different form from the microscope which was upon the table, which could only be used by one person at a time. If he wished to study flints for himself he should not ask for a better instrument than that on the table, but unfortunately he could only use it himself or ask others to come round one at a time to use it. In order to get over that difficulty he would endeavour to throw pictures of what was seen under a microscope on to a screen. The way to throw those pictures on a screen was to get an exceedingly powerful light, and to pass that light through the objective, and by means of lenses in front of the eye-piece, to form images on the screen. The great difficulty, however, was that this objective, especially if it magnified greatly, was of very small diameter, and the light used must go through a very minute aperture, and it was afterwards spread out by the lens on to a large surface. Now, in order to get sufficient light to show objects in a room of that size it was necessary to have a most powerful light, and for that purpose he used the form of electric light, which gave them very good results. It was worked, like the electric lights used for illuminating the adjoining museum, from a dynamo. Everything depended upon the light being sufficiently bright to retain a sufficient light when spread over a very considerable area. He had hoped he should be able to show them some things with tolerably high powers; but unfortunately the instrument had gone back to the maker, and he had retained it until the last moment, and even now he had sent it back without making those alterations which were specially demanded. He would, however, he hoped, be able to show them a sufficient number of objects with a moderate power, a power of magnifying something like thirty-five times or forty times; that was, every object would be magnified, as seen in the first instance, thirty or forty times their length and breadth. He hoped they would be able to see most of the points that he had called their attention to. Now, the question might arise, how should they examine flint with the microscope? If he put flint under the microscope they would see very little of it. Flint, however, was a translucent object, and if they took a hammer and struck it they might get off flakes so thin that light would pass through them. Moreover he had pointed out to them that flints, like some other forms of silica, could absorb liquids, and if it was placed in oil they

* Fourth Lecture to Working Men at the Royal School of Mines.

could make the flint very much more transparent than it would otherwise be. But for most purposes it was desirable to make a thin slice or section of the flint, and this was done by a very simple contrivance. If we take a piece of glass, and having broken off a convenient piece of flint, one side was ground down flat and smooth on some powder, like emery or other grinding material. Having done that, the smooth side of the piece of flint was stuck on a piece of glass and then turned over, and the other side of the flint ground until nearly all of it was ground away, and there was nothing left but a thin film of the rock, of which they wished to take the section. In practice, by using a lapidary's wheel they might shorten the task. He would now see if it was possible to show some facts about the microscopic structure of flint which would aid them in reasoning concerning the nature of the origin of flint. He would first endeavour to show some sections of chalk, a substance in which, as they learned in the last lecture, flint was always found. [Sections of chalk exhibited.] Sometimes, when the sections did not give them the information they desired, they might see what was the nature of the chalk by washing it with a stiff brush, when they could separate the number of minute shells of which it was made up, and study them individually. On the screen were shown a number of straight, wedge-shaped fragments, and there were a number of rounded bodies which had the forms of shells. He would endeavour to show them what was the nature of the globigerina-ooze which resembled chalk. Most of them could see it had those peculiar forms of shells that he exhibited to them the other day. There were a number of globular bodies united together, making up these shells. The darkness of those objects was due to the fact that the specimen exhibited was fresh ooze from the bottom of the Atlantic, and the dried-up bodies of the animals were in the shells. [Lantern slide : showing shells of great variety of forms.] When the sections of the chalk were carefully examined by the aid of the microscope, all the objects were found which were found in the mud at the bottom of the Atlantic. [Picture of objects taken from surface of water during *Challenger* Expedition.] Many of them were soft-bodied creatures which left no trace behind them, but the shells dropped to the bottom of the ocean, and formed the mud of which he had spoken. Now he must call their attention to the fact that there was one considerable difference between globigerina ooze and chalk. Hitherto he had dwelt on the close resemblance there was between globigerina ooze and chalk. Globigerina ooze differed from the chalk, however, in the fact that when they dissolved the chalk in an acid, such as vinegar, they got very little residue, and that residue seldom presented any definite forms. Here and there was found a trace of some wonderful structure composed of the substance silica, which was not dissolved by ordinary acids, but generally there were no traces of such organisms; but if they dissolved most kinds of globigerina ooze in acid, there was left behind a considerable number of skeleton organisms composed of the unsoluble substance silica, and these siliceous organisms composed of silica belonged to three sorts of organisms : first the plant known as diatoms or diatomaceæ; secondly, animals called radiolarians ; and thirdly, the spicules found in the sponges. Those sponges, like Venus's flower-basket, had skeletons made up of silica. In the diagram they had last week they had before them some wonderful varieties of structures which existed among those three forms of life—diatoms, which were plants; radiolarians and siliceous sponges, which were animals. [Specimens shown by lantern of siliceous organisms which exist in the ooze at the bottom of the Atlantic Ocean, but which were not found in chalk.] This was a very beautiful object, and that which looked like vegetable was an accumulated series of organisms which he had spoken of as diatomacæ and they required a very powerful microscope to under stand them. [Further lantern slides of a white powdery material, formerly largely dug for making dynamite, because it absorbed the nitroglycerine better than any other substance which had been tried were then exhibited. [Specimens were shown of material dredged by *Challenger* from the bottom of the Antarctic and South Pacific Oceans. Also specimens of radiolarians; and the lecturer spoke of the wonderful diversity of form and size they represented.] This was material dredged from the bottom of the Atlantic, but in many cases rocks were found made up entirely of these organisms. A work on the subject of these radiolarians had been published by Prof. Haeckel, of Jena, in which he described 4,000 forms, and said that he had far from exhausted all those brought home by the *Challenger* Expedition. [Numerous specimens of radiolarians and transparent rods, which were spicules of sponges, wonderful forms presented by siliceous organisms which went to build up the spicules of sponges; some formed meshes consisting of six branches. These objects were all composed of silica.] The next thing which he had to call their attention to was that the silica comprising these organisms was all in the condition of colloidal silica, and there was a test, as he had pointed out, by means of which they could distinguish colloidal silica from crystalline silica. Colloidal silica, as they had seen, was remarkable for the ease with which it passed into a state of solution, and he should be able to show them that in many cases these beautiful siliceous organisms, which were composed of colloidal silica, were easily dissolved. First he should endeavour to show by polarised light that those objects were composed of colloidal silica; and secondly he should endeavour to show that in many cases those objects had been dissolved, and were sometimes redeposited; and that this colloidal silica passed over into the crystalline condition. In the first place he would endeavour to show them the fact that these objects were really composed of colloidal silica, and not of crystalline silica. That was shown by the fact that colloidal silica did not affect polarised light. Therefore, if they attached the polariscope to the microscope, and put the prisms in such a position that it stopped off all light, these masses of colloidal silica remained dark, whereas if they consisted of crystalline silica they would get a coloured light. [Specimens of sponge spicule; dissolved globigerina ooze, the residue of which, however, did not contain any of the beautiful forms of radiolarians or diatoms or sponge spicules.] He wanted them to remember the fact that silica was, in the rocks they had studied, in a state of solution, and that it was frequently deposited from a state of solution, sometimes in a colloidal condition, and sometimes in a crystalline condition. The other limestones of the globe, if dissolved in acid, left behind a minute residue, and that residue, if examined in the way they examined it now, was seen to be composed of a great number of beautiful little crystals cf quartz. They saw nothing of the radiolarians etc. because the silica had passed into a state of solution, and been separated and deposited in the form of crystalline quartz. [Another example of the way in which silica was deposited in rocks, owing to its being continually in a state of solution, was shown by the lantern.] There were a number of sand grains which were remarkably opaque, because they were covered with iron rust or iron oxide; but if they were put into acid the iron rust was dissolved, and they got a crystalline form. The sand grains were little fragments of quartz crystals, and when silica in a state of solution came into contact with them the broken crystals were reformed, and thus they had that wonderful deposition of silica upon the outside of the sand grain. Now he must call their attention to certain very interesting facts which resulted from this circumstance of silica so constantly being present in a state of solution. As silica was almost everywhere passing through the rocks in a state of solution, it might constantly be deposited in the rocks, and it had a wonderful power of replacing other substances. Very frequently the remains of plants and animals might be entirely dissolved away, and as portions of the plant or animal structure were carried away in solution, particles of silica were deposited, which took the place originally filled by carbonate of lime or other substance, which formed part of the animal or vegetable structure. That was a form of fossilisation. When the materials of the organism were removed and the mineral substance deposited in its place, it was said to be fossilised, and this particular form was called silicification. Now the wonderful thing was the way in which this silicification went on. For example, in trunks of trees and vegetable objects every portion of carbon, oxygen, and hydrogen which composed the plant tissues might be removed particle by particle, and particles of silica put in their place, and this work might be done so perfectly that the structure retained its original form and all its delicate features. They could imagine it possible that a building like that (the Museum of Practical Geology), which happened to be built of stone, might have every stone taken out and bricks put into their places, and so the stone building would be converted into a brick building. Or they might have the limestone removed stone by stone, and sandstone put in its place. That was what was done in silicification, only the bricks were so minute, and so perfectly did Nature do her work, that when they took a section and examined it with the microscope, they found all the minutest structures reproduced in the silica. [Specimen shown with lantern, of piece of wood which had been completely silicified.] All the delicate cells and vessels were completely reproduced; and all the foreign substances which lay in those cells were reproduced in the silica, and if they were to analyse those flints they would find only a minute percentage of the original elements—the carbon, the hydrogen, the oxygen, and the nitrogen. This work of silicification had gone on in such a way that as each molecule of the plant-tissue had been removed a molecule of silica had taken its place, and its whole structure had been reproduced, and all its minutest details were produced with the greatest accuracy. Not only were plants silicified, but so were corals and many other structures. [Specimens of fossils building up some of the varieties of chalk were shown.] Those fossils originally consisted of calcic carbonate, or carbonate of lime. Sometimes a whole mass of chalk was converted into silica. [Specimen of mass of chalk from Scotland, which was full of organisms exactly like those of ordinary chalk, and the whole mass had been converted into flint. It was a mass of chalk, in which the process of silicification had gone on to the fullest extent.] Sometimes those objects had undergone a remarkable and considerable change. The colloidal silica, of which they were originally formed, had been converted into crystalline silica. Now he had to call their attention to the fact that when they studied a large series of flints they would find that some of those flints were most obviously nothing but chalk-mud, which had been silicified. All the characters that were seen in chalk-mud were found in these particular flints. But as they studied flints they would find a wonderful change went on in them. They would find that the colloidal silica forming the flints had been converted into crystalline silica; they would find that the colloidal silica which had filled up all the interspaces between the organisms had in some cases undergone a similar change, and that the material had assumed a more or less perfectly crystalline character. Thus in some flint they might recognise chalk mud in which perfect silicification had taken place; every particle of chalk mud had been removed in a state of solution, and colloidal silica had been put in its place. From that first stage they would trace a perfect series of gradations. They would find minute crystals taking the place of original colloidal silica, and this crystalline character might go on increasing and increasing until at last the whole of the original organic structures were completely obliterated, and there was nothing but a crystalline appearance. He would point out that flints presented too many different appearances. Sometimes flints appeared black, or, at all events, a dark colour. At other times they appeared perfectly white. As he pointed out in his last lecture, they sometimes found white flint in the interior of black flint, and a layer of white flint on the outside. Generally they found white flint in the interior, with black outside.

If they took a piece of black and a piece of white flint, and examined them carefully by means of chemical analysis, it would be found that they did not differ in their composition. Black and white flint consisted of silica and nothing but silica; but the difference between these two substances was entirely a difference of aggregation. A piece of blotting paper was opaque, but put oil on it and it became transparent. It was the same with black or white flint. When flints were examined microscopically they would find in the white flint a great number of particles of silica separated by air, but in the translucent black flint colloidal silica had been deposited in the interspaces, and they got a continuous light. The oil on the blotting paper had nearly the same effect upon light as the silica has in the interspaces of flint—they got a continuous stratum through which the light passed freely. [Pictures on screen by aid of lantern showing differences which are presented in flints.] He had introduced the last two slides in order to bring before them clearly the distinction of the two forms of silica, and the fact that one kind of silica was constantly found passing into the other kind. They had most of them that evening seen on the screen with the actual eye or with the eye of faith, a sufficient number of these objects to enable them to reason upon them as he hoped to do in their next lecture, in which he would endeavour to show how these facts that they had been collecting in the four lectures already given would enable them to frame a reasonable theory concerning the *origin* of flints.

RECENT INVENTIONS.

The following list has been compiled especially for the SCIENTIFIC NEWS *by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents, of* 234, *High Holborn, London, W.C.; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester; and* 6, *Lord Street, Liverpool.*

BATTERIES.—Mr. H. Thaine has patented a secondary battery. This invention dispenses with the use of perishable materials as far as practicable, and employs uncured or unvulcanised indiarubber, either in sheets or small pieces. The rubber is subjected to a gentle heat to soften it, and whilst soft lead in narrow strips or dust is mixed with it to render it porous. Plates thus formed contain a greater proportion of active material, and are practically unbreakable, and may be made into any suitable shape.

ELECTRICAL APPARATUS.—Mr. A. M. Taylor has patented an electrical transforming apparatus. It relates to means for compensating for the effects produced in a system where a constant electrical current is maintained in a primary circuit, and in which various inductors are arranged in series. It consists in combining with each of a number of inductors an independent core of iron, wound with a coil of low resistance in shunt from the primary inductor coil, with or without separate convolutions connected to the secondary.

AERIAL PROPULSION.—Mr. G. S. Parkinson has patented means for aërial propulsion. Any ordinary balloon is employed having a depending car to which is fixed an air-fan, or blower. To the axis of the fan is affixed a tube, which is passed into the body of the balloon from the base, and is divided into three channels, which terminate one at the end and on each side of balloon, opening into the air with trumpet-shaped mouths. The fan is worked by any suitable motive power, and air being drawn into the fan is driven through the tubing and out into the open air, thus reacting on the balloon and propelling it.

ELECTRICITY.—Messrs. W. Lowrie and C. J. Hall and H. W. Kolle have patented means for measuring alternating currents of electricity. When measuring the current deviation of a number of lamps in a lighting circuit a voltaic cell is placed in the circuit. This cell comprises two dissimilar metals placed in an acid. When the current is passed through it and the circuit the flow of the current is alternately retarded or assisted by the cell, causing a waste of the positive electrode. The current which acts upon the electrode varies, and is directly proportional to the electro-motive force of the cell and the resistance of the lamp circuit; the action of the cell, therefore, is available as a current measure.

ENGINES.—Mr. H. Jarman has patented improvements in high-speed revolving multiple cylinder engines. According to this invention, a revolving cylinder engine is provided, consisting of three or more single-acting cylinders enclosed in a stationary casing and disposed radially around and fixed to the engine-shaft, and provided with pistons having connecting-rods jointed thereto, and working jointly upon a fixed pin which is eccentric to the centre of the shaft, the casing having a bearing for the shaft and a trunnion bearing for the cylinders, the latter revolving on the trunnion, which is provided with steam ports corresponding with ports in the cylinder-bearing part.

STEEL OR IRON.—Mr. J. H. Darby has patented improvements in the manufacture of steel or iron. The metal is run from the open hearth furnace into a ladle fitted with an ordinary nozzle and stopper to regulate the flow. From the ladle the metal flows through a filter from which the metal takes up carbon. From the filter it runs into another ladle, in which it is allowed to stand, covered with small pieces of charcoal for a short time before being cast or returned to the furnace and submitted to a reducing heat. While in the furnace charcoal is spread over it, and the metal is left until the desired temperature and temper are attained, after which it is tapped in the usual way.

ELECTRIC LIGHT.—Mr. E. F. H. Lauckert has patented apparatus for indicating the time during which electricity is used for a lamp or other purpose. A counter mechanism is provided for each lamp; this counter is of any suitable kind, and is connected with clockwork by a magnetic clutch, which may consist of a pair of iron bosses facing each other, the one on an axle driven by clockwork, and the other on an axle belonging to the counter, both bosses being surrounded by a coil of wire forming part of the circuit of the lamp. When a current passes through the coil the two bosses are held together by magnetic attraction, and the counter is operated. When the current ceases the clutch is released and the counter stops registering.

CITY OF LONDON COLLEGE.—On Thursday last, the 6th inst., a visit of the Science Society to the Millwall Docks was arranged by Mr. Henry Adams, M.Inst.C.E., who accompanied the members. Mr. F. E. Duckham, the engineer to the Dock Company, met the party at the railway station, and was most assiduous in showing and explaining the many interesting details with which the dock abounds. Among the points noted were some economically built sheds with compound iron and wood roof trusses, and other very light galvanised roofs of 60 ft. span. When first opened the dock was fitted with fixed hydraulic cranes on the quay; these have been supplemented by portable hydraulic cranes, which are found much more convenient, and they have since been largely adopted elsewhere. The arrangement of the pipe mains was explained, and the method by which a breakage at any point could be shut off by means of stop-valves, so as to permit the machinery at other parts to continue working. Branches at intervals allow connection to be made with the portable cranes, and the telescopic pipes provided give a considerable range of movement. The grain machinery was next inspected with the automatic weighing-gear and self-emptying buckets, and Mr. Duckham's pneumatic apparatus for discharging mud from the dredger barges was seen in operation. Much interest was taken in the hydraulic engine-house and the various pumping appliances, which were fully explained to the visitors. To prevent damage to the engines an ingenious self-acting relief-valve is used, by which a large area is opened to allow the pressure-water to flow back into the tank when the accumulator reaches the top of its stroke and the draught of water from the main is suddenly reduced. The graving dock was fortunately empty, so that its construction could be seen, together with the flat-sided caisson at its entrance, a large ship being on the blocks in course of scraping and painting; and the noted 75-ton shears, by Messrs. Day and Sumner, of Southampton, were observed with some interest owing to that subject having been set for the home work of students in machine construction at the last May examination of the Science and Art Department. By the courtesy of Messrs. MacDougal, their extensive wood-fibre paper-making plant was next seen in operation, from the arrival of the spruce fir-logs at one end to the packing of the bales of finished paper at the other. The whole of the processes were in full swing, but an intimation was given that the visit was considered to be "private and confidential."

DIARY FOR NEXT WEEK.

Monday, Dec. 17.—Society of Arts, John Street, Adelphi, Cantor Lecture, at 8 p.m.—*Light and Colour*, by Captain W. de W. Abney, C.B., F.R.S.

Tuesday, Dec. 18.—Zoological Society, 3, Hanover Square, W., at 8.30 p.m.—*Descriptions of Fifteen New Species of Shells from China, Japan, and the Andaman Islands, chiefly collected by Deputy Surgeon-General R. Hungerford*, by Mr. G. B. Sowerby, F.Z.S.—*List of the Lepidoptera-Heterocera, with Descriptions of the New Species, collected by Mr. C. M. Woodford at Aola, Guadalcanar Island, Solomon Islands*, by Mr. Herbert Druce, F.Z.S.—*On the Lepidoptera of Japan and Corea. Part II. Heterocera*, by Mr. J. H. Leech, F.Z.S.—*Some Remarks on the Numbers and on the Phylogenetic Development of the Remiges of Birds*, by Dr. Hans Gadow.

Institution of Civil Engineers, 25, Great George Street, Westminster, at 8 p.m.—*The Friction of Locomotive Slide Valves*, by Mr. J. A. F. Aspinall, M.Inst.C.E.

Royal Statistical Society, School of Mines, 28, Jermyn Street, W., at 7.45 p.m.—*Recent Changes in Prices and Incomes Compared*, by Mr. Robert Giffen, LL D.

Wednesday, Dec. 19.—Civil and Mechanical Engineers' Society, Westminster Palace Hotel, at 7 p.m.—*Notes on the Oroya Railway, in Peru.*

Society of Arts, John Street, Adelphi, at 8 p.m.—*Standards of Light*, by Mr. W. J. Dibdin, F.I.C.

Royal Meteorological Society, 25, Great George Street, Westminster, at 7 p.m.—*Note on the Prolonged Spell of Cold Weather from September*, 1887, *to October*, 1888, by Charles Harding, F.R.Met.Soc. *Report on the Phenological Observations for* 1888, by the Rev. T. A. Preston, M.A., F.R.Met.Soc.—*A Winter's Weather at Massowah*, by Captain D. Wilson-Barker, F.R.Met.Soc.

Thursday, Dec. 20.—Chemical Society, Burlington House, at 8 p.m.

Manchester Microscopical Society, at 7 p.m. Mounting Section.

St. James's Hall, at 8.30 p.m.—*Lecture on Architecture*, by Messrs. G. A. T. Middleton and Cecil Orr.

CONTENTS.

SCIENTIFIC TABLE TALK.

By W. MATTIEU WILLIAMS, F.R.A.S., F.C.S.

THE structure of the interior of the earth is a much-vexed question. Direct evidence, derived from penetration of its crust in the operations of well-sinking, mining, etc., shows that its temperature gradually increases as we proceed downwards, without presenting any indication of a limit to such increase. On such data calculations have been made, showing that at a very moderate depth, *i.e.*, moderate in relation to the dimensions of the earth, materials such as compose its crust must exist in a state of fusion, and therefore the earth, regarded as a whole, is a fluid mass, encased in a solid crust the relative thickness of which may be compared to that of the rind of an orange as compared with the whole fruit.

Opposed to this we have the speculative deductions of certain mathematicians—Hopkins, Mallet, Sir W. Thomson, Prof. G. H. Darwin—and others, who maintain, on astronomical grounds, that the earth is solid throughout, with a rigidity about equal to that of a globe of steel, supposed also to be solid throughout. Hennesey, Delaunay, Sir G. B. Airy, and others arrive at an opposite conclusion, as a result of calculations based on the same data. This is not at all surprising, considering the refinement of the data, viz., the deformation of the earth as indicated by its nutation, and the precession of the equinoxes.

The researches of W. Spring, which have been in progress during the past eight or ten years, have rendered us no longer dependent on these inverted pyramids of complex calculations. He has proved by direct experiment that the materials of which the earth's crust is composed, when subjected to a compression corresponding to that which they suffer at a few miles below the surface, assume a fluid condition, and that this occurs at ordinary temperatures, though, of course, it is aided by heat.

He finds that lead filings, under a pressure of 2,000 atmospheres, unite into a firm block, which under the microscope exhibits no trace of the original filings, but presents all the appearances of a cast block; that under a pressure of 5,000 atmospheres the lead oozed out at the joints of the apparatus. A mixture of filings of bismuth, tin, and cadmium, in the proportion to form Wood's fusible alloy, when similarly compressed, interfused with each other, forming the alloy, which melted at 158° Fahr., the mean melting-point of its constituents being 468°. This shows true combination throughout. Copper and zinc similarly treated produced brass; magnesium, zinc, bismuth, lead, silver, copper, tin, and antimony, when mixed with sulphur and subjected to a pressure of 6,500 atmospheres (97,500 lbs. to the square inch), formed true sulphides. In all these cases there was an interflowing of substances usually described as solids.

A similar fluidity is momentarily produced in operations of coining and die-sinking. The metal flows into all the hollows of the die, as water would flow if poured upon it. The water flows in obedience to the slight pressure of its own weight, but the metal demands a much greater pressure. This, as it appears to me, is the essential difference between the two cases. Solidity and fluidity are but relative terms. We know of nothing that is absolutely rigid, nor of any absolutely fluid matter, *i.e.*, of no liquid nor gas that flows without some degree of viscosity or internal friction.

A pressure of 6,500 atmospheres corresponds to that to which the material of the earth is subjected at about 80,000 feet depth below the surface, *i.e.*, fifteen miles in round numbers, or $\frac{1}{528}$ part of the earth's diameter. On a globe of one foot diameter this depth is proportionally represented by a thickness of less than $\frac{1}{44}$ part of an inch, or that of a stout card, and yet there can be little doubt that the combined action of the increased temperature with the pressure must liquefy such materials as those of which the crust of the earth is composed.

Nevertheless, we need not be afraid of breaking through this pellicle of rock-ice as we travel over it, for the essential character of such fluidity, as Spring has demonstrated, is that it is only manifested under enormous pressure. Sir W. Thomson may possibly say that the demand for such a shearing force to effect fluidity constitutes a degree of rigidity corresponding to that of steel.

In selecting such a substance as steel for his standard of rigidity Sir W. Thomson has either intentionally or inadvertently chosen about the most variable solid, as regards rigidity, that exists. Its composition varies from soft steel, containing $\frac{1}{3}$ per cent. of carbon, to hard crucible steel, running up to 3 per cent., or nine times as much, its rigidity varying in similar proportion. Moreover, the same piece of steel varies through a still wider range of rigidity according to whether it is slowly or rapidly cooled. Ordinary tool steel, when annealed, may be beaten, or rolled, or "spun" into almost any shape. I have before me a steel vase, 4 inches high, and 2 inches in diameter at its widest part, shaped with foot, etc., that was hammered and spun into its present shape from a flat circular disc of rolled metal. On the other hand, if tool steel be made red-hot and suddenly cooled it becomes so hard and rigid that it will cut glass, and may not be bent at all without fracture. This same piece may be tempered through all the well-known gradations down to the softness and plasticity above described. It may be that Sir W. Thomson carefully considered these facts in order to be quite safe in stating, as the result of his calculations, that the rigidity of the earth nearly corresponds to that of steel.

That the earth, regarded as a whole, is elastic and fluid, or viscous, in the sense I have described above, is proved by the simple fact that great and small waves are propagated in the course of earthquakes, and that when the pillars of coal-mines are removed the roof of rock sinks down and the floor "creeps," up, this occurring in many cases without any fracture.

Describing the Jamaica earthquake of 1692, Lyell says, "A tract of land round the town, about a thousand acres in extent, sank down in less than one minute, during the first shock, and the sea immediately rolled in. The *Swan* frigate, which was repairing in the wharf, was driven over the tops of many buildings, and then thrown upon one of the roofs, which it broke." He also tells us that "the surface of the country during the Calabrian earthquakes often heaved like the billows of a swelling sea, which produced a swimming in the head like seasickness. It is particularly stated, in almost all the accounts, that just before each shock the clouds appeared motionless; and although no explanation is afforded of this phenomenon, it is obviously the same as that observed in a ship at sea when it pitches violently. The clouds seem arrested in their career as often as the vessel rises in a direction contrary to their course; so that the Calabrians must have experienced precisely the same motion on land."

In the report of the Committee appointed by the British Association (1885) to investigate earthquake phenomena in Japan, some very curious facts are stated. One of the instruments used for measuring the movements of the earth was carried to the summit of Fujiyama, a mountain 12,365 feet high, and it was found that the effects of the earth-waves' movements were there exaggerated, as is the rolling of a ship at the summit of its masts. But this was not all; the delicate level indicated that when a strong wind was blowing the bed-plate of the instrument was tipped upwards on the side from whence the wind was blowing, indicating a leaning over of the mountain due to the wind-pressure, as though the base of the mountain was temporarily thrust downwards into the yielding cushion of its rock-bed, on the side where the force of the wind temporarily increased its pressure, *i.e.*, on the side opposite to that from which the wind was blowing.

ASTRONOMY IN CHINA: THE PEKIN OBSERVATORY.

FIG. 3 shows that for observations the Chinese astronomers make use of a ladder on rollers, analogous to those employed in European observatories, and moving upon a double rail. But we must not honour the Chinese imagination for this improvement, for the ladder appears of recent construction, so has probably been imported from Europe.

There are, further, upon the terrace an armillary sphere, an equinoxial sphere, and a celestial sphere of six feet in diameter (fig. 4). This last instrument attracted the admiration of Father Lecomte, and is, in fact, very remarkable. All the stars are shown in relief in their proper places. It is so well suspended that a child could turn it in the direction of the diurnal movement, though it weighs 2,000 lbs.

He describes the ornaments shown in the figure, and

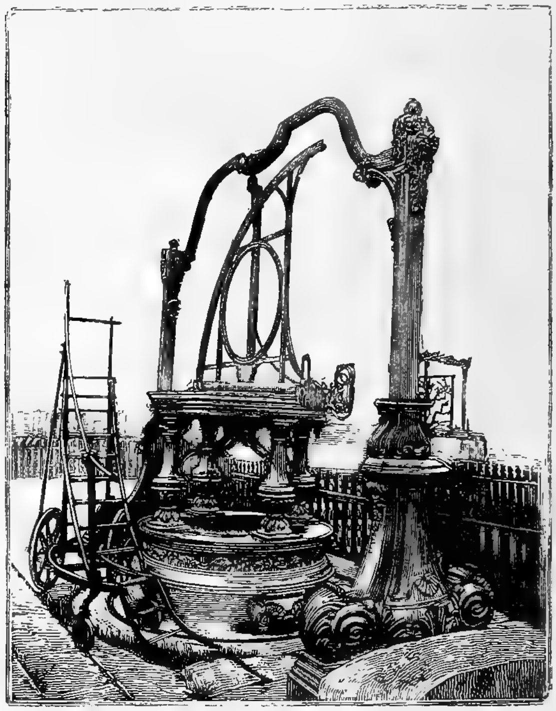

FIG. 3.—OBSERVATORY LADDER.

the concealed wheel-work which gives the axle any desired inclination.

One of the most remarkable instruments is the gnomon, analogous to that used by Kuo-Shou King, astronomer to the Emperor Kublai Khan, founder of the first Tartar dynasty and creator of the first Tartar dynasty. This astronomer used it for executing certain observations, of which Laplace speaks in laudatory terms in his *Mécanique Celeste.*

In addition to the instruments just named, we figure a very ancient armillary sphere dating back to the thirteenth century (fig. 5). The inevitable bronze dragons supporting it are remarkable for their delicacy of execution. Father Verbiest effected a reorganisation of the observatory in 1670, very near the time (1667) when Dominic Cassini created the Observatory of Paris for Louis XIV. He removed the instruments of Kuo-Shou King, most of which still exist, and which have been recently photographed. They differ from those of Father Verbiest chiefly by their profusion of ornaments and by being less easily handled. They are graduated in 365 degs., so that the sun traverses daily one of their degrees. They are similar to those which Tycho constructed at his observatory in the Isle of Huen, with

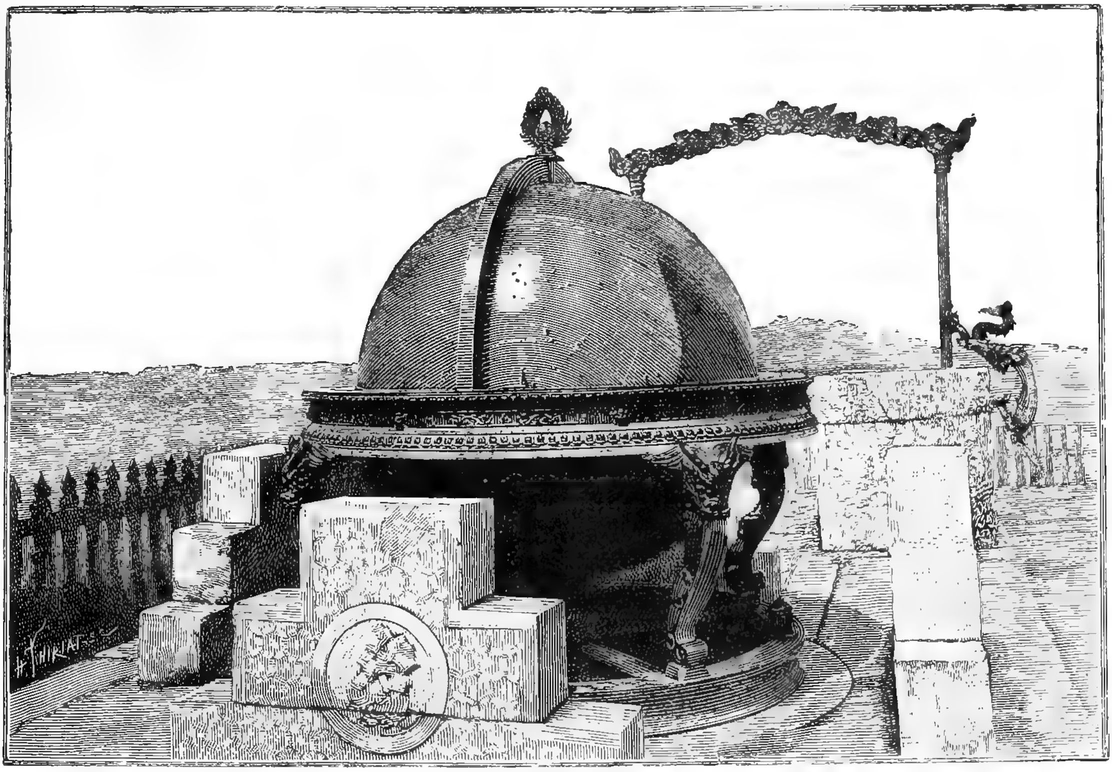

FIG. 4.—CELESTIAL SPHERE (6 FT. IN DIAMETER).

which he observed up to the end of the sixteenth century. They only differ from modern instruments because in these latter the sights have been replaced by telescopes which the Chinese do not want, and of which they have no need.

Father Verbiest, the second creator of the Observatory of Pekin, died in that city exactly two centuries ago.

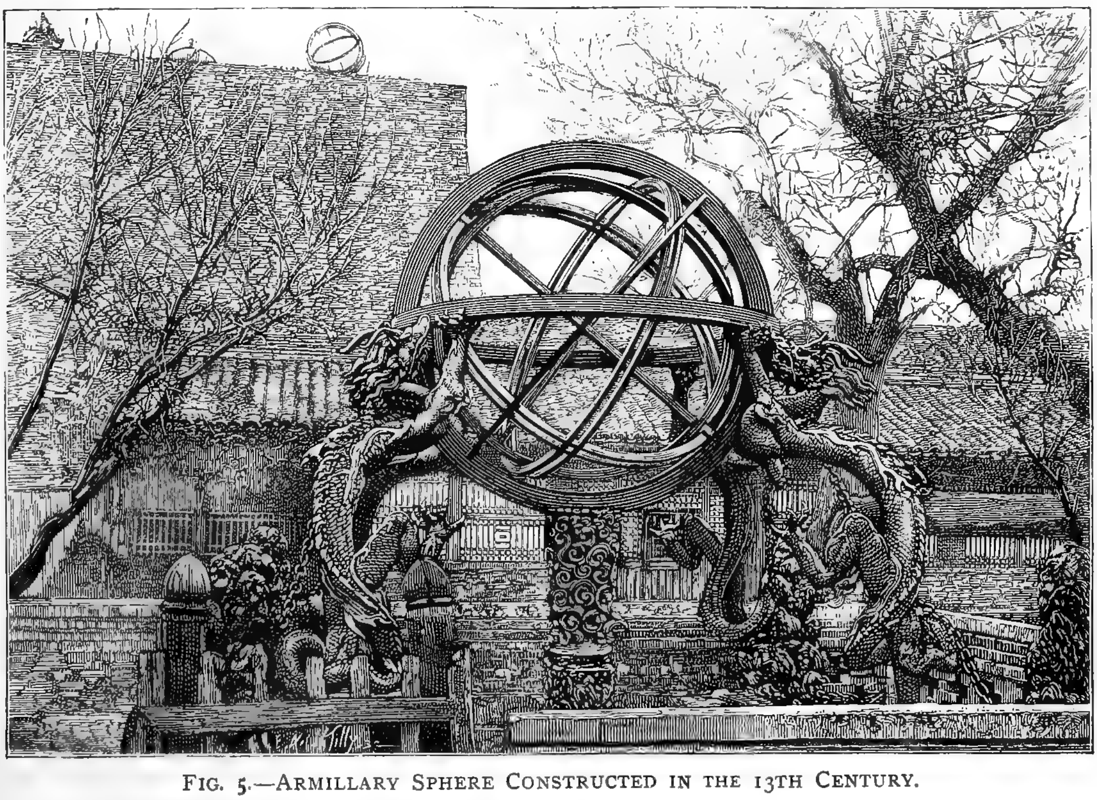

FIG. 5.—ARMILLARY SPHERE CONSTRUCTED IN THE 13TH CENTURY.

SOME RECENTLY DISCOVERED FORMS OF MICROSCOPIC CRUSTACEA.

(*Part II., continued from p.* 598.)

ALTHOUGH our British species of Copepoda present a large variety of form, they must for colour and size yield the palm to foreign species, and it is now proposed to describe a few recently discovered forms obtained last year, during a biological visit to Madeira and the Canary Islands. Over sixty varieties were found about these islands, some adorned with brilliant hues, which are still preserved after being mounted on slides as microscopic objects.

The majority of them are well figured and described in Dr. Brady's excellent *Challenger* monograph on the Copepoda, six, however, being new to science, of

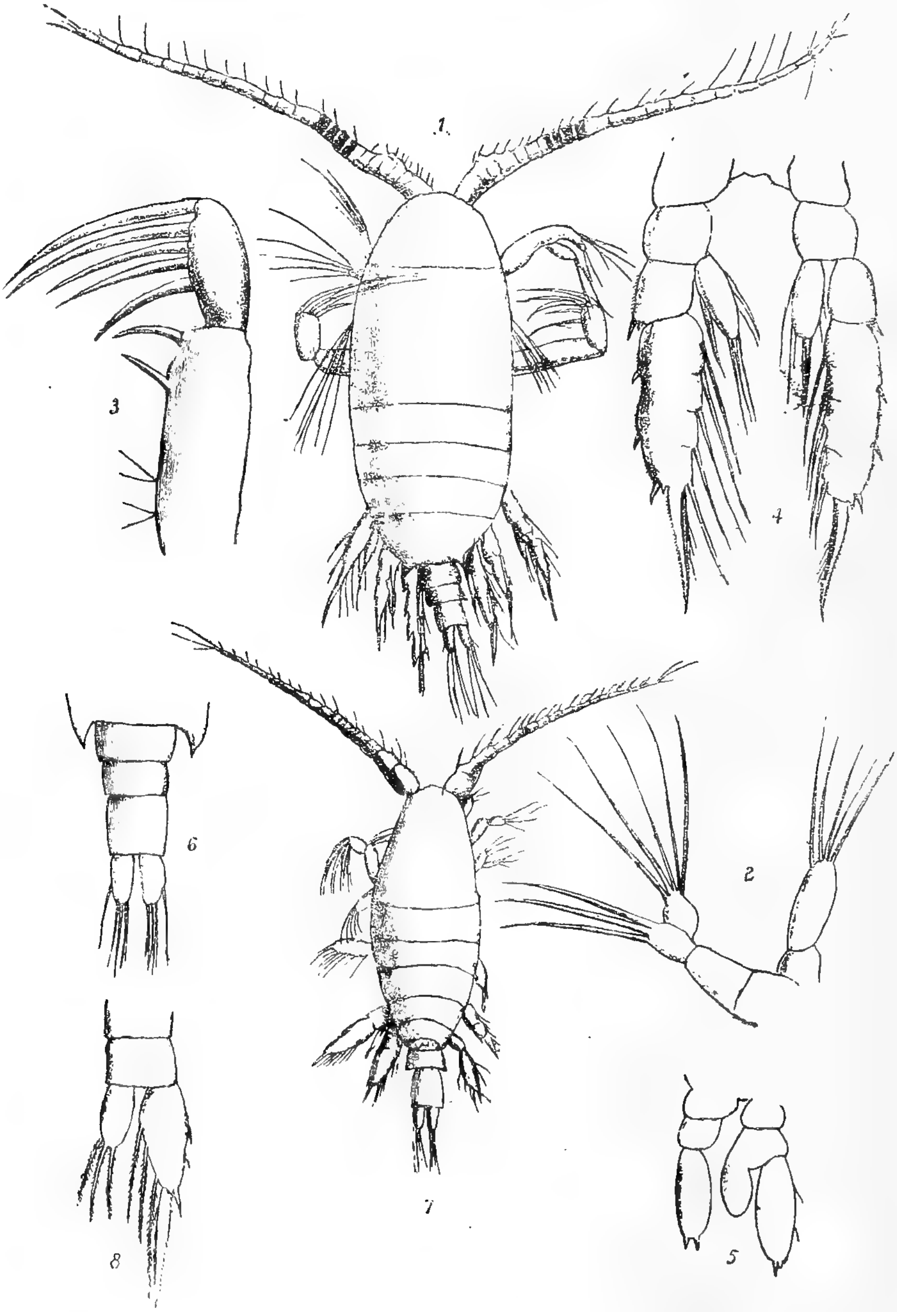

PLATE IV.

Fig. 1. *Candace nigrocincta*, I.C.T., male. × 250.
Fig. 2. Posterior antenna of ditto. × 400.
Fig. 3. First foot-jaw of ditto. × 400.
Fig. 4. Fourth pair swimming-feet of ditto. × 400.
Fig. 5. Fifth pair swimming feet of ditto. × 400.
Fig. 6. Abdomen and caudal segments of ditto. × 400.
Fig. 7. *Candace brevicornis*, I.C.T., female. × 250.
Fig. 8. Fourth swimming-foot of ditto. × 400.

which a description and figures are here given. There appears to be but little difference as regards their geographical distribution amongst the various islands, although much more plentiful in the sheltered bays and harbours than in the more exposed open sea.

Candace nigrocincta, I.C.T., plate iv. The genus Candace is characterised by the presence of dark black pigment markings in various parts of the animal's body, the black rings on the antennæ of this species being sufficient to distinguish it from those hitherto known.

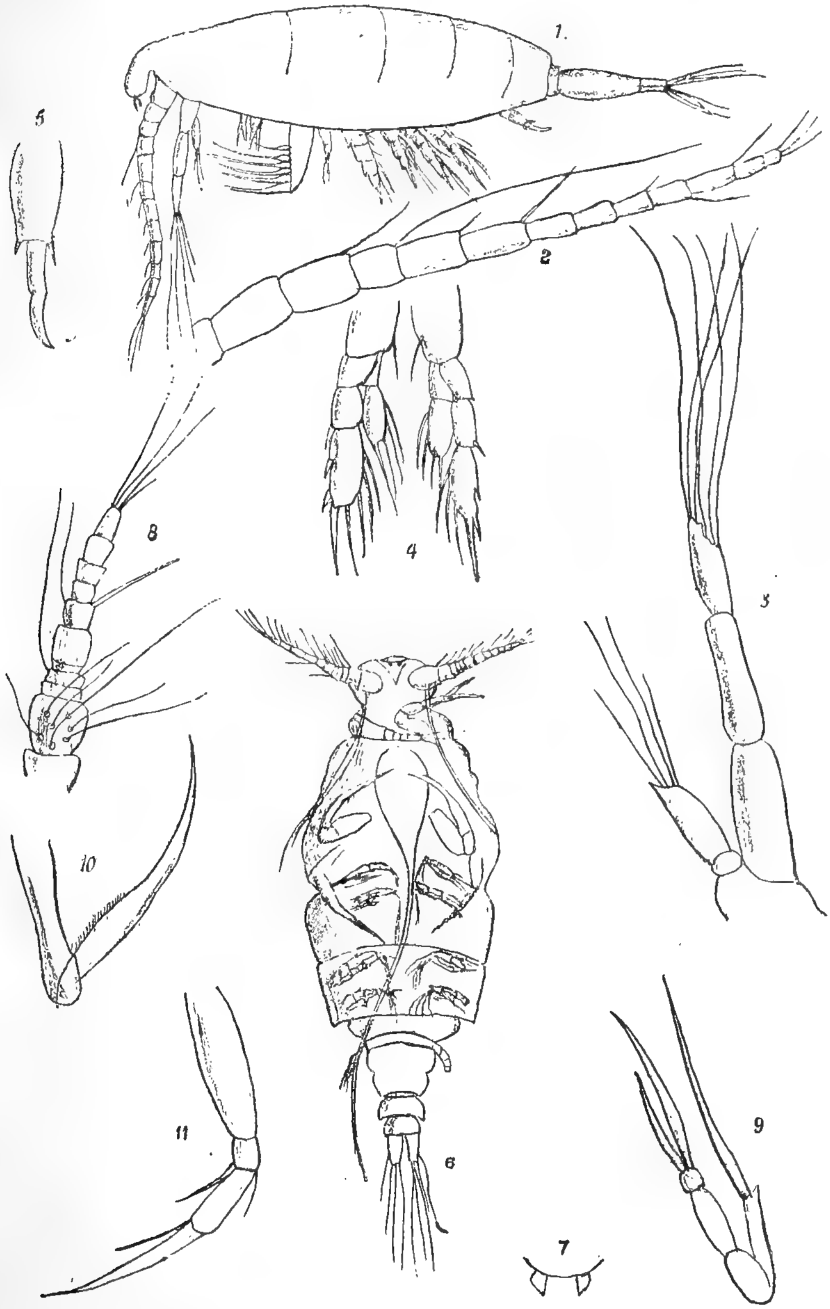

PLATE V.

Fig. 1. *Machairopus Sanctæ-crucis*, I.C.T. ×250.
Fig. 2. Anterior antenna of ditto. ×400.
Fig. 3. Posterior antenna of ditto. ×400.
Fig. 4. Fourth pair swimming-feet of ditto. ×25.
Fig. 5. Fifth swimming-foot of ditto. ×250.
Fig. 6. *Acontiophorus angulatus*, I.C.T., female, ×250.
Fig. 7. Rostrum of ditto. ×400.
Fig. 8. Anterior antenna of ditto. ×400.
Fig. 9. Posterior antenna of ditto. ×400.
Fig. 10. Anterior foot-jaw of ditto. ×400.
Fig. 11. Posterior foot-jaw of ditto. ×400.

Its length is about $\frac{1}{16}$ inch. The body is oval, and rounded in front. The posterior segments are terminated by two lateral spines. The anterior antennæ are 23-jointed, bearing several spinous processes on the inner margin, and short setæ at the termination of each joint. The 8th, 9th, 10th, and 11th joints (fig. 1) are deeply pigmented with a blackish-brown colour, the same pigment tinging the setæ of the posterior antennæ and the terminal spines of the swimming feet. The posterior antennæ (fig. 2) are similar to those of *C. truncata*, but with fewer terminal setæ. The anterior foot-jaws (fig. 3) are 2-jointed, large, and powerful, with two small claw-like spines on the basal joint, and five large ones on the second joint. The posterior foot-jaws are small and 7-jointed. The first four pairs of swimming feet (fig. 4) are alike; the inner branch has one joint only; the outer edge of main branch is finely serrated. The pigment does not extend above the terminal spine, which is somewhat bent and finely serrated, and clothed with dark hairs on the dorsal side. The fifth feet of the male (fig. 5) are each 3-jointed, the right foot having extension on the inner side of the middle joint, both being terminated by two small claws. The abdomen of the male (fig. 6) is 3-jointed, the third being nearly equal in size to the other two; the caudal segments are about twice as long as broad, and are terminated by short, strong setæ.

Several specimens of this strongly marked form were taken at Orotava, Teneriffe, all of which appear to be males.

Candace brevicornis, I.C.T., plate iv. A much more diminutive form than the last, and characterised by its antennæ being 18-jointed instead of 23 or 24, as is the case with most of the genus.

Machairopus Sanctæ-crucis, I.C.T., plate v. One specimen only was taken by tow-net at Santa Cruz, Teneriffe. Length, $\frac{1}{18}$ inch. The rounded head (fig. 1) is of a deep pink colour. The anterior antennæ (fig. 2) are 12-jointed. The posterior antennæ (fig. 3) have long, whip-like setæ, extending to the length of the anterior antennæ. The swimming feet (fig. 4) have three joints to the outer branch, and two joints to the inner. The terminal spine is narrow and finely serrated. The basal joints of the swimming feet have long spine on the inner margin. The fifth feet (fig. 5) have one joint, terminated by a long, stout, curved spine, with a small one at each side. The first joint of abdomen is small, the second long, and wide in the middle. The caudal segments are about four times as long as broad, and are terminated by short, non-plumose setæ.

Acontiophorus angulatus, I.C.T., plate v. One specimen only of this new species was taken at Funchal Bay, Madeira. The angular shape of the posterior segments of the cephalothorax readily distinguish it from *A. scutatus*, which it resembles in general characters.

Length, $\frac{1}{30}$ inch. The anterior antennæ are 11-jointed short, and gradually tapering from base to apex; the posterior antennæ (fig. 9) are 2-branched, the first being 3-jointed and terminated by two long, lancet-shaped spines; the second has one joint, and is terminated by a long, sword-shaped spine. First and second foot-jaws (figs. 10 and 11) each have a long apical claw; the first is composed of two, the second of four joints.

First four pairs of swimming feet nearly alike, both branches being 3-jointed (plate vi., fig. 5); the base and second joint of the chief branch have very fine serration on inner edge, formed by minute hairs. Fifth feet (plate vi., fig. 6) are composed of two stout joints, the outer bearing a number of long setæ, some of them plumose; the outer edge of both joints has fine hairy serration.

Siphon very long and slender, reaching to the ends of caudal segments.

(To be continued.)

MEMORANDA.

Of all mechanical modes of assisting study, perhaps none are so important as wise methods of making and preserving notes. The commonplace book of the old scholars is the most obvious receptacle for scraps of knowledge, but not at all the best. The habit of transcribing passages without the alteration of a word gives dryness to the style, and in the long run to the mind. Examples could be quoted to show that pleasure comes at last to be taken in the mere occupation of copying, however unimportant the remarks may be. Southey's "Commonplace Book," copies of which used to load the shelves of secondhand booksellers, shows what may become of a student who gives way to the passion of accumulating curiosities. We must never forget that the end in view is not the production of a neat book of extracts, nor any kind of learned trifling, but the concentration into manageable form of the products of genuine thought, and that thought in some sense our own. Let us not suffer the love of pigeon-holing to overpower, as it easily may, the love of research. What is wanted is a rapid and flexible system, which can alter with altering needs, and greater experience, and by means of which we can bring into one view the results of years of reading and observation. Perhaps no better methods can be recommended to the young student than those practised with such memorable results by Charles Darwin. The first and simplest resource is to fasten a sheet or two of paper into any book which contains materials likely to be wanted hereafter, and write down the headings with references to the pages. Of works which are to be got up throughout abstracts must be made. Let the abstract be brief and carefully arranged to avoid repetition as well as to promote quick examination. Nothing beyond a single sentence should as a rule be given in the words of the book, and even so much is rarely necessary. The inexperienced student must be ever on his guard to see that the work of the pen is not allowed to stand for the close application of his mind to the subject. As materials accumulate, they want classification and storage. A range of shelves or drawers is wanted. We have found nothing better than Stone's cabinet for law-forms, which costs £3 12s., and will hold enough for a life-time of abstracting. As need arises, special indexes can be made, or the materials resorted. It is an indirect advantage, not to be lightly esteemed, that the student soon becomes used to note the heads of whatever he is interested in, and is led to adopt that useful maxim of Lagrange—"Always read pen in hand."

The Lily of the Valley Poisonous.—According to the *Revue Horticole*, the lily of the valley (*Convallaria maialis*) is a powerful poison for poultry. Of ten young hens which had been eating the flowers of this plant, nine died shortly after.

General Notes.

The Inhabitants of Ancient Egypt.—In opposition to the hypothesis that the people of Ancient Egypt were of a negroid type, Prof. Virchow shows that they were of old, just as at present, a straight-haired race.

The Sewage of Paris.—In spite of all the boasts concerning the fertilising properties of the Paris sewage, no one will have it. The last suggestion is a canal for taking it to the coast between the Somme and Arthe.

A New Chair of Botany.—Dr. Holbrook Gaskell has promised to the Liverpool College of the Victoria University the sum of £5,000 towards the endowment of the Chair of Botany. The total sum required will be £10,000.

Sweeping Adulteration.—At Stoke-upon-Trent "sublime olive oil" has been sold which consisted entirely of cotton-seed oil with a slight trace of some animal oil. There can be no objection to cotton-seed oil if sold under its own name.

The Satellites of Mars.—M. Poincarré, in a communication to the Academy of Sciences, calls in question the hypothesis of M. Dubois that the satellites of Mars are small planets which have passed some years back in the vicinity of Mars, and have been retained by the attraction of that planet.

Injurious Effects of the Telephone.—Dr. C. J. Blake (*Science*) has communicated to the American Otological Society a paper on the injurious effects of the telephone on the hearing power. He thinks that the ear is fatigued and rendered liable to injury. Other medical men present gave confirmatory evidence.

Executions by Electricity.—*Science*, commenting on the manner of applying the current as proposed by the Medico-Legal Society of New York, thinks that it should be passed from one arm to the other so as to traverse the region of the heart. In almost all the fatal accidents recorded the current has passed in this manner.

Interruption of Electric Conductions by Snow.—On November 9th, at the town of St. Joseph, in Montana, a heavy snowstorm first broke down the telegraph and telephone wires, and by 4 p.m. rendered the electric-light wires useless. The electric tram-lines, however, were not in the least interfered with, but went on working as usual.

The Persistence of Human Races.—According to Prof. Virchow (*Verhandl. Berlin. Gesellsch. für Erdkunde*), the hereditary persistence of races is so strong that it is maintained in spite of admixtures, and the ultimate fusion of individuals to one common type is not so much a product of the mixture as the elimination of some element out of the mixture.

A Chinese Soap.—According to Father A. Chausse (*Cosmos*), the favourite soap of the Chinese is the cake left after pressing out the oil from the seeds of *Camellia oleifera*, a near ally of the beautiful *Camellia japonica*, so much cherished in our conservatories. The cake is ground to powder and dissolved in boiling water, and is said even to take out oil-spots.

The Universal Meridian.—*Cosmos*, deeply dissatisfied, like many other French organs of opinion, with the proposed universal adoption of the meridian of Greenwich, again proposes Bethlehem as the first meridian! It is needless to say that a place which has no observatory and which lies outside the life of the present age is eminently unsuitable for such a purpose.

Rain in Greenland.—According to *Cosmos*, violent rains are not confined to the tropics. At Ivigtut, in the south of Greenland, a rainfall of seven inches was registered on October 12th and 13th, 1887. In December it rained without ceasing from the night of the 18th to the night of the 29th, the depth of the rain being above ten inches. During the last seven days the daily average was close upon an inch.

Progress of Cremation.—According to the *Flamme*, the organ of the Berlin Cremation Society, the number of bodies cremated in different countries up to August 1st last is, in Italy 998, Germany 554, America 287, Sweden 39, England 16, France 7, and Denmark 1. The members of the cremation societies number 3,012 in Sweden, 1,326 in Denmark, 1,326 in Holland, 1,050 in Germany, 580 in Italy, and 390 in Switzerland.

The Sanitary State of Manchester.—The medical papers are much exercised touching the high death rate of Manchester, which is pronounced to be more unhealthy by 70 per cent. than the average of other large towns in the United Kingdom. Whatever may be the cause, or causes, of this unsatisfactory state, it cannot be the soil or climate, since the rural districts a few miles to the west rank among the healthiest places on the earth.

A Subterranean River.—M. Martel informs the Academy of Sciences that he has recently performed a voyage of about $1\frac{1}{4}$ mile in the underground passages, in which circulates a stream which disappears in the region of Causses. The author's results lead him to propose a theory on the formation of the celebrated *canons* such as are met with in the State of Colorado, and, although on a smaller scale, in France, at Montpellier-le-Vieux.

Dreams of the Blind.—Jastrow (*Humboldt*) has recently confirmed the conclusions of G. Herrmann that persons who have lost their eyesight prior to their seventh year never dream in visual imagery, whilst in those who have become blind later in life the dreams are like those of persons who can see. Jastrow believes that the blind dream unusually little, women more than men. Dreams decrease in frequency from childhood to age.

The Sight-Seer's Headache.—The *New York Medical Record* examines the origin of this affection so well-known to the visitors of museums, picture-galleries, and exhibitions. The principal causes seem to be a close atmosphere, defective in ventilation, the mental fatigue from long-continued observation, and the bodily weariness from maintaining an upright position, and especially the strain from continually moving the head and the eyes in an upward position.

MICROBIA IN ARTIFICIAL MINERAL WATERS.—Hochstetter (Humboldt), after examining samples of such waters for the German Imperial Sanitary Department, finds that pathogenic (disease-producing) micro-organisms die in course of time if kept in closed bottles. The propagation of cholera by water which has been in stock for some days is improbable, but an epidemic of typhus may be produced by water which is from five to seven days old.

INFLUENCE OF EXERCISE UPON DIGESTION.—Dr. Kohn has recently conducted a series of experiments in the laboratory of Professor Rossbach to decide whether rest or exercise after a meal is more favourable to digestion. The results showed that exercise decidedly retards digestion, leading to the production of large quantities of lactic acid in the stomach, while hydrochloric acid and peptone were much below their normal proportions.

POISONOUS EFFECTS OF CIGARETTE SMOKING.—Dr. W. L. Dudley, Professor of Chemistry in the Vanderbilt University of Nashville, gives, in the *Medical News*, an account of his researches on this subject. He finds that the most poisonous constituent of tobacco-smoke is carbonic oxide. More injury results from cigarette than from cigar or pipe smoking, because, as a rule, the smoke of the former is inhaled. Without inhaling, the cigarette is not more hurtful than the pipe or the cigar.

CLASSIFICATION OF LIGHTNING.—Arago divides lightning into three classes:—(1) Zigzag lightnings, or those of the first class, their name indicating their form, and sometimes splitting up into two or three branches. (2) Lightnings of the second class. The light of these flashes, instead of being concentrated in winding lines almost without breadth, covers vast surfaces. They often seem to illuminate the outlines of the clouds from which they emanate. (3) Lightnings of the third class, which take a globular form.

BLACK RIVERS OF SOUTH AMERICA.—Among the tributaries of the Amazon and the Orinoco there are several so-called *rios negros*—streams of the colour of coffee without milk. During his exploration of those regions M. Marcagno collected several samples of these waters and sent them to Professor Müntz for analysis. The colouring matter consists entirely of free humic matters in the proportion of 16 parts per million. There is scarcely any mineral matter, lime is totally absent, and there are mere traces of potash and oxide of iron. If a black stream falls into an ordinary river, the dark colour disappears at once.

PREPARATION OF PHOSPHORESCENT MATERIALS.—According to M. Becquerel, very small quantities of foreign matter incorporated with the alkaline earthy sulphurets greatly modify the character of the light emitted after exposure to the rays of the sun. Thus, with traces of peroxide of manganese, a fine yellow light is obtained; with persulphuret of potassium a green, and with compounds of bismuth a blue. An absolutely pure sulphuret of calcium gives off only a feeble light, which soon fades away. This shows the reason why the shells of oysters, etc., after calcination with sulphur, give a more phosphorescent mass than any pure carbonate of lime.

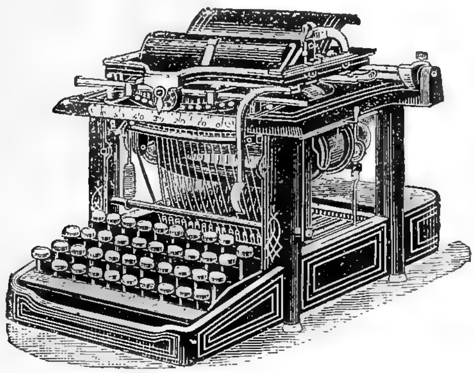
THE SALE OF MUSHROOMS.—According to *Cosmos*, the Council of Hygiene of Paris is about to adopt special measures to prevent the sale of unwholesome or poisonous fungi. It is proposed that all wild mushrooms shall be sold wholesale only at one market, where they will be duly examined by experts before being supplied to the retail trade. Cultivated mushrooms require, and will receive, a much less severe examination. It will be forbidden to cry, sell, or hawk mushrooms in the streets, or from door to door.

PREVENTION OF HYDROPHOBIA IN BAVARIA.—In the kingdom of Bavaria, during the years 1863 to 1876, there were annually at least 14 cases of hydrophobia out of a population of $5\frac{1}{2}$ millions, and in some seasons the number rose to 23, 29, and even 31. Since the introduction of a new law the number of such fatalities has been *three* in seven years. Every dog must, on pain of being immediately destroyed, have a responsible owner, and must wear round its neck a metal collar on which is engraven a receipt for the tax. The tax is paid *monthly*, on which occasion the dog has to be produced for veterinary inspection.

PUBLIC HEALTH.—The deaths registered last week in twenty-eight great towns of England and Wales corresponded to an annual rate of 18·6 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The highest death-rates, measured by last week's mortality, were:—From measles, 1·7 in London, 1·8 in Leicester, 2·6 in Portsmouth, 2·7 in Leeds, 3·0 in Oldham, 3·2 in Salford, 3·8 in Liverpool, 4·8 in Blackburn, and 7·7 in Cardiff; from scarlet fever, 1·0 in Liverpool and in Sheffield, 1·6 in Derby, and 2·2 in Blackburn; from whooping-cough, 1·0 in Birmingham and 1·9 in Cardiff; and from fever, 1·0 in Cardiff and 1·6 in Salford. The 48 deaths from diphtheria in these towns included 35 in London, 3 in Nottingham, 2 in Birmingham, 2 in Salford, and 2 in Newcastle-upon-Tyne. No death from small-pox was registered in any of the twenty-eight great towns. In London 2,644 births and 1,461 deaths were registered. Allowing for increase of population, the births were 41, and the deaths 357, below the aveage numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had been 17·2 and 16·5 in the two preceding weeks, rose last week to 17·8. During the first ten weeks of the current quarter the death-rate averaged 18·6 per 1,000, and was 1·7 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,461 deaths included 139 from measles, 30 from scarlet fever, 35 from diphtheria, 13 from whooping-cough, one from typhus, 12 from enteric fever, 19 from diarrhœa and dysentery, and not one from small-pox, ill-defined forms of continued fever, or cholera; thus, 249 deaths were referred to these diseases, being 24 above the corrected average weekly number. In Greater London 3,494 births and 1,764 deaths were registered, corresponding to annual rates of 33·0 and 16·7 per 1,000 of the estimated population. In the Outer Ring 12 deaths from measles, 9 from diphtheria, 4 from scarlet fever, and 4 from "fever" were registered. Measles caused 5 deaths in West Ham and 3 in Willesden sub-districts. Two deaths from scarlet fever occurred in Enfield, and 4 from diphtheria and 3 from "fever" in Tottenham sub-districts.

TYPE-WRITERS.

MOST persons who can combine a little mechanical ability with a knowledge of the use of tools and of the construction of machinery, and who have also had some experience with type-writers, must marvel at the ingenuity, skill, and dogged perseverance of those who



THE REMINGTON TYPE-WRITER.

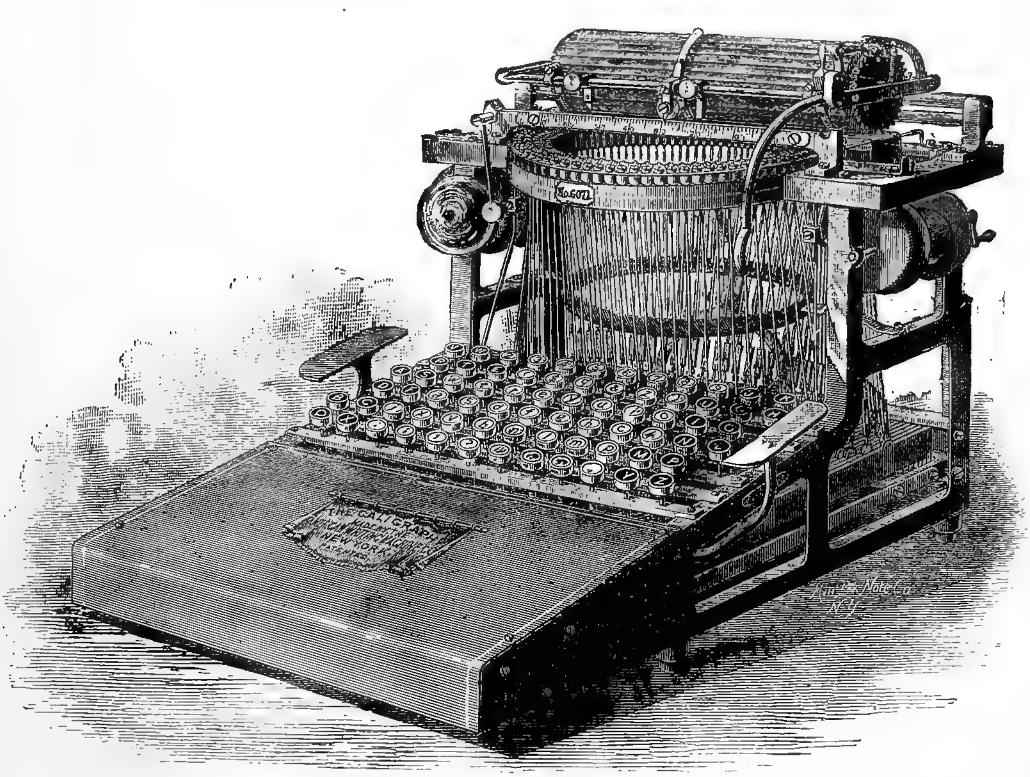
first attempted to produce a machine for writing in printed characters, and who succeeded in producing anything better than a troublesome toy.

Some amateurs are endowed with a delicacy of manipulation and patience that is seldom to be found in a skilled workman; and the fruits of their labours are often nothing more than marvellous ivory pagodas, balls within balls, and snuff-boxes whose beauty is rivalled only by their uselessness. We have not yet met with one who has had the skill to make, much less to invent, a satisfactory type-writer. Americans are as much before us in bringing out and perfecting such things as type-writers and sewing machines, as they are behind us in locomotive and marine engine work.

The sewing-machine has not only taken the bread out of the mouths of thousands of needlewomen, but its use is far more injurious to those who remain, than sewing in the old-fashioned way. The type-writer, on the other hand, is rapidly creating a new industry which is eminently adapted to female labour.

Of the two main advantages offered by the type-writer, perhaps legibility is more important than speed. A few weeks' practice is sufficient to enable any one to write as fast with a machine as with a pen, and constant use will make it possible to attain some eighty words a minute, or about three times the speed of fast writing. The fatigue is far less, especially for long spells of several hours in succession. The legibility cannot be compared so readily; but a good machine, with well selected type, produces a sheet, which, though it may contain errors due to the attempt of the operator to work at too high a speed, almost equals ordinary print, and has the great advantage of perfect uniformity, each letter being distinct, with none of those endings in which the last few characters melt away into a wriggling line.

The best known type-writers are the Barlock, Crandall, Columbia, Hall, Hammond, Remington, and the World. This alphabetical order places one of the latest inventions at the top of the list, while the well-known Remington, of which greatest numbers have been made, appears last but one. These machines may be conveniently divided into two classes: the Remington, Hammond, Caligraph, Crandall, and Barlock, which are key machines, and the Columbia, Hall, and World, which have moving type wheels or



THE CALIGRAPH TYPE-WRITER.

plates, operated by means of an index. The former class are provided with keys arranged in rows like an organ.

The inking is effected by means of a tape or ribbon, which is gradually reeled off from one spool to another. The inking arrangements of the second class sometimes give a good deal of trouble; for though only requiring a few drops of aniline ink, such as is used for rubber stamps, they alter considerably with changes in the weather. The Hall, for example, supplied with ink specially prepared for it, may be in good condition in the evening, and the next morning, being rainy, the inking pad may have become so wet that the writing is quite blurred and blotted. There is, however, considerable convenience in being able to obtain ink almost anywhere for a few pence a bottle, compared with the key machines for which inked tapes are supplied, in some cases at fancy prices; the process of inking being kept a secret, to ensure that they shall be sent back from time to time for re-inking; the type-writer meanwhile standing idle for several days. We are assured by the representative of a certain type-writer that not only is there no one in this country who understands how to ink a ribbon, but that there is only one individual in America who can do it properly. And our informant is his agent!

We propose to give a brief description of the various machines to which we have alluded, without attempting to give a complete list of the advantages of each, or weigh to their comparative merits.

The *Remington* is naturally the first that claims our attention, since it was practically the earliest in the field, and is the most generally known. Until competition arose a few years ago, it was only provided with capital letters, figures, and stops. The machine shown in fig. 1 has 41 keys, each of which prints two characters. The keys are arranged in four rows, and are supplemented by a spacing bar, running the whole length in front of the keys; and two changing keys, by which either the capitals or the small letters are thrown into action. The keys are pivoted at the back of the machine, and attached to each is a pull-down wire, connected to a lever which hangs nearly vertically. These levers are arranged in an oval, and are so proportioned that when a key is struck the lever to which it is attached is thrown upwards. The end of the lever carries the type, and each impression is made at the same spot. The upper part of the machine consists of a carriage provided with a rubber roller round which the paper passes. The carriage is moved one step to the left immediately after each impression has been made, or by a depression of the spacing bar. The movement is effected by a spring, which is wound up by the act of pushing the carriage back at the end of the line. The handle projecting downwards towards the keys serves both for pushing back the carriage, and, by pulling forwards, turns the roller, and moves the paper on for a fresh line. When the end of a line is approached, a bell rings at each depression of a key, warning the operator that there is room for only a few more letters, and that he must either stop at the end of the next word, or divide it, and use a hyphen. The difficulty of ending the lines evenly makes the right-hand margin of a type-written sheet more uneven than ordinary manuscript. In setting up type for ordinary printed matter, the compositor "justifies" each line, or brings the end of it to an even margin, by selecting spaces of different widths. This can be done after the type is arranged; but with a type-writer it is not until the last two or three letters that it can be seen how the line will end. Where a particularly neat copy is desired, the sheet may be copied again on the machine, using a rather longer line, to allow for a double space here and there. With the Remington typewriter, a sharp "staccato" is required, but not much force is needed. An improved pattern has just been brought out, having provision for a wider sheet of paper, together with other improvements which we have not had an opportunity of inspecting, as there was not one to be seen at the depot when we called for that purpose.

A very important advantage offered by the Remington over most other machines is one which is not due to any inventive skill; this is, that the agents have the means for effecting repairs, and can supply broken or worn-out parts, and have skilled men to send out to put their machines in order, while most other typewriters labour under the disadvantage which was so much felt when sewing machines were first introduced, viz., that no repairs could be made without sending to America for the new parts; and then there was the risk of some improvement having superseded the very part which had proved defective. It is to be regretted that large numbers of type-writers have been sold in this country before they had been properly worked out. Defects were said to be due to the want of skill of the operator, when they were really faults of construction in the machines. The agents having a few more in stock, and being quite unable to effect repairs, frequently had to take them back again.

The agents for the Remington are alive to the fact that a type-writer is not of much use without paper, though, as with other machines, we are assured that "its appearance is ornamental, and it is a beautiful piece of furniture for any library." They have accordingly made arrangements for providing suitable material for writing on, though any type-writer will write fairly well on almost any ordinary paper. It is, however, of great importance for producing manifold copies that the proper kind of paper be used. Six or eight copies can be produced at the same time by placing carbon paper between the sheets. Ordinary thin post paper and common carbon paper are quite useless for the purpose. The agents of other type-writers are following this example, and it would be well if they would also be as ready to admit defects in the machines they sell, and to execute repairs themselves, instead of asserting that an accident is so rare that they do not find this to be necessary.

The *Caligraph* may be noticed next, since it professes to be an improved Remington, and resembles the older machine closely, at first sight. The levers are made of sheet steel, like the ribs of an umbrella, and the joints are provided with adjusting screws to take up the wear. The levers in the earlier forms of Remington were liable to get loose, and the levers being long compared with the length of their pivots, wrote an uneven line. A polygonal roller is provided, so that the type may strike against a flat, instead of a round surface. There are no less than seventy-two keys, each of which prints one character; they are placed on a level, instead of in steps. *(To be continued.)*

INTERNATIONAL CONGRESS OF METEOROLOGISTS.—The French Meteorological Society has announced its intention of holding or trying to hold an International Congress of Meteorologists by the inopportunity of the Paris Exhibition of 1889.

Natural History.

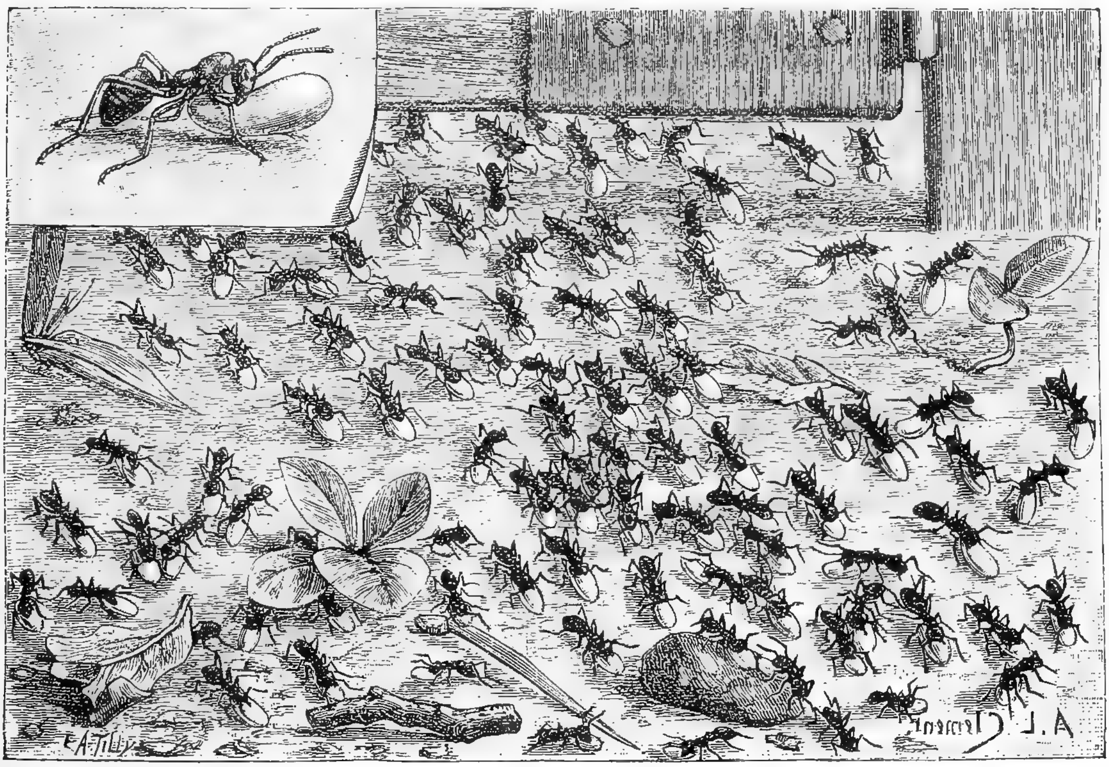
ON THE MANNERS OF ANTS.

M. G. A. Hirn, the well-known physicist, gives in *La Nature* an account of a slave-hunt among ants, which will, perhaps, not be thought less interesting from the absence of certain technicalities which a biological specialist would have introduced. He writes :—

On Saturday, July 14th, 1888, in very bright sunshine, I was walking along a road passing from south to north, running, at the place where I was, along the walls of a garden. I soon observed at my left hand, by the wall, a legion of brown ants, of a large size, marching rapidly and in good order all in one direction. The column, rather more than an inch in breadth, was more than five yards in length. It set out from a plot of ground rather higher than the road, covered with grass and weeds. It descended by a bare path having an incline of more than 45 degrees. At the end of this track it turned abruptly at right angles to follow the main road. I quickened my steps, and reached the head of the column, which was distinctly limited, and I followed attentively to see what might be the object of this expedition, which was clearly the execution of some well-conceived plan.

I had already noticed that during the march of this army several ants, seeming to have changed their minds, returned towards the rear, traversing all the ranks. But I saw that after communicating with some one of their comrades whom they seemed to be seeking, they resumed their onward journey. On arriving at the gate of the garden the head of the column halted, and all the rest, as they came up, arranged themselves in a circle of considerable diameter. It was evident that they were holding a council of war, and concerting measures to be taken. Soon the circle opened, and the ants began to pass under the gate, no longer in a serried column, but spread out over a large space, and marching more slowly and with circumspection. I saw them moving towards a plot of grass, where they were lost to view.

That day I felt unwell, and I walked on sadly, thinking of what I had just seen. Here was, I thought, an unfortunate nation, exiled from its homes, and in search of a more propitious abode. This was all a mistake. What I had just witnessed was an expedition for the purpose of plunder. On returning by the same road about half an hour later, I saw the brown ants coming home in triumph, each grasping in its jaws the pupa (commonly, but erroneously, called eggs) of some other species. They no longer marched in order. Each ran on independently, keeping a firm hold of its prey, as it may be seen in the figure.



Was this merely a prey which they were with a barbarous refinement of taste seeking for their diet? Or were not rather the pupæ intended to be reared so as to become slaves? Was this an odious act of rapine which I had just witnessed, or do the ants thus deprived of their freedom submit willingly to their lot, as to a predestinate career? In any case the defence, if defence there had been, cannot have been energetic; no one pursued the victors, and none of them appeared to be wounded.

The first part of the drama had saddened me, though I had misinterpreted the facts. The end was still more painful. Yet I consoled myself with the reflection that slave-holding ants, if they are no more righteous than their human imitators, understood better their own true interests. They do not maltreat their victims too much.

The species of ants whose pupæ are thus carried off continue to exist, so that they are not deprived of all their brood.

Since the epoch when Descartes, by an unhappy inspiration of his genius, tried to reduce (lower) animals to machines, and when his fanatical disciple Malebranche carried this theme to extravagance, since the day when Buffon, in contradiction with his pompous tirades on the dog and the horse (the echoes of which still haunt us), strove to prove that in the animal every thing is mere instinct and mechanism, a considerable advance has been made in this order of questions. Just as no astronomer now contests the plurality of worlds, no naturalist denies the manifestations—often very exalted—of intelligence, reasoning, and other psychic faculties, not in the animal kingdom taken in the lump, but in certain species, and in certain individuals of such species. Man being considered—of course by himself—as the highest type of animated nature, we might be led to think that those lower species which in certain respects are comparable are those which approach him nearest in their structure. If this is, generally speaking, the case, we find exceptions the most enigmatical. How widely does our organisation differ from that of an ant, and yet in the scene just described we recognise actions where instinct falls into the background, actions which presuppose consecutive observations, reasoning, and communication between individuals which no one would suspect *à priori*.

The two ant-hills which I have described—that of the plunderers and that of the plundered—are remote from each other, and the latter is in an enclosure. Instinct might tell the large brown ants that there exist other ants capable of doing work which themselves are unwilling or unable to perform. But here the revelations of instinct would stop. To satisfy their demand it is evident that the idle or incapable ants must have scouts ranging in search of a nest of industrial ants and penetrating boldly into it (?) to see when the pupæ are fit for transportation, and then returning home to inform their companions that the time is come. This information must be rapidly communicated to the whole society, and the marching orders must be perfectly understood since the head of the column advances quickly and in good order. The legion must have guides quite sure of their object and of the road to be taken. The ants which turned back and traversed all the ranks to see if all was in order, knew doubtless that in their species, just as it is the case among mankind, intelligence and the sense of duty are not alike in all individuals. The council of war held before the attack is the proof of intelligent foresight. No empty head in command had said, "Everything is ready."

Why I have enlarged on this subject is because I had never previously seen among these tiny beings a sequence of varied acts all combined, leading the observer to the same conclusion. To recognise in the scene which I had witnessed merely mechanism and instinct, I must have been myself a mere automaton.

Pisciculture.—All attempts made to acclimatise the true salmon (*Salmo salar*) in the rivers of Southern France, Italy, and other countries of the Mediterranean basin have failed, as the waters are too warm for the fish at the season when they ascend the rivers in order to spawn. The Society of Acclimatation of France has therefore undertaken to introduce the salmon of the Sacramento (*Salmo quinnat*). No fewer than one hundred thousand ova of this species have therefore been brought over from America in the steamer *La Bourgogne*, and have been placed for incubation in the tanks of the piscicultural laboratory of Quillan. As soon as the young fish have reached a sufficient degree of maturity, they will be set at liberty in the river Aube. It is hoped that the climate of the Mediterranean basin will be sufficiently like that of the Sacramento to allow of their multiplication.

Abstracts of Papers, Lectures, etc.

PHYSICAL SOCIETY.

At the meeting held on December 8th, 1888, Professor Reinold, F.R.S., President, in the chair, the following communications were read: Note on a Modification of the Ordinary Method of Determining Electro-magnetic Capacity, by Mr. J. W. W. Waghorne, D.Sc. In determining capacity absolutely from the throw of a galvanometer, and a steady deflection through a known resistance produced by the same battery, error may arise from the imperfect elasticity of the fibre (when short), and the resistances required are often greater than can be conveniently obtained. The latter difficulty may be overcome by taking a known fraction of the potential difference used for charging the condenser to produce the steady deflection, and the former error may be reduced by observing the first swing due to the permanent current, instead of the steady deflection produced by that current. By adopting this latter device, the logarithmic decrement need not be determined, and the time required to make a measurement is considerably reduced.

Dr. Thompson pointed out that error frequently arises from the capacity of the key being appreciable where small condensers are being used, but the author stated that the modification was not intended for such cases.

Professor Ayrton remembered having used, in conjunction with Professor Perry, the throw due to the permanent current instead of the steady deflection, when experimenting with condensers containing E. M. F.'s, and believed they abandoned it on account of the difference in decrement on closed and open circuits.

Mr. Sumpner regarded galvanometers with small differences in damping on closed and open circuits, as unsuitable for ballistic purposes, and mentioned a case in which the latter was only half the former.

Mr. Boys considered the damping would be modified by having the condenser joined to the galvanometer terminals, and thought the decrement should be decidedly different from that on pure open circuit.

In thanking the author for his paper, the President said that any improved arrangements of well-known experiments or of lecture apparatus, would always be gladly received, and reminded members that in bringing such before the Society they would be carrying out one of the chief objects for which it was founded.

"On Some Facts connected with the Systems of Scientific Units of Measurement," by Mr. T. H. Blakesley, M.A. The author considers that the C. G. S., and Practical (Quadrant, Volt, Second), system of units do not satisfy the requirements of a perfect system in which the chief ends to be kept in view are:—(1)

Correlation, (2) *Simplicity*, (3) *Comprehensiveness*, (4) *Naturalness*, and (5) *Convenience*.

In a properly *Correlated system* all the quantities considered should be so connected by the equations representing the laws of nature, that no co-efficients are required in expressing any unit in terms of others, for *Simplicity*, quantities essentially the same should be measured by the same units, and to be *Comprehensive*, the system should embrace all the physical ideas which occur; to be *Natural* its units should be closely or decimally connected with natural units, and for *Convenience*, they should agree with established (though arbitrary) units, either actually or decimally. In the two systems referred to, correlation has been more completely realised than any of the others, but simplicity is by no means satisfactory, and the want of comprehensiveness was discussed by Professor Rucker at the last meeting. The "second" is unnatural in not being a decimal subdivision of the solar day, and the gramme is derived from the centimetre by assuming the density of water to be unity, whilst the inconvenience arising from the relation between the horse-power and the watt or the erg, is universally acknowledged.

Two general formulæ are given in this paper for converting magnitudes expressed in Practical, and C. G. S. electro-magnetic measure into C. G. S. Electrostatic units.

Though the formulæ may be found useful, the author thinks it would be far better to adopt one system for all measurements, and suggests a "Coalition System," in which v is taken as the unit velocity. If in this system the "second" be retained, then the unit of length will be 30 earth-quadrants, and if the quadrant be taken (as in the present practical system) as the unit of length, then the unit of time will be $\frac{1}{30}$ sec. The influence of such changes on present standards is then discussed, and the relation between the new unit of power and the horse-power found to be unsatisfactory.

To endeavour to bring the horse-power and the unit of power into decimal relation, the author expresses the physical quantities in terms of length, time, and power, from a table of which it is evident, what units will be affected by changing the unit of power, and tables of converting factors are given when the latter unit is taken as ·746 watt or as 7·46 watts.

A summary is given towards the end of the paper in which the union of the two electrical systems by choosing $\frac{1}{30}$ sec. as the unit of time is recommended, the effect of which is to make the unit of capacity $\frac{1}{900}$ Farad., and that of resistance 30 ohms. Before concluding, the author deprecates the practice of giving specific names to particular units, for by so doing subsequent necessary changes are made much more difficult.

Dr. S. P. Thompson thanked the author for his prefix, *megisto*, denoting multiply $\times 10^{12}$. Referring to the choice of air as the standard for specific heat, he remarked that convenient coincidences were not always to be trusted, and that the specific heat of air depended on the pressure to which it was subjected.

Some Improved Polarising Apparatus for microscopes were exhibited and described by Dr. S. P. Thompson. For polariser, he uses an Ahrens prism, and for analyser a flat-ended one of his own design. The Ahrens prism is formed from a rectangular block of spar, two faces of which are perpendicular to the optic axis; two cuts parallel to the axis are made from the middle of one side to the ends of the opposite, and the cut faces are polished and cemented by Canada balsam. A short prism with wide angle is thus obtained which can be readily fitted to the substage of the microscope. The analyser, which consists of two wedges of spar, is mounted in a tube which fits on the eyepiece, and by recognizing that the upper end need not be larger than the pupil of the eye, the author has been able to considerably reduce the length of the prism, and still keep the bottom end large enough to collect all the rays passing through the eye piece.

Several ingenious methods of cutting spar so as to produce prisms with minimum waste, were described and illustrated by models, and a "nicol" made by the inventor at the age of seventy-nine was exhibited.

Mr. Lant Carpenter asked the author why he condemned analysers placed directly behind the objective, for in his experience this arrangement gave the most satisfactory results.

In replying, Dr. Thompson said his experience was decidedly different from that of Mr. Lant Carpenter, and mentioned that Zeiss had abandoned the common arrangement and now introduced his analysers between the two lenses of his Huyghenian eye-pieces.

ZOOLOGICAL SOCIETY.

At the meeting held on December 4th, Professor Flower, C.B., LL.D., F.R.S., President, in the chair, Mr. Oldfield Thomas, F.Z.S., gave an account of the Mammals obtained by Mr. C. M. Woodford during his second expedition to the Solomon Islands. The author stated that the total number of species of mammals known from the Solomons was brought up by the present collection from thirteen to twenty-two, and that of these no less than eight had been discovered by Mr. Woodford, his previous collection having contained examples of two and the present of six new species There were also two new genera of bats to be added to the one previously described. Mr. F. E. Beddard read a paper upon the genus *Clitellio*, which had been recently investigated by him at the Marine Biological Station at Plymouth. The paper contained an account of the anatomy of two species, *Clitellio arenarius* and *C. ater*; the most important fact referred to was the presence of an oviduct, which had only lately been found in the Tubificidæ (in the genus *Psammoryctis*). The paper also contained some remarks upon the synonymy of the two species, particularly of *C. ater*, which was probably identical with d'Udekem's *Tubifex benedii* and with Zeuger's *Peloryctis inquilina*. It was also pointed out that *C. ater* is not congeneric with *C. arenarius*, but probably belongs to Eisen's genus *Hemitubifex*. Professor Howes and Mr. Davies read a paper on the distribution and morphology of the supernumerary phalanges in the Anurous Batrachians. The authors described for the first time the primary mode of development of a supernumery phalanx. They concluded that the same is in the Anura identical with the interphalangeal syndesmoses, and that the syndesmoses and phalanges are derivatives of a common blastema. In its fully differentiated condition the structure in question was shown to be functional in receiving the direct thrust under the weight of the falling body in saltation; all the variations in structure being readily intelligible on that view.

The authors discussed the bearings of the facts upon classification and upon the broader question of the morphology of supernumerary phalanges in general. They showed that the facts of development indicated a probable intercalary origin of the latter from the interarticular syndesmoses; and that the numerical increase of the phalanges in the Cetacea may have been associated with the loss of ungues, somewhat similarly to the way in which the muliplication of segments of the cartilaginous rays in the paired fins of the Batoidei would appear to have been connected with the disappearance of horny fin-rays.

The authors also showed that the Discoglossidæ alone among the Anura retained for life the undifferentiated syndesmoses, and that this feature testified more forcibly than anything else to their low affinities. They also described a community of structure between the modified syndesmoses in certain Anura and the apparatus of the knee-joint in Mammals, and urged that the facts were such as to necessitate a reconsideration of the morphological value of the latter. A communication was read from Mr. J. J. Lister, F.Z.S., giving a general account of the natural history of Chrismas Island, in the Indian Ocean, which he had visited 1887 as naturalist to H.M. surveying-vessel *Egeria*. Mr. Lister gave a detailed account of the birds obtained in Christmas Island. Of these, seven were land birds, all of which belonged to species peculiar to the island, though some of them approach their allies in the Indian Archipelago very closely. Mr. Oldfield Thomas, F.Z.S., read a paper on the Mammals of Christmas Island, obtained by Mr. Lister during the same expedition.

This was followed by reports on the Reptiles of Christmas Island obtained during the expedition, by Mr. G. Boulenger, F.Z.S.; on the Terrestrial Mollusks, by Mr. Edgar A. Smith, F.Z.S.; on the Coleoptera, by Mr. C. J. Gahan; on the Lepidoptera, by Mr. A. G. Butler, F.Z.S.; on the other Insects, by Mr. Kirby; and on the Annelida, Myriapoda, and Land-Crustacea, by Mr. R. I. Pocock.

ROYAL HORTICULTURAL SOCIETY.

At the last meeting of the Scientific Committee specimens of oak wood, forwarded by Mr. Burbidge, which had been used for spokes of wheels, but found to be remarkably brittle, and consequently useless, were submitted to Professor H. Marshall Ward for examination and report. The following communication was received from him: "I have cut numerous sections of the pieces of oak, and have made a very thorough examination of the wood, but must say I can find no traces of fungi or pronounced decomposition. Nevertheless, the tracheides of the wood seem to be abnormally short, and have occasionally granular 'deposits' in them—also in the medullary ray cells—which I should like to know more about. I cannot explain the matter, but should be glad of further specimens for examination."

Mr. Henslow submitted some specimens of abnormal ivy blossoms to a microscopical examination, which were exhibited at the last meeting by Dr. Masters, together with drawings by Mr. G. W. Smith. The dried condition of the flowers precluded a very exact determination of the abnormality, but there appeared to him to be little doubt but that stamens replaced the carpels. The sepals, petals, and stamens were normal, but above the superior disc—which is normally formed by the upper and exposed part of the carpels—were a crown of supernumerary anthers. The vascular cords which normally represent the dorsal ribs of the carpels bore the anthers. In the centre was a depression in lieu of the ovary cells, and apparently some minute and rudimentary anthers occupying their place. These seemed to be due to staminody of the placental cords, which normally occupy the centre of the inferior ovary.

Professor Church gave an account of an analysis of the tubers of the new vegetable *Stachys tuberifera* which he had himself made, and by which he confirmed those of Dr. A. v. Planta, recorded in *Landwirthschaftliche Versuchstationen*, Nos. 5 and 6, 1888. It appears that they contain 78 per cent. of water, 1·5 per cent. of albuminoids, 1·7 per cent. of non-albuminoids or amides, 16·6 per cent. of sugars, ·7 per cent. of fibre, ·1 per cent. of ash, ·2 per cent. of fat, and a trace only of starch. Comparing this analysis with that of potatoes, it appears that the water is in larger quantity, it being 75 per cent. in them; the flesh-forming albuminoids are rather more than in potatoes, while the sugars replace the starch, of which there is some 15 per cent. in the average analysis of the potatoe.

Mr. O'Brien exhibited palmate tubers of some South African species of *Satyrium*, which showed two years' growth, having been plunged in moss only; the tubers, instead of developing a leafy axis, had formed fresh tubers only, the stem and leaves being produced in miniature, being about half an inch in height. Mr. Wilson mentioned the fact that lilies sometimes behave in the same way, and that the process was identical with "supertuberation" in potatoes, in which case the "eyes" gave rise to fresh tubers instead of stems, when situated too deep and with too much heat, according to the experience of Mr. Boscawen. Mr. O'Brien remarked that the importance of the knowledge of the above phenomena lay in the fact that it was often supposed that tubers and bulbs were lost or decayed, from the non-appearance of the flowering stems, while they might still be present in the soil, but were for two or three years simply reproducing bulbs at the expense of the old one, without flowering at all.

Mr. G. Swailes forwarded a young live tree grown from a layer, the only one of 500 which exhibited peculiar contorted boughs. A graft taken from it in the spring exhibits the same peculiarity. Dr. Hogg remarked that it appeared to resemble the "contorted" variety of the hawthorn. The curving and twisting were apparent even in many of the minutest twigs. It was thought by some to be due to mischief or injury by insects, but the above facts seem to point to other causes. It was referred to Chiswick, to be grown, to prove the constancy of the feature or otherwise.

Mr. T. Christy, of 25, Lime Street, sent a new production for antiseptic bandages called *Christia*. It is constructed of thin whity-brown paper, expressly made of Manilla hemp (*Musa textilis*), which consists purely of remarkably long liber-fibres, which doubtless tend to give it greater tenacity. It is then subjected to a process with glycerine, olive oil, and other substances, which render it translucent, with the appearance of oiled silk. It subsequently is treated with salicylic acid, carbolic acid, or other disinfectant, and rendered antiseptic. Its advantages are great tenacity, extreme lightness, being not more than one-third of the weight of oiled silk or gutta-percha sheeting, antiseptic, and perfectly impervious to moisture. It was thought that it would prove so exceedingly useful in horticulture, *e.g.*, for binding up budding, sending specimens by post when the exclusion of air is essential, while strips would be serviceable for tying plants to stakes, etc.

Mr. Henslow showed specimens of Korsambi nuts, received from Mr. Christy, of the seeds of *Schleichera trijuga*, of the order *Sapindaceæ*. It was supposed to be the source of Macassar oil, but this was strongly doubted. Mr. Morris observed that it is called the "Indian oak-tree," and is abundant in India and Ceylon, and is valuable for its timber.

A specimen of *Juniperus occidentalis* (Hook), collected in Eastern Oregon, U.S.A., by Mr. William Stewart, was forwarded by him from Greenock, N.B. It was first found by Douglass in the Story Islands, in the Columbia River. It was also found in the Klamet Mountains, in the Oregon territory, at 5,000 feet. It grows from 40-80 feet high, and like other species, varies in foliage in passing from the young to the older stages. The specimen sent was spiny-leaved, or in the characteristic condition of the young stage. It is remarkable for the strong and disagreeable odour when bruised (Gordon's "Pinetum," p. 163).

Mr. Henslow called attention to the fact that the year 1889, besides being the centenary of the chrysanthemum in Europe, was also that of the dahlia in England. It was introduced by the Marchioness of Bute in 1789, and figured with single and double forms in *Bot. Mag.*, vol. xliv., t. 1885, and *Bot. Reg.*, vol. i., t. 55.

ROYAL METEOROLOGICAL SOCIETY.

At the first meeting of this Society for the present session, held on the 21st November, Dr. W. Marcet, F.R.S. President, in the chair, the following papers were read :—

"Results of an Investigation of the Phenomena of English Thunderstorms during the years 1857-59," by Mr. G. J. Symons, F.R.S. This paper was written nearly thirty years ago. It has now been communicated to the Society at the request of the Thunderstorm Committee. The paper contains a summary, chiefly in statistical form, of some of the results of an investigation into English thunderstorms and the accidents produced by lightning during the years 1857-59. The author found that in sheet lightning the most prevalent colour is white, then yellow, blue, and red. In forked lightning the order is nearly reversed, blue being more than twice as frequent as any other colour; then red, white, and most rarely yellow. Sheet lightning was seen about twice as often as forked.

"Notes on the Meeting of the International Meteorological Committee at Zurich in September, 1888," by Mr. R. H. Scott, F.R.S. The Committee recommended certain rules for the publication of data by travellers, etc., so as to ensure their being useful for the advancement of sound climatological knowledge. The proposals for an international cloud nomenclature, as recommended by Mr. Abercromby and Professor Hildebrandsson, did not commend themselves to the Committee, who suggested that the subject should be further studied. At the conclusion of the meeting the Committee was dissolved.

"On a Method of Photographing Cirrus Clouds," by Dr. A. Riggenbach. The author exhibited some photographs of cirrus and other fine clouds which had been obtained by using the surface of a lake as a polarising mirror.

Mr. A. C. Stratten exhibited some models of very large hailstones-spheres about 2½ inches in diameter, which fell at Montereau, about forty miles south-east of Paris, on August 15th, 1888.

BRISTOL NATURALISTS' SOCIETY.

At the meeting held on December 6th, the Rev. T. Hincks, F.R.S., being in the chair,

Dr. Burder exhibited specimens of a rare fungus, *Spæria polymorpha*, found in his garden, and Professor Leipner commented upon the life history of this, and an allied species, *S. concentrica*, which grows on some old ash trees near the Westbury Road.

Mr. C. J. Trusted then read a paper on the common mole and its habits. After giving a brief description of its structure, he said that their favourite breeding-places were woods, and that the large mole-hills they make their nests in are usually well hidden in briers and brushwood. Usually there are five young ones in each nest, which is lined with dry leaves, and never with dried grass or moss. Many galleries and passages run round and to the nest. In some parishes there used to be a regular annual charge for a mole-catcher, but the old custom has died out. That there was some need for the custom Mr. Trusted explained by telling of a disastrous flood caused by moles piercing and undermining a river wall put up to keep the river Wye from overflowing. Moles require some depth of soil, and hence are never found on the Downs, though Mr. Trusted has found two colonies of the meadow-mouse. He said that though weasels were sometimes caught in mole-traps, it was very doubtful if they preyed on moles. One very interesting point about moles is that they have a great intuitive knowledge of changes in the weather, being very active just before a hard frost or the beginning of a thaw. This may be due to their food being near the surface at these times. He said that in some fields near a large wood in which moles did a great deal of damage he shot nine in one winter's day. Moles do a great deal of damage to grass land, and also to corn crops, by raising the young wheat or barley when it has just sprouted. Mr. Trusted then mentioned the interesting fact that there are no moles in Ireland, though very few authors mention the fact. The mole is probably a long-lived animal. Its chief enemy is man. Its structure and fur are particularly adapted to its underground life. It is an extremely voracious animal, as the following will show: A mole was captured while trying to make its way into the hard frozen ground, and put into its captor's pocket. Soon afterwards a field-mouse was caught, and put in with the mole. Very soon afterwards there was a considerable disturbance, and when the narrator returned home he found that the mole had eaten the whole of the mouse except the head.

Mr. Charles Jecks then read a paper entitled "Suggestions as to Causes of the Difference in Colour between the Flowers and Foliage of Tropical and of Temperate Regions." He first said that it was certain that tropical flowers and foliage are not so brilliant as those of more temperate climes; the opposite opinion being due to our seeing tropical plants under exceptional conditions in greenhouses, and also plants collected from many regions grouped together. Mr. Jecks then suggested that the disparity of colour might be due to the great richness of the soil and the large amount of moisture in a tropical forest, for with a bright sun and dry, poor soil we find the flowers more brilliant, and he said that in our own climate the same was true, a richer soil and a moist atmosphere deepening the colours of the flowers; and further, in a dry season and with plenty of sunshine the colours of the flowers were more brilliant. With respect to some mountain flora, which seem an exception to this, he suggested that they might be remnants of more tropical ones. He said that the greater number of brilliantly coloured scentless flowers in our climate might be accounted for by the visits of butterflies, etc, a variation towards increased brightness inducing more frequent visits from insects, and hence the plant has a greater chance of setting its seeds and propagating the species; and hence, by the law of heredity, the variation in the colouring matter is passed on and rendered permanent, and even increased in amount. He gave, as an instance, the flowers of East Norfolk, where the soil is dry and light; they are distinctly brighter than the same wild flowers in Northamptonshire, where the soil is heavier and the air more moist. Foliage, Mr. Jecks said, is, as a rule, much deeper in colour in the tropics than in the temperate zones, the only exception being the foliage of the trees in New Zealand. The condition in a tropical forest, namely, the comparative absence of light, and the warm, damp atmosphere, would tend to produce a deep foliage, whereas the cool, dry atmosphere of more northern regions would produce a lighter hue.

DUNDEE NATURALISTS' SOCIETY.

At the meeting held on December 5th, Mr. James Durham, F.G.S., President of the Society, read the concluding paper of a series which he has given at intervals on "The Geology of Dundee and District." On this occasion Mr. Durham dealt specially with the geological period known as the post-glacial. He explained that towards the end of that great time of cold—the glacial period—the land sank into the sea until it stood at a level more than 100 feet lower than it does at present. In the course of this subsidence floods of water from the melting glaciers swept vast quantities of the *débris* of moraines from the land into the sea, where it accumulated to a great thickness round the shores, so that when in course of time the land rose again a vast terrace of sand and stones was found spreading all over the low-lying country. The remains of this terrace now form a striking feature in the landscape of the seaward parts of Fife and Forfar, and, indeed, all round the Scottish coast. If we desired to picture to ourselves the Dundee district during the formation of this 100 feet terrace, we must imagine all the ancient burgh of Dundee under the sea, whose water would stand, roughly speaking, two-thirds the height of the Old Steeple, and consequently well up the Constitution Road and Hilltown slopes. All the flat lands between Dundee and Perth and the valley of the Earn would be far under the water level. The Howe of Fife and nearly all the land between Dundee and Arbroath would be submerged. Indeed, a large part of Scotland would be cut up into groups of islands, round which rolled the waves of a sad and melancholy sea, in which icebergs floated. It would be a dreary and miserable land, into which no man or animal cared to come, which was perhaps the simplest reason for the absence of the remains of living creatures in the remains of the sea bottom represented by the 100 feet terrace. Mr. Durham went on to describe how the action of denudation removed the greater part of this terrace, especially when the larger rivers ploughed their way through it, while the wave of the sea materially aided in its destruction. As the land rose, standing much higher than now, the action of various denuding agencies formed upon the remains of the terrace an earthy soil suitable for vegetation. The climate having become mild and temperate, a luxuriant growth soon covered the ground, and great forests spread over the valleys far up into the high lands, and out over parts of the present bed of the North Sea. Remains of this forest bed are still found at many parts of the Firth of Tay, and Mr. Durham exhibited a collection of roots, twigs, leaves, and nuts found at the Stannergate. After a period of unknown duration the land was again depressed to the extent of 40 or 50 feet, and the sea swept over the low-lying forest parts. Simultaneous with this the climate became colder, and probably in the Highland glens glaciers again formed, as the Tay and Earn were at the same time laden with extremely fine material likely to be derived from the grinding action of glaciers on the rocks of their valleys. This fine clay, with sand and gravel, covered the submerged forests, and formed what are now called the carse lands of our Scottish firths. At length the land again rose steadily until it stood 25 to 30 feet lower than at present, resting at this level for a very long time, and a great and most important beach was now formed, for on the terrace which is now represented by this beach nearly all our seaport towns are built. Indeed, as the lecturer pointed out, the fact that it forms such a convenient means of approach to the ocean makes it not improbable that the maritime supremacy of the British Islands is greatly owing to the existence of this beach. After this the land again rose until it reached its present level, at which point it has probably stood for many thousands of years. Mr. Durham, in the course of his paper, pointed out the localities which helped to bear out the story of the geological history of Dundee and neighbourhood.

BOURNEMOUTH SOCIETY OF NATURAL SCIENCE.

At a meeting held on Nov. 30th, the Rev. G. H. West in the chair, a paper was read by Dr. Hyla Greves upon "The Hand; its Mechanism in Man and Brute." The lecturer said, to prevent misconception, he would first define the term "Hand," which was intended to include not only the human hand and that of the quadrumana (or four-handed animals), but all modifications of the fore limb of the vertebrata. We may, he continued, here enumerate the various uses which the hand and arm serve in the animal kingdom. In its simplest form, as in fishes and birds, for example, it is used almost entirely for the purpose of locomotion in water and air respectively; in man, on the other hand, its use in locomotion is practically nil (its use in swimming excepted), but it is as a prehensile instrument and organ of touch that it finds its chief use. Again, in the monkey tribe and the sloths it serves for both the purposes of locomotion and apprehension, and to a less extent the same may be said of the carnivora, *e.g.*, the lion and cat, which use the paw firstly as a means of locomotion, and secondly as a prehensile organ in procuring prey; while in the ungulata, or hoofed animals, it is solely used as an organ of locomotion. In comparing the structure of the human hand with that of other animals we recognise the bones which form the upper extremity or arm of man in the fin of the whale, the wing of the bat, the paddle of the turtle, and the wing of the bird. We see the same bones perfectly suited to their purposes in the paw of the lion and the bear, and equally fitted for motion in the foot of the horse and camel, and adjusted for climbing or digging in the long-clawed foot of the sloth or bear. It is obvious, then, that we have to consider the human hand only as presenting the most perfect combination of parts, and exhibiting the bones and muscles, which in different animals are suited to particular purposes, so combined as to perform actions the most minute and complicated, consistently with powerful exertion. During an explanation of the bones and mechanism of the arm and hand, the lecturer showed, with regard to the elbow joint, a mere bending and straightening was all that was necessary for purposes of simple locomotion, but that in those animals who use the hand for other purposes—as for digging or burrowing—it was necessary they should be able to rotate the hand, and therefore the two bones of the forearm are so constructed that they can partially roll over each other, giving rise to the movements of pronation and supernation of the hand. It might be imagined that the easy motion of the hand resulted from the structure of the hand itself; but on the contrary, the movements which appear to belong to it are divided amongst the bones of the whole extremity. The power of opposing the thumb to any of the other fingers is the chief characteristic of the hand of man. Without the thumb the power of the fingers would avail nothing, and accordingly the large ball formed by the muscles at its base is the distinguishing characteristic of the hand of an expert workman. As we progress downwards through the animal kingdom, in every instance where the fingers become rudimentary the thumb is the first withdrawn. In the quadrumana, which comprises apes and monkeys, the thumb may be entirely wanting, but when present it is more or less opposed to the other digits, but to a less extent than in man. In the bats we find a very curious modification of the hand and arm to form a kind of wing, all the digits, with the exception of the thumb, being exceptionally elongated, these elongated fingers being united by an expanded membrane, which also extends between the fore and hind limbs and the side of the body. This membrane serves for flight. In the horse and other hoofed animals the leg is used solely for locomotion, and modified accordingly. The characteristic feature in the foot is that portion of the toe which touches the ground being always encased in a hoof, or greatly expanded nail. Dr. Greves took the fore leg of a horse as a typical illustration of the hand adapted purely to the purpose of locomotion, and by diagrams explained how the fore limb was constructed to withstand shock, and beautifully adapted for strength and elasticity. Taking the lower part of the leg, the wrist was shown to occupy the middle of the leg, and to constitute what is improperly called the knee. Below this point is a most radical change in the arrangement of the bones as compared with the hand of man: no resemblance at first sight seems to exist between them. Dr. Greves carefully traced the connection in structure between the hand of horse and man, showing them to be composed of the same elements, modified to suit in each case their special uses.

The lecturer, after describing the hand of the various orders of animals, and explaining the special adaptation in each case to the special use, made a few remarks on the hand as an instrument of expression.

Society of Chemical Industry (Edinburgh Board).—On December 5th a paper on "Natural and Artificial Foods for Farm Stock" was read by Professor Ivison Macadam. These foods, the lecturer said, might be divided into the substances on the farm itself, and those bought in by the farmer. He first discussed the chemical and feeding properties of the grasses, cereals, and roots classed under the first heading, and gave some details as to the comparative feeding values of hay obtained and grown in various counties in Scotland and England, as well as from America, Canada, Germany, Switzerland, and Algeria. Large quantities of hay, he said, were annually shipped by the latter country to Leith and other Scottish ports, and found a ready sale for the winter feeding of sheep, etc. The process of making ensilage was described, and the chemical properties explained, as well as the changes which plants undergo when being made into ensilage. The process was specially recommended in hill districts or in very wet seasons, the principal drawback being the cost of the necessary erections. Reference was then made to a series of letters published during last summer, in which the writer urged that the cereal crops in such very backward seasons should be made into hay, and eaten in that form either before or after being thrashed out from the grain. Afterwards, the various seed cakes were considered, and the method of manufacture explained, also the substances with which they were adulterated or mixed, and the paper was brought to a close by the valuation of cakes for feeding and manurial purposes. Specimens of the various substances mentioned in the paper were on exhibition in the hall. Afterwards a paper entitled "Note on Filter Stands" was read by Mr. D. B. Dott, F.R.S.E., giving a description of a stand to ensure the stability of filters while persons were working with chemicals; and a paper was also read by Dr. L. Dobbin, "On the Detection and Estimation of Caustic Alkali in Presence of Alkaline Carbonates," which was stated to be a test based on a new version of Nessler's test for ammonia.

Liverpool Geological Association.—This association held a conversazione on December 3rd, which was opened by the President, Mr. A. Norman Tate, F.I.C., by a short address. He afterwards referred to the exhibits of the evening, and some of their special features. Amongst these exhibits were microscopes and slides, shown by the President and others, illustrating micropetrology, etc., also a large number of specimens in connection with mineralogical science, these latter being under the special charge of Mr. D. Clague, F.G.S., and included a new goniometer and other novel instruments now used in research, and illustrations of their uses were given by Mr. Clague during the evening. Some excellent photographs of Tarawera (New Zealand), kindly forwarded by Professor Judd, F.G.S., were shown, and Mr. Joseph Lomas, A.N.S.S., gave a short address on the same district. There were also exhibited specimens and diagrams of Arran pitchstone, and syenite, showing metamorphism, and Maus rock specimens from Castletown Bay by Mr. J. Hornell, and diagrams showing glacial action in the same neighbourhood by the Secretary, Mr. J. E. George; sections across the London basin by Mr. Joseph Lomas; crushed and weathered boulders from the boulder clay of this district, by Dr. Ricketts, F.G.S.; a model of the quarry at Oxton, showing interesting geological features, by Mr. H. C. Beasley; collection of coral by Mr. R. Wilson. There were also shown by Mr. T. R. Connell, Vice-President, a a fine work on fossil saurians, by Prof. Owen, and there were many specimens and prize drawings by geological students.

FLINTS.*

PROFESSOR JUDD, in asking those present to study with him the subject of flints, said it had been his special aim to illustrate the methods in which a scientific inquiry should be conducted. The object of science was to study the phenomena of nature with a view to discovering the causes by which these phenomena were produced. Now, the legitimate method of doing this, as he had pointed out to them already, was, first, to collect as many facts as possible bearing upon the subject, and secondly, to arrange these facts so as to illustrate the subject under consideration; thirdly, to frame a theory, it might be a tentative theory, that should harmonise with all these facts; and fourthly, to try the theory, when it had been framed, by the whole of the facts that could be discovered, and if it was verified, to accept it; but if the theory were not verified, to reject it. Now, many people seemed to think that this was a very cumbrous and round-about way of proceeding, and that there was a short and easier method by which the desired results might be obtained. The method might be shorter, but he thought a little consideration would show them that it was neither sounder nor so satisfactory as the scientific method. The method which these people would employ was, "First make your theory, then look out for facts which seem to support the theory, and most carefully shut your eyes to all such facts as do not fit the theory." Now that might be characterised as the unscientific method.

He did not know how it was—perhaps it was due to the fantastic forms and curious appearances which these flints often presented—but from some cause or another flints seemed to exercise a wonderful fascination for a speculative mind, and they would not be surprised, therefore, that the attempts to settle the question of the origin of flints by a short and easy method were by no means few in number. For example, there was a very worthy and gallant colonel who used to reside on the Wiltshire Downs, and as the hills around were covered with chalk-flints, he thought he ought to know all about these chalk-flints, and that he must tell the world all about them, especially the way they were formed, and he wrote a book called the "Old Chalk Cemetery," in which he clearly proved, to his own satisfaction, that the flints had been brought by the general deluge, and mixed up in the chalk, and that it was obvious these flints were remains of once living things, the forms of which he could easily recognise. More than this, he gave a great deal of trouble —unnecessary trouble he (the lecturer) was afraid—to the curators of museums, for he was continually getting friends to put questions in Parliament why museums were filled with the class of objects they contained, whereas there were more interesting objects with which he undertook to fill not only those museums, but as many museums as the nation liked to build. He never gained his object in getting flints into museums, but what the museums would have been like they might judge from the book, which contained a number of remarkable photographs. Turning over the pages of that book, he found the echinus eating into the back of the bird of paradise. Now, considering the habits of the bird of paradise and of the echinus, it must have been only during the general deluge that they could have been brought together. Of course, he had the unicorn and the sea-serpent—that goes without saying; and as for noses, and arms of men, women, and children, he had sufficient to stock any number of museums. To take another example, there was an equally worthy old clergyman, who had written a book, which bore the title of "The Chalk and Flint Formation; its Origin in Harmony with the Ancient and Scientific Modern Theory of the World." At all events, they would have no difficulty in guessing that the "scientific modern theory" was no other than the author's own. His work was illustrated by photographs of big flints. Then he went on to insist that all chalk flints were nothing but meteorites that had tumbled down in the chalk mud, and somehow or another had got laid into bands. He (the lecturer) must not follow these amusing flights of imaginations; there was no end to them. As Lyell used to say, "When the human imagination is untrammelled by those awkward things, facts, it revels with all the freedom characteristic of motion in vacuo."

Now, let them come down from those wonderful flights, and, curbing their imagination, look at the facts which could be obtained by the use of experiments and observations, and see what they could find out concerning the origin of flints. If they were puzzled at any point they would confess it; but they would try, nevertheless, to find out what were the theories which the study of flints would lead them to form. He thought he could best do that by inviting them to consider, first, what were the sources of the silica, which, as they had now learned, formed flints; secondly, what was the way in which that silica was separated to make flints; thirdly, let them ask what was the way in which the silica of flints reached its present position, so that it occurred in nodules and bands in the chalk; and fourthly, what were the changes which it subsequently underwent so as to present the forms that they had seen it did at the present time. First of all let them ask what were the sources of the silica which formed flints. Now they would remember an experiment he tried in the earliest lecture in which he took a substance which was a compound of silica and one of the alkalies, potash or soda, formed by melting those two substances together —it would dissolve in water. They would recollect that to that solution of this compound of silica and one of the alkalies he added a little acid, and the result was that the compound was decomposed, the alkali and the acid remaining dissolved in the water, and the silica remaining also dissolved in the water; and he showed them how, by a method of dialysis, could be separated from the acid all the alkali left in the water. Now, that was the operation which was continually going on in the earth around us. Everywhere that experiment was being continued on a small scale. All those rocks which were formed by the action of fire, which were called igneous rocks—all those rocks contained silicates of the alkalies. It was a compound of potash or soda and silica, and wherever water was percolating through rocks they found small quantities of this substance—silica combined with one of the alkalies—passing into solution; and if the water contained an acid, however weak it might be, then this decomposition of the silicate was going on, and silica was passing into a state of solution. It was true that this action went on very slowly indeed, like many of the processes in nature, and that it would take many years in a large mass of rock to produce as much silica in a dissolved state as he produced in the course of a few seconds by the experiments he performed. But

* Fifth Lecture to Working Men at the Royal School of Mines.

nevertheless the process was continually going on, and silica, by that series of actions which had been demonstrated by actual experiments, was passing continually into a state of solution. That slow and gradual action, in contradiction to the sudden and brutal mode of treating things which was characteristic of our chemical laboratories, was very characteristic of the operation of nature. The result of that action was that all natural waters contained silica in solution. As they had seen, the waters of those hot springs, the geysers, contained an enormous proportion of silica in solution—which was rapidly deposited, but all these natural waters of the globe, and the waters of rivers and lakes, as well as of springs, the waters of the ocean—all these natural waters contained silica in solution, but in very minute proportions. Indeed, the proportions were so minute that it almost defied the art of the most careful chemist to determine what the proportion was. For example, he had a number of analyses of different rocks, and the quantity of silica in many of them was very minute; but if they had an analysis of natural waters the quantity of silica present in each of them would have to be represented by he did not know how many noughts following the decimal point, and then followed by some small figure. The experiments on the waters of the ocean had shown that the quantity of silica in the ocean was always less than one in 50,000, and in most cases less than one in 100,000, and in some cases much less than that; so they saw the natural waters, whether they were the waters of springs, or of rivers, or of lakes, or of the ocean, contained silica in solution; yet they contained almost inconceivably small proportions of silica; and the question might arise, how could that almost inconceivably small proportion ever become separated from the enormous quantity of water in which it was dissolved? Of course they might take large quantities of this water and boil it down, thereby turning the water into steam, in which case all the dissolved matters, including the silica, would be left at the bottom. But that was not an operation that went on commonly in nature. The ocean was not boiled down periodically, or even the lakes, in order to get out the silica; but there was an agency at work, a very important agency indeed, by which this silica was concentrated and separated from the water of the ocean, from the waters of lakes, from the waters of rivers, of springs even, and the water flowing over the surface of the earth, when it fell as rain, silica was taken up in all these cases, and it was concentrated from this water, separated from this water by the wonderful agency to which he had already called their attention. As he had already pointed out to them, there were remarkable organisms which took water into their organisation with their food, and in the process of breathing which went on in marine animals. Those waters were taken into their organisation, and the silica was separated from the water, minute as it was in proportion; it was separted in the solid form, and formed the skeleton, or the hard part, of these organisms. They would recollect that he pointed out to them that there were three classes of organisms which had that wonderful power of separating silica from its state of solution. The first of these organisms were the excessively minute ones, the plants known as the diatomacæ, or, for short, diatoms; and he would bring before them those diatoms as showing them the wonderful forms assumed by their skeletons. They were exquisite little objects, each consisting of two valves, like portions of pill-boxes, one fitting inside the other, but so excessively minute that many of them could be only just seen even by the highest powers of the microscope, and in many cases they were covered with the most exquisitely beautiful ornamentation, as shown in some figures he exhibited, which were only a few selected out of many, many thousands of known forms. These skeletons were composed entirely of colloidal silica which had been separated from its state of solution in water. Then there was a class of minute animals that lived both in marine and fresh water, and in water which was a mixture of both, and some of them inhabited fresh water, and all the forms that lived under these different conditions were very distinct. The radiolarians only lived in the sea. They were strictly marine forms. These radiolarians were so minute that many of them hardly reached the size of a pin's head, but they were gigantic compared with diatoms. The radiolarians assumed an enormous variety of forms. (A small selection of forms were exhibited.) 4,000 forms were described as being found by the *Challenger* Expedition, and Dr. Haeckel admitted that he was far from having described the whole of them. There was still a third class of organisations, the *silicospongia*, siliceous sponges, which had skeletons which were as much larger than the radiolarians as the radiolarians were larger than the diatoms, and some of the forms of the rods building up the skeletons of the siliceous sponges were shown. Now, these organisms were all very minute—the diatoms excessively minute—but, nevertheless, they made up in numbers what they wanted in size; and as they had already seen, there was at the bottom of the ocean extensive deposits of white, sticky mud, some of which were entirely made up of diatoms, and these were called the diatomaceous oozes, and others were made up of radiolarians, and these white muds were called the radiolarious oozes; and although they did not find mud made up entirely of sponge-spicules, there were many that were largely made up of them. But besides that, they found among the rocks of the globe many deposits, made up of these organisations, consisted chemically of silica and nothing but silica, which formed those materials known as tripoli and diatomite. These were made up of the skeletons of these diatoms. If they took the minutest fragment, they got hundreds and thousands of these marine creatures sprouting together. They could be examined under a microscope, and a wonderful variety of forms could be seen; hundreds and thousands of forms might be detected in one of these deposits. So again, in other parts of the earth they found rocks made up of radiolarians. In the Island of Barbadoes there was a rock covering many miles of country, and of considerable thickness, entirely made up of these radiolarians; and in other places, again, they might find beds of siliceous rock, as Dr. Hinde so well showed, which, when examined by a microscope, were seen to be made up of sponge-spicules. The part played by those organisms seemed to be in inverse ratio to their size. The deposits were greater as the things were smaller. They did not find great rock-masses made up of bones of elephants, but they did find them made up of microscopical foraminifera. The most important deposits were made up of the smallest organisms, the diatoms; the next important were made up of the radiolarians; and comparatively thin and unimportant deposits, though not insignificant, were made up of siliceous sponges. This was Nature's way of effecting most astounding results by means of the smallest and most insignificant agencies.

What they had seen of the microscopical structure and character of flint would convince them that though flints consisted entirely of silica, they were nevertheless not deposits made up of radiolarians and sponges, or of diatoms. Now let them consider if it was possible that the materials which had been collected to form these organisms could be by any process collected so as to form these nodules and bands which were found in the chalk, and which were called flints. He had also called their attention to the way in which those nodules and bands occurred in the chalk; he had also pointed out to them a series of chemical analyses which showed that when there existed chalk without any flints they found silica distributed through the mass, but that chalk with flints did not contain silica distributed through it, and the suspicion was at once aroused that by some process or other the silica which formed the organisms deposited with calcareous materials which formed the chalk mud; that this silica had been separated by some means and collected into these nodules. Now let them see if there were any grounds for believing that such takes place. He had already pointed out how readily colloidal silica passed into a state of solution, and he had also brought before them evidence that this dissolved silica was everywhere present in different kinds of rocks. They would recollect that he showed them how old limestone rocks, when dissolved, were found to contain little crystals of quartz, which must have been formed from silica distributed in a state of solution through those rocks, or, rather, in solution in water, that percolated through those rocks. In the same way he had shown them how sand-grains, which were broken fragments of quartz crystals, were continually being formed into perfect quartz-crystals by the deposition upon them of silica, which had been also in a state of solution. He had shown them, too, that, when flints got broken, they became cemented together again. If they tested that with acid they would find the cement was siliceous cement. It was silica, which had been deposited to repair the flint; so that they readily saw that the colloidal silica forming these siliceous organisms in a mud such as that which gave rise to the chalk might easily pass into solution; and he showed them a case where, in globigerina-ooze, the silica forming these organisms had clearly passed into a state of solution and been deposited in a fresh form.

Now, he must recall to their mind the facts to which he pointed with regard to silicification. They would recall the case of a plant he brought before them—there was no mistake about it being a plant originally. He put before them a section showing all the cells and vessels having their different forms, and the whole was perfectly silicified. Particle by particle the carbon and the other elements present in the wood had been dissolved away, and each molecule of the complex organic compound had been removed, and the molecules of silica had been put in its place, so that the whole structure had been built up just as a red brick building would be restored if one knocked out a red brick and put in a white, and did this with every brick in succession until the whole of the original red brick building had been removed and the white brick, having exactly the same form and characteristics of the red brick building, pnt in its place. This was what went on on a finer scale in nature when a substance was undergoing silicification. The original structure, particle by particle, was removed, and a fresh particle of silica was put in its place until in the end there was scarcely a vestige of the old substance. There was nothing but silica, but this silica presented all the forms that were found in the original mass of wood, or whatever it was that was silicified. He must ask them to bear in mind how completely this process of silicification took place.

The result of the study of all those microscopic sections to which he called their attention the other day, was to show that flint was silicified chalk mud. Chalk mud consisted essentially of the substance calcic carbonate, or carbonate of lime, but this calcic carbonate of the chalk mud can be silicified particle by particle. The carbonate of lime might be dissolved and silica put in its place, and the whole mass become a mass of silica. This chalk mud was sometimes found perfectly silicified and formed into flints. Every particle of each of these rounded shells is dissolved and particles of silica put into its place, so that but for the fact that it does not dissolve in acids they might at first sight think they were dealing with actual chalk, but they were dealing not with actual chalk but with silicified chalk—a piece of chalk which had undergone precisely the same change as the silicified wood had undergone. Now it was very true that all flints that were examined did not look like chalk mud. There were many flints in which evidently a very great change had taken place, and the way in which that change had taken place he must proceed to show them, but from these changed flints to those which were manifestly nothing but chalk mud, there was every possible graduation. They found some flints which if put side by side with a piece of chalk, and in thin section, appeared so much alike that they would say there was no difference between them, yet the one was chalk and the other was flint. There could be no doubt that silicification had taken place because these were all forms of shells which were contained in carbonate of lime. There were no siliceous shells like these. It was clear that these shells had been originally carbonate of lime, and had been converted into silica by this wonderful process of replacement and silicification. Now, he must ask them to accept the fact, which was the result of an enormous number of observations of different specimens, that from the flint which was most obviously and clearly nothing but silicified chalk mud, they had every possible gradation in the flints that showed none of this structure. He must just call their attention for a moment to some of the curious phenomena seen during the silicification of the chalk mud.

He had already pointed out to them how curious were the results that arose from heteromorphism — the same forms which the same substance silica could assume. We have two totally different substances or different properties of the most startling character, and both consisted of silica. There were other substances besides those two which were especially important—the crystalline silica known as quartz, and colloidal silica. Now, just as silica existed in two different states with different properties, so calcic carbonate or carbonate of lime, which formed chalk mud, existed in two forms. There was the crystalline form, known as the mineral calcite, and there were the less stable forms known as aragonite. He wanted them to recognise that there was a form which was stable, and which was not liable to change, and which was not easily passed into solution, and there was another that easily changed and passed into solution. They saw the effect of that in many fossils which they found in flints. These fossils were sea urchins, very much like in structure some of the sea urchins living at the present day—sea-eggs some people called them—but really different in species. Now in these cases the original sea urchin was completely filled with flint, and it was so completely filled that the holes through which the arms of the animal passed, stood out as little needles on the surface, but the shell itself was not represented. The shell itself was represented by a hollow space; the outside of the shell had left its markings on the flint. There was what was called an external cast, and where the original shell was there was an empty space. The reason of that was that the shells of these animals were composed of this comparatively stable substance, calcite, but all round was the unstable chalk-mud. Now this chalk mud most easily passed into solution, and was therefore silicified. The calcite of the shell being more stable resisted this process and therefore remained as carbonate of lime. Occasionally they might find flints with shell remaining as carbonate of lime, but in other cases it would be found that water had percolated through the mass, after the silicification of the other part had been completed and had dissolved out of the calcite, leaving a hollow space. There was in the case on the table one of the most curious burrowing sponges. This sponge had burrowed into the shell, and the result had been that the hollows had been filled by that chalk mud, and wherever those hollows existed, silicification had taken place; but in the shell around the cell, silicification had been resisted, and afterwards the shell had been dissolved away, and thus they had got the curious appearance that was presented. There was no end to the number of very interesting features which they might find exhibited in shells fossilised in flint, and he hoped that the facts they had been considering would enable them to interpret them.

He must confess that although it was perfectly clear that flints were silicified mud, and that silicification had taken place by the series of processes he had described—he must confess that there was a problem still unsolved—why did silica concentrate itself along certain bands, and form certain nodules? That problem was still an unsolved problem. There were several old experiments which were tried many years ago, but which were unfortunately not confirmed. They must not rush too hastily to the conclusion that the author of these experiments made a mistake. He took a material like chalk mud through which he distributed a small quantity of dissolved silica—matter containing silica in solution. He then put a number of minute bodies consisting of silica, bodies like sponge spicules, in the hope that these would serve as centres of aggregation—that where these siliceous bodies were, the silica would tend to collect in masses analogous to chalk flint. Probably, as it seemed to be an experiment which was not yet fully confirmed, they must admit that there was still a problem remaining unsolved with regard to these shell flints.

Now, he must call their attention to the fact that many flints did not exhibit the characters of silicified chalk mud, and in order to explain the reason of this he must recall their attention to the doctrine of allomorphism—a doctrine that substances having the same composition might have their molecules so arranged as to form a substance with totally different properties. A most remarkable example of this was frequently pointed out to them in the case of silica. Silica existed in two forms. Colloidal silica, which was unstable and easily passed into solution, was unstable because it was constantly tending to pass over into the other form, crystalline silica; and crystalline silica, or quartz, which was stable—almost insoluble. There was a constant tendency for this unstable colloidal silica to pass into the stable form known as quartz. Perhaps he could illustrate these paramorphic changes by an experiment with a substance he had with him, which like silica had a great tendency to pass into another state; this substance was mercuric iodide. If they examined a little of that material under a microscope, they would find it consisted of red crystals of very definite shape, but he could make it assume a different form of crystal which had a bright yellow colour, and make it pass into the allomorphic form, though the composition of the material did not change. One of the ways in which it might be made to assume the allomorphic form was by heating it. They saw by the simple action of heat the red substance had passed into its allomorphic yellow form. Now the red substance was a stable form, and the yellow substance was the unstable form. The stable answered to crystalline quartz, and the unstable to colloidal silica. The yellow was a particularly unstable substance, and mechanical pressure would cause it to change. He would take a hard substance, and they would see that wherever the hard substance had touched those yellow crystals, they had instantly broken up and arranged themselves in the forms of new crystals which had a bright red colour. Although there were not many cases which by a change of colour this paramorphic change was manifest, such paramorphic changes were continually going on. If he left the paper with which he had been experimenting for three or four days, he would find the whole of the yellow material had gone over to the red material—that paramorphic change had taken place spontaneously, so unstable was the yellow material that he had produced. Now in the same way the colloidal silica which was deposited in sponge spicules was constantly tending to pass over into crystalline silica or quartz. When they examined any of the rocks which were made up of sponge spicules, with a microscope, they constantly found the sponge spicules re-arranging themselves in crystalline form. The first change which took place when masses of chalk mud were silicified was that colloidal silica gradually passed particle by particle into minute crystals, forming bodies known as microlites. These microlites built up structures which were of great beauty, and which were at once recognised by the fact that they polarised light when examined between cross angles; instead of having a dark body, they polarised in wonderfully brilliant colours. The white flint which was found in the centre of chalk flints, and on the outside of chalk flints—this white flint was formed by the silicification of the white chalk mud, and, like the white chalk mud, it was white, and it retained its colour, although a greater or smaller proportion of the siliceous replacement might pass into a crystallised form by this paramorphic change. But when this white flint has this colloidal silica added to it, the change produced was exactly like that change which was produced when a piece of blotting paper was put into water, or still better into oil. In that case opaque blotting paper became translucent, and when they dried it again it became opaque. The introduction of this colloidal silica between particles of silicified white chalk might make it assume a grey tint, and pass from the opaque to the translucent condition. On the other hand, on the outside of flints the action was continually going on. Percolating water was eating out the colloidal silica, which filled up the interspaces between the silicified particles, and then the mass became white, in just the same way as a piece of white blotting paper becomes white and opaque on the water being driven out of it, and on its being held before a fire. Such were the changes which went on in the mass of silicified chalk mud constituting flints, and that so far as had yet been made out was the process of flint-making. Now, he must call their attention to another process that was going on in nature—the destruction of flints. At first sight flints seemed the most indestructible of bodies. The flint instruments he would have to point out in the next lecture seemed to be the most imperishable of objects. Objects made of iron, bronze, gold, and silver even, got lost and perished, but articles chipped out of flint remained apparently unchanged even from very remote periods; but although, speaking in the historical sense, flints were very indestructible, geologically, when dealing with not thousands but millions of years, flints were extremely perishable, and the reason of that was that they consisted in part of this unstable substance, colloidal silica. Quartz, on the other hand—perfectly crystalline quartz—was almost the most imperishable of substances. It had no tendency to change its state. It was in its stable condition, and it only passed into solution with the greatest difficulty, so that grains of sand which built up the sandstone and quartzite and other rocks, were many of them of inconceivable antiquity. Many little grains of sand could be proved to have been washed out of one formation and gone into another, and to have been washed out of that and gone into another, and the process repeated again and again, perhaps a little being worn from the outside of the sand grain on each occasion, but nevertheless the quartz grain retained its identity. Now flints were continually rubbing against one another, and being worn down, first into sub-angular flints, and then at last into perfectly rounded flints or pebbles, and it might seem that they ought to find among the rocks of the globe large quantities of little fragments broken off the flints, and when, as at Blackheath and many other places about London, they found beds wholly made up of rounded flint-pebbles, they might well expect the sand in which they were embedded to be made up of flint-particles. But they would find it was not sand composed of flint, but sand composed of little bits of quartz. He would see if he could make them understand why that was. First he must call their attention to the fact that if they wanted to dissolve a thing quickly they must reduce it to powder. The reason of that was very obvious. The action of the acid could only take place in a solid substance at the surface where the two met together. The consequence was when they had a mass with an increased surface, the action between the acid and the substance took place immediately, and solution was very rapidly effected. That was the way in which they always proceeded in chemical laboratories; if they wanted to proceed quickly they pounded the mass up. They reduced it to powder so as to increase the surface. Nature did not chose to reduce flints to powder, but did the thing in a slightly different way. They would remember what he said the other day about the conchoidal fracture of flint, and they would recollect those beautiful specimens which he put before them abstracted from a church which he did not chose to mention, the surfaces exhibiting the taps that fell from the old mason's hammer; the hand was dead long ago, but the force of the blow, and the weight of each particular blow, could be calculated to a nicety from the way the cracks had been produced in these flints. They were like the negative of a photograph, quite invisible when first struck, but they had been revealed by the weathering process going on in nature, and told their tale. Nature was continually doing things of that kind in ordinary flints. Here were some flints taken up on the shore during his summer vacation. It was one of the sorrows of geologists that they could never let their trade alone; it followed them everywhere—even to their holiday excursions to the seaside—and these flints, when the surfaces were examined, seemed to be covered with most beautiful curved cracks. If the flint was of fine grain, the fracture would be a fine one; if of course grain, a course one. If they picked up flints on the shore, they would find that a wonderful change had gone on—that along the line of cracks there had been a process of change. White flint had been developed along both sides of the crack, and the reason of that was that solvent action had penetrated along those cracks, eaten out the soluble silica on each side, and rendered the flint on both sides white and opaque. If they made a microscopic section of the flint, they could see how that process was going on. The white flint became opaque, the black clear and translucent, and they would see how this whitening of flint by solution of colloid silica between the particles was going on. In that way the whole mass of the flint was gradually broken up. The crystalline parts came off in the mud, and in time the whole flint was destroyed. If they took any specimens of those instruments which had been fashioned out of flint, they saw the beginning of the change. The original black flint was covered with a skin of a light colour. The process went on much more rapidly wherever the flints were rattling against one another on the sea shore. Wherever that process was going on they knew that nature was doing her work of making fresh fractures, producing new surfaces by which the solvent action of the water could operate on the flint. He had brought that fact before them, because it was a very characteristic way in which nature did her work.

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents, nor can he take notice of anonymous communications. All letters must be accompanied by the name and address of the writer, not necessarily for publication, but as a guarantee of good faith.

THE SPARROW AGAIN.

Having noticed in your valuable paper a short controversy on the sparrow, I beg to add a few remarks concerning its behaviour to other birds. It has latterly been observed to seize upon the nests of the bank-swallow or sand-martin just as it does upon that of the common martin. Whether this is a novel habit or an old one, which has previously escaped observation, I am unable to say.

Sparrows habitually monopolise crumbs thrown out in the winter for the relief of starving birds. Being always in the majority, they attack and drive away the robin.

SANDY.

RECENT INVENTIONS.

The following list has been compiled especially for the SCIENTIFIC NEWS *by Messrs.* W. P. THOMPSON *and* BOULT, *Patent Agents of* 234, *High Holborn, London, W.C.; Newcastle Chambers, Angel Row, Nottingham; Ducie Buildings, Bank Street, Manchester, and* 6, *Lord Street, Liverpool.*

EXPLOSIVE.—Mr. C. D. Abel has patented an explosive compound as a communication from H. Schoneweg. This explosive is cheap, effective, and explodes without flame, and is not hygroscopic. It is made by adding to a mixture of an explosive nitro-compound and oxalic acid a large proportion of potassium nitrate.

HUT.—Mr. J. C. H. Peacocke has patented a portable hut. It consists of a framework of wood strengthened by tension rods without obstructing the passage through the building, and having walls, flooring, and roof of roller shutter, which will serve as a covering for the parts of the building when taken apart for transport.

LOCKS.—Mr. H. Steinke has patented a safety-lock. The object is to dispense with the use of springs in safety-locks, and substituting therefor a number of locking plates which are actuated by one or two keys, so as to slide rectilinearly, or turn, or swivel on pivots, and provided with notches for the entry of the shackle hook.

WATER-COURSES.—Mr. A. Langues has patented a method of excavating or deepening water-courses. It consists in causing a vessel provided with blades projecting down beneath its bottom to travel up stream so as, by narrowing the section of the water way, to effect an increase of velocity of the water, and cause it to impinge upon the bottom, whereby the material of the latter will be dislodged and carried by the current out to deep water.

ROLLER-MILLS.—Mr. P. Tofel has patented a roller-mill. The invention relates to the driving-gear, and by the use of it the differential velocity of the grinding rollers can be increased at will, without necessitating the employment of rollers of unequal diameter. The invention consists in the employment of rope driving-gear working in grooved pulleys, and effecting a differential velocity of the grinding rollers; the ropes are made of any suitable material, mechanism being provided to take up the slack.

ELECTRIC RAILWAYS.—Mr. W. L. Madgen, a communication from E. Manville, has patented a method of supplying electric railways or tramways with electricity. The secondary lead is divided into sections, each arranged to supply the locomotive as it passes along it, and each of these sections is connected to the primary lead, which extends continuously the whole length necessary to supply the last of the secondary sections, this main lead including appliances, whereby the currents transmitted from it to the discontinuous sections are caused to be of moderate tension.

PROJECTILES.—Messrs. M. Von Foerster and C. Wolff have patented an explosive projectile. The shell is provided inside with a tube rigidly connected therewith and open at its forward end; the fuse is lodged within this tube in such position that its initiating cartridge is separated from the charge of the shell by the walls of the tube. The fuse is secured by a fastening adapted to give way when, upon the shell striking against its mark, the fuse is impelled forward within the shell, and a channel is provided into which the fuse can fly, so that the initiating cartridge, on exploding, will be in immediate contact with the charge.

WATER METERS.—Mr. J. C. Panwels has patented a water meter. It consists of a cast-iron box, divided in two parts and fastened together. Inside this is a wheel with a groove; this wheel is connected by arms to a central axis, the arms being provided at one end with fans. The wheel has a part cut out, and at each end is a pipe leading outside the case for inlet and outlet of the water. The central pivot is connected to registering mechanism, and the spaces between the fans can be made to hold any desired quantity. The water passes into the wheel, and by its pressure operates the fans, which drive the registering mechanism.

CHURCH ORGANS.—Mr. H. T. Newbigin has patented means for automatically regulating the wind supply to church organs blown by motive power. A rocking lever is employed, having a constant angle of oscillation, in which slides a bar having attached thereto the connecting rod which works the air feeder. This bar is so connected that as the air-receiver expands it moves the point of connection of the bar nearer the centre of oscillation, thus diminishing the travel of the air-feeder, and as the receiver contracts, the point of connection is moved farther from the centre of oscillation, thereby increasing the travel of the feeder, and consequently the air supply to the instrument.

SHIPS.—Mr. J. H. Milne has patented apparatus for steering, manœuvring, and propelling ships which may be used as a screw propeller or paddle, and may be fitted at the stern or side of a vessel. In a screw propeller two diametrically opposite blades are fixed to a box upon a shaft. These blades are connected by a spindle which is fitted to turn in the box about an axis at right angles to the shaft. Internal gear is applied to the shank of the blades, and by it the blades can be turned, when desired for steering, so as to cause them to act transversely when passing the highest or lowest point of their circular course, and edgeways when passing the opposite point, accordingly as the ship is required to deviate to starboard or to larboard.

GAS GOVERNORS.—Messrs. H. W. and A. F. Cole have patented a gas governor. In this governor the gas enters at an inlet and passes down a centre tube, through holes and underneath a float, the quantity of gas passing through the tube being greater than can pass through a regulating screw. The gas raises the float and closes a valve sufficiently to admit only the quantity of gas that can pass through the regulating screw. The gas pressure at the outlet side of the regulating screw and the upper side of the float is maintained equal by a free gas passage, and the weight of float and valve being properly adjusted, it follows that any increase of pressure must first act on the underside of the float, raising same and closing the valve in proportion to the increase, and as the pressure decreases the float falls and opens the valve in proportion, thus ensuring a regular and uniform flow of gas for use.

SELECTED BOOKS.

Astronomy with an Opera Glass. Popular Introduction to the Study of the Starry Heavens with the simplest of Optical Instruments. With maps and directions to facilitate the recognition of the constellations and the principal stars visible to the naked eye. By G. P. Serviss. London: Sampson and Son. Price 7s. 6d.

Industrial Education. (Education Library) By Sir P. Magnus. London: Kegan and Co. Price 6s.

A Text-Book of Elementary Metallurgy, for the use of Students. By A. H. Hiorns. London: Macmillan and Co. Price 4s.

A Sketch of the First Principles of Physiography. With Maps and numerous Illustrations. By J. Douglas. London: Chapman and Co. Price 3s. 6d.

The World's Inhabitants; or, Mankind, Animals, and Plants. Being a Popular Account of the Races and Nations of Mankind, Past and Present, and the Animals and Plants inhabiting the great Continents and Principal Islands. With about 900 Illustrations, representing all the Types of Mankind, their Home and their Public Life, together with many of the Principal Types of Animals and Plants. By G. T. Bettany. London: Ward and Lock. Price 7s. 6d.

Seas and Skies in many Latitudes; or, Wanderings in Search of Weather. Maps and Illustrations. By R. Abercromby. London: Stanford. Price 18s.

A Short History of Natural Science. Fourth edition. With Corrections and Additions. By Arabella B. Buckley. London: Stanford. Price 8s. 6d.

Electric Bells, and all about them. A Practical Book for Practical Men. With more than 100 Illustrations. By S. R. Bottone. London: Whittaker. Price 3s.

Elementary Commercial Geography. A Sketch of the Commodities and Countries of the World. By H. R. Mills, F.R.S.E., Lecturer on Commercial Geography in the Heriot Watt College, Edinburgh. London: C. J. Clay and Sons. Price 1s.

On the Senses, Instincts, and Intelligences of Animals. With Special Reference to Insects. By Sir John Lubbock, Bart., M.P. With 100 illustrations. London: Kegan Paul, Trench, and Co. Price 5s.

DIARY FOR NEXT WEEK.

Thursday, Dec. 27.—Royal Institution, Albemarle Street, at 3 p.m.—*Clouds and Cloudland*, by Professor Dewar, F.R.S.

Saturday, Dec. 29.—Royal Institution, Albemarle Street, at 3 p.m.—*Clouds and Cloudland*, by Professor Dewar, F.R.S.

SALES.

The Charge for Advertisements in this Column is Sixpence for the first sixteen words, and Sixpence for every succeeding eight words. Advertisements for this Column should be received by first post on Tuesday to insure insertion in the following number.

NOTICES.

The Title Page and Index to Vol. I., now ready, price 3d.

Cases and Binding, Vol. I., including Title Page and Index, price 3s.

Vol. I., bound in cloth, with Title Page and Index, 9s. 6d. —by post 10s.

The Back Numbers of SCIENTIFIC NEWS can be obtained from all Booksellers and Newsagents, or direct from the Publisher, 138, Fleet-street, London, E.C. Price 3d. each, or by post 3½d.

METEOROLOGICAL RETURNS

For the ten weeks ending on Monday, Dec. 10th, 1888. Specially prepared for SCIENTIFIC NEWS from official reports.

	Mean Temperature.	Rainfall.	Duration of Sunshine.
Scotland, East	44·1 degs., being 3·3 degs. above average.	8·1 ins., being 0·8 ins. above average.	92 hrs., being 62 hrs. below average
England, N.E.	46·0 ,, ,, 2·3 ,, ,, ,,	4·8 ,, ,, 1·8 ,, below ,,	141 ,, ,, 2 ,, above ,,
England, East	45·7 ,, ,, 0·8 ,, ,, ,,	4·8 ,, ,, 1·4 ,, ,, ,,	173 ,, ,, 13 ,, ,, ,,
Midlands ...	45·6 ,, ,, 1·3 ,, ,, ,,	6·4 ,, ,, 0·3 ,, ,, ,,	155 ,, ,, 1 ,, below ,,
England, South	47·3 ,, ,, 1·5 ,, ,, ,,	7·0 ,, ,, 0·4 ,, above ,,	163 ,, ,, 3 ,, above ,,
Scotland, West	46·3 ,, ,, 2·4 ,, ,, ,,	13·5 ,, ,, 1·8 ,, ,, ,,	104 ,, ,, 39 ,, below ,,
England, N.W.	46·9 ,, ,, 1·1 ,, ,, ,,	8·7 ,, ,, 0·1 ,, below ,,	115 ,, ,, 13 ,, ,, ,,

The Kingdom...	46·6 ,, ,, 1·8 ,, ,, ,,	8·3 ,, ,, 0·1 ,, ,, ,,	140 ,, ,, 16 ,, ,, ,,

The above period is fairly representative of the autumn of 1888.

Scientific News

FOR GENERAL READERS.

Vol. II. DECEMBER 28, 1888. No. 26.

CONTENTS.

NOTICE.

We beg to announce that after this date the publication of Scientific News will be discontinued. A year's experience has shown that, though the number of readers has increased, the rate of increase has not been sufficient to justify the continuance of this journal. An honest endeavour has been made to give in untechnical language particulars of many of the interesting and instructive advances made by scientific workers; and if we may judge from the many expressions of approval that have reached us, the endeavour itself has been successful. But, unfortunately, there does not yet seem to be a public numerous enough to give adequate support to such a paper as ours; so we have no choice but to thank heartily the contributors, readers, and correspondents who have given us their kindly help, and to bid them a reluctant farewell.

Subscriptions in hand after this date will be returned.

SCIENTIFIC TABLE TALK.

By W. Mattieu Williams, F.R.A.S., F.C.S.

In Scientific News, November 30th, is a very interesting report of Mr. J. E. Bedford's inaugural address to the Leeds Geological Association on "Natural Gas." In the course of this, Mr. Bedford says, "The remarkable purity of this gas is another important feature in its favour, and for this reason it is especially valuable in puddling furnaces, where the iron is very likely to be deteriorated by sulphur, etc., from inferior fuel."

Mr. Bedford has abundant text-book authority in support of this usually accepted idea that the fuel used in puddling furnaces may supply sulphur to the iron it is melting, but he is wrong nevertheless. When I went to Sheffield early in 1868, I believed the same, and many other things concerning iron and steel that I had learned from the writings of high authorities on pure science, and from the customary routine of laboratory teaching, which were afterwards refuted by the unsophisticated teachings of black-faced puddlers and other workers.

On entering upon my duties as chemist to the Atlas works, where about 5,000 of such men are employed, I found that the coal supplied to the works came from various pits, and was visibly variable in quality, some of it being very "brassy" *i.e.*, containing sulphur in the usual form in which it exists in coal, viz., as golden-coloured scales and crystals of iron pyrites. With the customary self-righteousness of the man of science, I looked down with pity upon the ignorance of the people who should use such coal indiscriminately for all the purposes of the works, instead of obtaining analyses of each brand and assigning the sulphurous coal to the work of heating boilers, and using only the purest for the puddling and reheating furnaces. I communicated these ideas—mildly, of course—to Mr. Ellis, the managing partner, who at once perpetrated the daring heresy of affirming his belief that the sulphur of the coal used in puddling furnaces had no effect whatever on the iron; but he had no objection to my full investigation of the subject.

I accordingly set to work by first determining the sulphur in each brand of coal supplied to the works, then superintending the puddling of a few charges of given pig first with the purest coals, and second with the most impure. On analysing and mechanically testing the results, I was surprised to find no measurable difference. The sulphurous coal was very variable; there were veins of pyrites running through certain lumps and none visible in others. I accordingly made a second series of experiments by using as fuel selected lumps of the worst quality. Still no increase of sulphur in the finished iron.

I then obtained a supply of pyrites in lumps and mixed this with the fuel, first in moderate quantities, then increasing them up to the extravagant amount of 56lbs. in the fuel of one charge ($4\frac{1}{4}$ cwt. of pig iron). No mischief was done; the finished iron was neither better nor worse than average, whether tested by chemical analysis or by the usual mechanical tests.

The facts being known, the rationale is not difficult to work out. The sulphur comes over with the reverberated flame as sulphurous acid, and this only strikes the cinder, *i.e.*, the fusible silicates, that float on the surface of the melted iron. The conditions are quite different in the blast furnace, where the pyrites come in contact with the iron in the midst of reducing, instead of oxidising, surroundings.

The first evening meeting of the winter session Middlesex Natural History and Science Soc[illegible] opened by an address by the annual Pres[illegible] Flower, Director of the Natural History [illegible] the British Museum, the subject of the address being an account of the general arrangements of the Natural History Museum and the recent additions thereto. In the course of this very lucid exposition a subject was touched which must be interesting to all the readers of the SCIENTIFIC NEWS, viz., that of the much-vexed question of opening our national museums on Sunday *afternoons.* Readers should note the italics.

One of the objections commonly urged against this innovation—the only one that, in my opinion, deserves any serious consideration—is that it may throw Sunday work upon the museum officials. Prof. Flower disposed of this by telling us that at least three-fourths of the staff are in favour of opening on Sunday afternoons, and many are so enthusiastic that they say that they will come and take their turns at attendance even without remuneration. In the course of the conversation that followed, Mr. Lant Carpenter told us that his father, the late Dr. Carpenter, and other men eminent in science had offered their services gratuitiously as guardians, taking turns on Sunday afternoons.

This, however, is not necessary. What is demanded is the evolution of parliamentary common sense, in sufficient quantity to enable our legislators to understand that the contemplation of a magnificent panorama of creation is no outrage upon the very sensitive religious scruples of a nation that permits the public sale of unlimited quantities of intoxicating drink at the time in question.

In reference to the employment of the museum officials, the increase of labour is practically trivial. Some people—including members of Parliament—imagine tha all the staff of the museum is occupied in standing in the rooms with wands in their hands, and staring at visitors. Such people do not, probably cannot, understand that a great collection of tens of thousands of specimens requires general and detailed attention involving a vast amount of work, and that besides all this it is part of the duty of the museum officials to assist *bona fide* students who use the museum for purposes of specific research. Like all others who have done this, I can give personal testimony to the efficiency of such aid and the courtesy with which it is afforded. About two years ago some bones were found in the London Clay, at Harlesden, and given to me. I took them to the museum for purpose of identification, and Professor Flower himself took them to the skeletons of the animals to which they belonged, and by placing each bone by the side of the corresponding one of each skeleton enabled me to settle the question of their origin in spite of my lack of special skill in comparative anatomy. Collectors and students in every branch of natural history use the museum for the purpose of identifying their specimens, and much other work.

The mere guardians are chiefly policemen, some of whom are on duty every Sunday, whether the museum is opened or closed. The additional guardianship demanded by opening on Sunday afternoon need not afflict the consciences of even the most tenderly constituted and most demonstrative of Sabbatarians.

As Professor Flower said, the one or two members of the staff and the few attendants will not be expected to sweep and clean, nor to stuff birds, nor arrange tablets, nor write labels; they will only have to walk to their [illegible]es, walk about a little in the museum, and then walk [illegible]gain; and these being very few out of a large [illegible]r turns to do this on Sunday afternoons would [illegible] distant intervals.

TYPE-WRITERS.

(*Continued from p.* 650.)

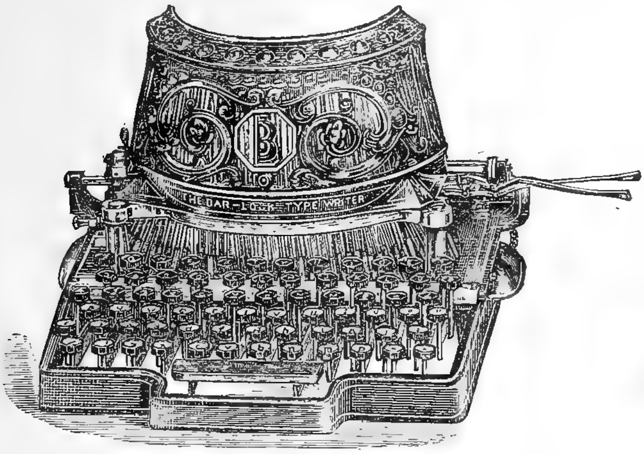
THE difficulty of "alignment," which is experienced in some type-writers, has been attacked by the *Barlock* The mechanical principle resembles that which we have described, but the arrangement of the parts is totally different. The keyboard is provided with seventy-two keys, one to each character, but the levers strike downwards. This has the great advantage of enabling the printed matter to be seen by the operator, up to within a few letters of the last one printed.

With the two machines already mentioned the whole paper carriage has to be lifted on a hinge in order to see what has been written. This is a matter of great importance to authors, or others who use the type-writer for producing their own compositions direct, since it is easy to fall into errors of tautology, if the last few words cannot be readily seen. The inking tape, which in other machines is gradually fed direct from one roller to another, passes round a wire guide, doubling back on itself, thus allowing all the writing to be seen but the last letter or two. In the only machines of this make which we have seen, this advantage is lessened by a bar which hides the whole of the last line. We understand that this is being altered in a new pattern.

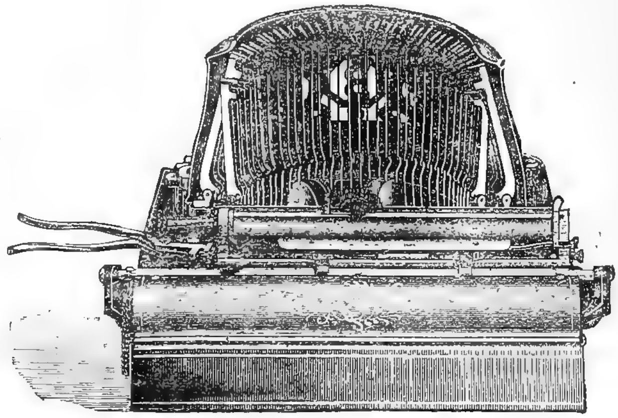
The feature from which the Barlock takes its name is the method by which the alignment of the characters is ensured, even if the levers become slightly bent or worn. A number of tapered pins project upward from a semi-circular plate which surrounds the point at which the type make their impressions. The type-bar, at the end of its stroke, falls between two of these pins, thus locking it, and ensuring that each letter shall fall exactly in the same place. The precautions which it is found necessary to take in the construction of such machines, to ensure their alignment, arise not only from wear of the pivots, but from the effects of an accident to which all machines of this class are liable, viz., the clashing of two type-levers if simultaneously depressed. This may occur either from carelessness, from writing at too high a speed, or from inexperience on the part of the operator. These machines are all heavy, and are suitable for use in offices, or for other purposes in which it is not necessary to move them about. They are generally mounted on iron stands, like sewing machines. The parts are numerous; repairs cannot easily be effected, even by a skilful workman; the type cannot be changed; and the price is about twenty guineas.

The *Hammond* type-writer occupies structurally, an intermediate position between the machines already mentioned and those in which the type are carried on a wheel or plate. This machine has a keyboard of only 30 keys, but they each control three characters, or 90 in all. The keys radiate from the centre, and are arranged in two rows. The curvature is a slight disadvantage, and might be easily altered to two sets, inclined to each other, thus V, one for each hand. The movement of the fingers in this instrument is more like playing on a piano than in other keyed type-writers, which are generally "pounced" upon with the first finger of each hand. Under ordinary circumstances, the keys print small letters and the four most common punctuation marks. On depressing a key marked "Cap." the capitals and four other punctuation marks are ready for work; and by the use of a key marked "Fig."

the figures, and no less than eleven other marks, such as £ % [*] and six fractions, can be employed. The type are arranged in three rows on two ebonite segments. Each of these resembles one-sixth part of a broad-tyred wheel, with the type set like three rows of nails around it. Each segment is attached to the centre by

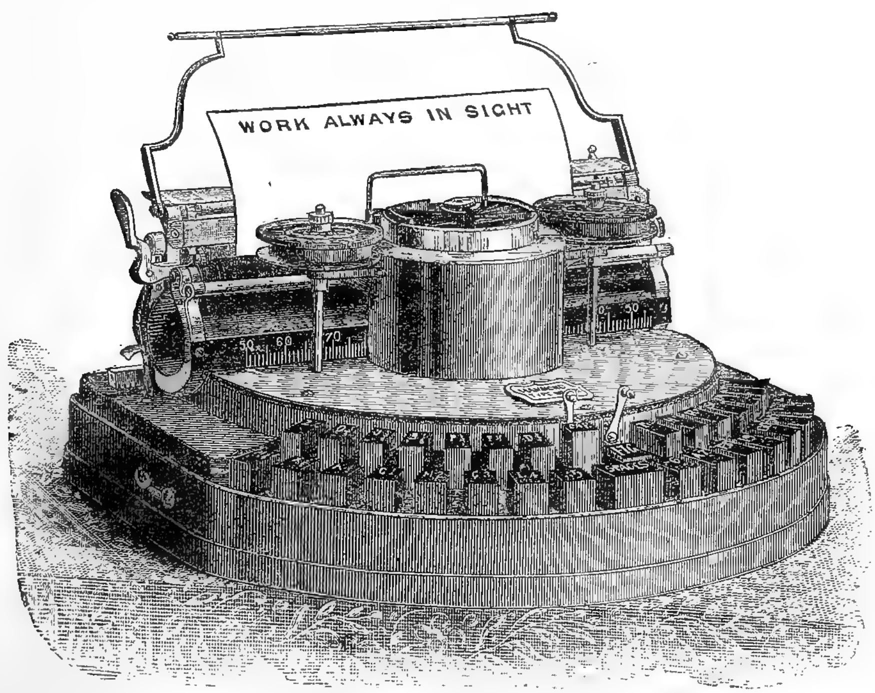


BARLOCK TYPE-WRITER: FRONT VIEW.



BARLOCK TYPE-WRITER: REAR VIEW.

five broad spokes. The segments lie wide apart when at rest, and the act of depressing a key moves one of them round, and at the same time raises a stop pin, against which it comes to rest, the proper type being then in position. Continuing the depression, a spacing



THE HAMMOND TYPE-WRITER.

hammer at the back of the machine is released, giving a blow which is quite independent of the force with which the key is depressed. The hammer is moved by the escapement action of the spring driving the carriage, which, as in most type-writers, is wound up by the act of pushing it back to commence a new line. It is impossible to damage the machine by depressing more than one key at a time. If several keys are depressed at once, the type segment stops at the stop pin raised by the key nearest the middle of the key-board, and the corresponding letter is printed.

The mechanism is most ingenious, and not only would it be impossible to describe it without drawings, but when seen in operation, is rather difficult to understand. The parts, however, are very strong, and require practically no oil. The alignment is perfect, since this merely depends on the level to which the type segments are raised by depressing the "Cap." or "Fig." keys. Another important advantage possessed by this machine is that the writing is visible up to the last two or three words, the paper rising up immediately in front of the operator. Even this might be improved to allow the writing up to within nine or ten letters to be seen, by a very slight alteration. The last word or two can be easily seen, if needed, by merely pushing the paper away from the inking tape. The method of giving the blow ensures that each impression is exactly of the same strength; but it cannot be made to "manifold" well, as the blow required needs so strong a tension of the spring that a considerable amount of friction is introduced. It has been asserted that the difficulty of stopping the type segments, dead at the right spot, and of overcoming the momentum and vibration, have been so completely overcome that it can be worked (we presume by some mechanical contrivance) "at the astonishing rate of from 400 to 500 characters per minute." The present writer has used a Hammond type-writer constantly for more than a year, and writes, when in a good light, at an average of 38 to 40 words per minute, and if pressed, can write 50 words against time. At the former speed, the letters situated at the outside ends of the keyboard often show signs of vibration, or that the type has rebounded. The appearance of the work produced by this machine is excellent. This is due to the good alignment, the uniform blow, and the well-designed type. In the other key machines, it is necessary to strike an *l* or an *i* with less force than an *m* or a *w*. The blow in this machine is given from the back of the paper, the inking ribbon being on the other side, between the paper and the type. It might be imagined that it would not print on stout paper, but it will just give a fair impression on a thin post-card. The feed for moving up the paper for a fresh line is effected at the same time as the pushing back of the carriage, by merely pressing on a lever. It would seem that even this might be improved by providing an arrangement for moving it by a cord, passing down to a treadle, to be moved by the foot; thus leaving the fingers entirely free for the manipulation of the keys.

We have had less opportunity of examining the Crandall type-writer than any other machine, having only heard of it since this article was in type. It has two rows of keys, arranged radially as in the Hammond, which it resembles in several respects. The type are arranged on the surface of a brass cylinder. This has three different motions—a rotatory and an axial motion, as in the Hammond, produced by the letter keys and the shifting keys respectively; it also has a striking motion, rocking forwards to impress the type on the paper. At the back of the machine is a segment of a wheel, having grooves on its periphery. These grooves are more or less curved. Into each one the end of a key lever fits. When the key is depressed, the back end of it rises, and in so doing causes the segment to turn, the amount of motion depending on the curvature of the groove. The type cylinder is geared to the segment, and moves with it. The first action then of the key, as in the Hammond, is to bring the proper type forward into the printing position. Continuing the depression of the key, the cylinder is rocked forwards, and a small taper pin which is fixed in the frame of the machine immediately under the printing point, enters a hole in the cylinder immediately below the type which is to be printed. As the type cylinder moves forward, the pin entering the hole locks it, and finally the type strikes the paper. The system seems an improvement on the stop motion of the Hammond, but we have had no opportunity to give the machine a test, or to minutely examine the other parts. The whole of the written matter may be seen by depressing a key provided for that purpose, but one of the lines is completely hidden by a bar, as in the Barlock. An inking tape is provided, and passes between the type and the paper.

Passing now to the wheel and plate machines, we come to lighter, cheaper, and more portable type-writers; but what we gain in these advantages, we lose in speed. In a busy office, or for transcribing shorthand reports for the press, speed may be of the greatest desideratum; and a practised operator will, as we have said, write eighty words a minute. Many clerks who spend most of their time in writing with a Remington, can produce sixty to seventy words a minute, though these will probably include several blunders which have to be corrected afterwards. The strain of such work is, however, more than most authors would find compatible with their intellectual efforts, or most secretaries with their dignity.

The *Columbia* is a neat little machine, only 9 by 6 by 5 inches, and weighs $3\frac{1}{2}$ lbs. The work produced by it is superior to that of other type-writers, for it has an automatic spacing arrangement, which allows a smaller side motion of the carriage for a narrow letter than for a wide one. A test for this is the writing of the words

committee, commission, willing,

which most type-writers print as above, but which are produced by the Columbia in a style which much more nearly resembles ordinary print.

The motion is quite unlike that of any other machines, and is rather difficult to learn. A type-wheel carries the type in a single row round its periphery. A handle projecting from the wheel is twirled backwards and forwards by the finger and thumb; a movement which can be produced with any amount of rapidity, but which is rather hard to effect with certainty of stopping at the right point. An improved form of this machine has an adjusting screw, by which a certain amount of friction can be applied, and which must be arranged to suit the strength of the operator's fingers. The type-wheel is geared to an index which travels round on a dial facing the operator. The upper part of the machine, as in all those of the second class, travels along step by step to the right. The distance travelled is regulated by the thickness of the type-wheel at the point where the type, which is in the printing position, is set. This method of regulating the feed is very simple, and does not complicate the machine, though it would be very difficult to apply it to most type-writers. The type-wheel is carried on an axis which is hinged at the left-hand side of the machine, and which can be depressed so as to bring the type down on the paper, the pressure being applied by the handle which is used for twirling the wheel.

The Columbia does not profess to be a fast machine.

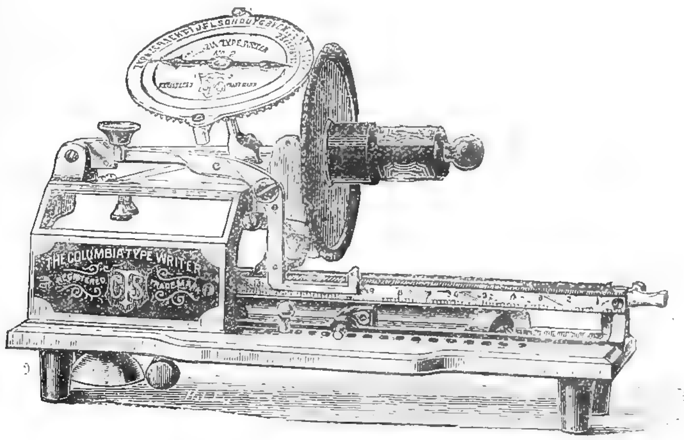
The type are of metal, and are inked by a wheel covered with cloth. When the type-wheel is at rest, the inking-wheel hangs between the type and the paper; when the handle is depressed, the inking-wheel moves out of the way, returning when the type-wheel rises. Each letter is thus inked before and after printing, and the same letter may be repeated a number of times with uniformly black impressions, with the exception of the first, which is generally darker. This somewhat defeats the object. The writing can be seen tolerably well.

The use of ink gives a much sharper impression than can be obtained from a tape, but the writing is equally liable to be blurred by rubbing, unless copied in a copying press as soon as it is written. This has a drawback to which makers of type-writers should turn their attention. Inking tapes are sold which give a capital black impression, but which will not copy; while the copying tapes, though giving a good and indelible colour after being copied, are both faint and easily smudged if not copied.

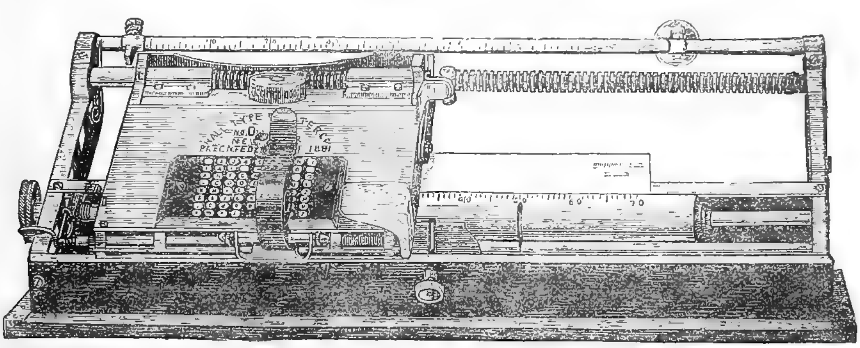
The *Hall* type-writer was one of those which suffered at first from being placed in the market before it was ready, though it was more complete when first introduced into this country than some of those which we have already described. Several improvements have been effected which no doubt make it a more durable machine than the two specimens which the present writer used daily for several years. The first one becoming worn out, there was no way of having it repaired but sending part of it back to America, but another machine was found also sadly out of order, and between the two a new one was patched up.

As in the Columbia, the paper remains stationary during the printing of each line, while the upper part of the machine moves step by step to the right. The types are formed of soft rubber on the face of a sheet of that material, being arranged in nine rows of nine characters. The plate is attached to a system of link work forming a double parallel motion. The plate can thus be moved in any direction, but always remains parallel to itself. Beneath the type plate, that is, between the plate and the paper, is an inking pad, which can be lifted out. In the centre of the pad is a square hole, through which one type at a time can be pressed on to the paper benaeth. At each stroke, therefore, all the other type are being pressed on the ink pad. The result is that if the same character be printed several times in succession, impressions rapidly become faint. In practice this inconvenience is not often felt, but the machine will not print "1,000,000" without a good deal of trouble with the inking of the "o."

The motion of the type plate is controlled by a bar, furnished with a hinged handle which carries a conical pointer. The handle therefore carries with it the type within the limits of an index plate. In this plate are nine rows of nine holes, corresponding to the arrangement of the type. At the bottom of each hole appears a letter. When the conical pointer is pressed into any hole, the type corresponding to the letter is brought opposite the square hole in the inking pad. On applying pressure, the whole carriage is depressed on to the paper, and the soft rubber of which the type plate is composed, allows the proper type to protrude through the hole. On the under side of the cover or lid of the carriage is a flat-headed pin, which is fixed exactly opposite the square hole: this gives the pressure on the type.



THE COLUMBIA TYPE WRITER.



THE HALL TYPE-WRITER.

It might be supposed, not only from this description, but from a trial of the machine, that it would be impossible to write at any considerable speed. While not attempting to rival the key machines, there is little difficulty in attaining forty words per minute, after several months' use; but it is necessary to have a very good light. Plenty of light is needed for working any type-writer in comfort, but for the Hall it is specially necessary, since the letters are at the bottom of holes in the index-plate. Two improvements have recently been introduced to meet this difficulty, but they by no means remove the defect. The weight of the machine, in its wooden case, is only 7 lbs. The type-plate can be readily changed for one of another style, there being a considerable variety. A type-plate of sufficient hardness to produce "manifold" copies, has been promised for some years, but had not made its appearance on the occasion of our visit to the agents; though several improvements appear to have been made with the view of reducing wear and tear.

It is possible with this machine to use the comma as an apostrophe, or to combine two vowels to make a diphthong, or to raise the *r* of Mr. by depressing the carriage while the pointer is not fairly in the hole, but is forced to one side. A disadvantage, however, arises from this peculiarity, for if the pointer is not held with a very light hand, allowing it to go straight into the hole in the index-plate, without any side strain, the result will be an irregularity in the printing, and a want of alignment. The Hall is of very simple construction and few parts.

The last type-writer on our list is the *World*, and it stands on the borderland between machines and toys. It cannot boast of speed, but an hour's experiment with it is sufficient to show that it may be classed among the more elaborate machines that have been mentioned. Its chief merit undoubtedly is that its price is about one-tenth of the key machines. The paper is passed under a bar and over a rubber roller.

The type are arranged on a soft rubber segment which is connected to an index-handle, and are moved over an index-plate by the right hand, while the left is used to depress a bar, which brings the type down on the paper, and pushes the carriage on for the next letter. The inking is effected by means of a pad on either side, over which the type-segment is continually sweeping. Considering its price, and that it measures 12 inches by 6, weighing $3\frac{1}{2}$ lbs., it is very possible that it may be worth getting when time and trouble are of little consideration.

The first cost of the type is a serious expense in the construction of a type-writer. Several letters have to be specially cut, the *g* and *y* having shorter tails than usual, and the *m* and *w* have to be a little cramped. Considerable skill has been expended on the arrangement of the keyboards and indices, with the view of placing the letters which are in most frequent use in the most convenient position. If this were all, the arrangement would be simple enough, but care is also taken in most machines to place near to each other letters which often come together. In the following examples, the characters which may be produced by depressing changing keys are not given. The Remington keyboard is arranged thus:—

lower case
2 3 4 5 6 7 8 9 -
· O W E R T Y U I O P
A S D F G H J K L :
upper case Z X C V B N M , .

The Hammond thus:—

Z Q J B P F D cap. fig. T H R S U W V
? X K G M C L , spaces . A E I O N Y :

It will be seen that the word *the* is easily written by striking the *t* with the first finger of the right hand, the *h* with the second finger, and the *e* with the same finger, sliding off the upper row on to the *e* below.

The keys for the words *that, these, their, on, is,* come together in a very convenient manner.

In the Hall type-writer, the index moves with the carriage to the right after each letter is printed. The arrangement of the characters is therefore from right to left.

1	2	3	4	5	6	7	8	9
o	"	"	§	‡	†	*	£	$
K	B	F	G	N	I	A	S	Q
J	C	D	O	E	H	T	W	V
X	M	Y	L	&	R	U	P	Z
k	b	f	g	n	i	a	s	q
j	c	d	o	e	h	t	v	w
x	m	y	l	.	r	u	p	z
[	$\frac{3}{4}$	'	;	,	-	?	:	]

In printing the word *the*, the pointer is pressed into the hole marked *t*, and, on releasing the pressure, the carriage moves on a step to the right, thus bringing the *h* under the pointer, which need not be moved at all; the *e* follows the *h* in the same way. The frequent termination, *ing*, presents itself to the hand in the same way. The characters *th, in, ly*, are also arranged with the same view.

Since writing the above, we have sought to supplement our personal experience and the glowing account of their own machines which all agents are so ready to give, by a visit to the Westminster Type-writing and Shorthand Office, at 2, Victoria Mansions, Westminster. This is one of the already numerous establishments which is conducted entirely by ladies, for whom, if work they must, no work could be better adapted. In this office a special point is made of perfect accuracy, and we are surprised to hear that a speed of about sixty words a minute is generally kept up. When the subjects undertaken are, one day, sermons; another, copies of actors' parts of plays; then a surgical MS. bristling with technicalities—besides all kinds of legal work and authors' "copy"—even this speed must entail a good deal of close attention and care.

Should any of our readers feel that they have arrived at that time of life when it is their duty to society to publish their "reminiscences," they need only send for a lady who will take down the matter in shorthand and send it back in print, this being a class of work undertaken by the office we have mentioned; nor will they be unprepared if the work is to be translated into Russian or Hindustani.

A Remarkable Meteorite.—The heaviest purely metallic meteorite as yet known is the "thunderbolt" of the Arab Sheik Kalaph Ben Assab. This chieftain saw it falling in the Valley of Kalede, in Central Arabia, in the year 1863, and presented it to the Persian Governor of Bunder Abbas. The latter sold it, along with a formal attestation of the finder, to the English authorities, and it has since been chemically examined. It consists of 91·04 per cent. of iron, 7·40 nickel, 0·66 cobalt, traces of copper, phosphorus and sulphur, and 0·39 of amorphous carbon. It contains no stony matter, and only includes scattered traces of troilite and graphite. Its weight is 120 lbs., and it is consequently the largest purely metallic meteorite or "holosiderite" known. The meteorite of Pallas, now in the St. Petersburg Museum, is much heavier, but it contains many cavities filled with olivine, and is consequently a "syssiderite." It is the tenth meteorite which has been seen actually descending. It fell during a thunderstorm, and made a deep hole in the earth.

General Notes.

Basic Slag in Agriculture.—The quantity of "basic slag," the by-product of the Gilchrist and Thomas process, now consumed annually by farmers in Germany reaches 300,000 tons.

Locusts in Madagascar.—Father Paul Comboné (*Cosmos*), writing from Tananarive, mentions that Madagascar is at present visited by the "Valala" (*Pachytylus migratorioides*), a species distinct from the locusts of Algeria and of Western Asia. They are eagerly eaten by the natives, and are consequently not regarded as a scourge. They are captured by the uneconomical process of setting fire to the herbage upon which they alight.

The Height and the Speed of Waves.—The subjects have been re-investigated by Mr. Buchanan, formerly of the *Challenger* staff, during a sounding voyage on board a steamer belonging to the Indiarubber, Gutta-percha, and Telegraph Works, Silvertown, a vessel commissioned to study the track for laying a submarine cable to St. Paul de Loanda. Mr. Buchanan's observations were made near the island of Ascension, the wind being so violent that the signals were hoisted to warn ships from attempting to enter the harbour. The height of the waves was determined at 20 ft., the mean distance from crest to crest at 625 ft., and the speed from 23 to 25 miles per hour.

The Electric Cultivation of Plants.—It has been frequently asserted that electricity applied at the roots of plants or to the soil in which seeds are sown should be a powerful promoter of vegetation. Professor Wollny, of Munich, has submitted this question to the test of experiment. He surrounded plots of ground, each of rather more than a square metre of surface, with boards, sunk in the soil to the depth of a foot. In one of these he arranged two earth-plates connected by a conductor, in which he introduced a battery of five elements; in another he placed an induction apparatus, and in a third a plate of zinc on the one hand and a plate of copper on the other, so as to form a natural element. Peas, potatoes, carrots, etc., were planted in these enclosures, and it was found that the application of electricity, either at a high or a low potential, proved either inert or injurious. Professor Wollny believes that electricity occasions perturbations in the protoplasm of plants, the greater in proportion to the conductivity of the sap. He infers from his experiments that electro-cultivation has scarcely a future.

The Laboratoire d'Erpetologie at Montpellier.—This establishment is for the purpose of effecting the sale and exchange of serpents and other reptiles and amphibia. Any traveller can here dispose of living specimens. It has 147 members in Europe, and 203 in other parts of the earth. The purpose of the association is to furnish the members with reptiles and amphibia at cost price, in order to facilitate their study. The superfluous specimens are disposed of to outsiders, and the profit is applied to the purposes of the society. Every member pledges himself to write yearly at least two memoirs on reptiles, which are to be published in any journal. The society possesses an "Encouragement Fund," endowed by certain members for the purpose of sending out young naturalists to countries not sufficiently explored, in order to collect and to make observations. Prizes, such as, *e.g.*, a Zeiss microscope, are awarded for the best collections. Rare animals can be lent for observation to any member who can prove that he has accommodation for such specimens, on condition that he publishes his results.

The Public Health.—The Registrar-General's return for the week ending December 15th shows that the deaths registered during that period in twenty-eight great towns of England and Wales corresponded to an annual rate of 18·9 per 1,000 of their aggregate population, which is estimated at 9,398,273 persons in the middle of this year. The six healthiest places were Halifax, Brighton, Hull, Bristol, Sunderland, and Wolverhampton. In London 2,291 births and 1,455 deaths were registered. Allowance made for increase of population, the births were 452, and the deaths 404, below the average numbers in the corresponding weeks of the last ten years. The annual death-rate per 1,000 from all causes, which had been 16·5 and 17·8 in the two preceding weeks, were last week 17·7. During the first eleven weeks of the current quarter the death-rate averaged 18·5 per 1,000, and was 2·1 below the mean rate in the corresponding periods of the ten years 1878-87. The 1,455 deaths included 154 from measles, 17 from scarlet fever, 39 from diphtheria, 14 from whooping-cough, 18 from enteric fever, 11 from diarrhœa and dysentery, and not one from small-pox, typhus, ill-defined forms of continued fever, or cholera; thus, 253 deaths were referred to these diseases, being 20 above the corrected average weekly number. In Greater London 2,891 births and 1,817 deaths were registered, corresponding to annual rates of 27·3 and 17·2 per 1,000 of the estimated population. In the Outer Ring 22 deaths from measles, and 5 from diphtheria were registered. The fatal cases of measles included 8 in West Ham and 4 in Croydon sub-districts.

Fauna of a "Pile Dwelling."—A "pile-village" on the Szontag Lake in the district between Lotzen and Lyck was examined by Heydeck in 1887, and appeared very similar in its construction to the pile-dwellings in the Arys, Czarnikock, and Tulewo Lakes. The remains were of a very remote date, as no articles of iron were found, and of bronze only a decorative disc. The earthen vessels had been made without the use of a wheel, and had very little attempt at decoration; only marks of finger-nails and a stroke in the shape of N. The very numerous bones were examined by Nehring, and were found to belong to the wolf, fox, wild cat, otter, bear, beaver, hare, wild boar, ur, stag, roe, domestic dog, horse, swine, ox, sheep, and goat; capercailzie, black cock, duck, crow, hawk, owl, and pike. The most abundant are the bones of domestic animals, especially of the pig, and the next most plentiful are those of the stag and the roe. Most of the marrow-bones have been broken. The ur (*Bos primigenius*) is represented only by the core of a horn, which shows many traces of human elaboration. From the antlers of the deer many pieces have been severed, probably for the manufacture of implements. Nehring emphasises the absence of the reindeer, which, indeed, he has never discovered in pre-historic finds, in company with the roe, pig, and tame cow. The only dog's teeth discovered are decidedly of a wolf-like type, and belong not to the "peat dog," of Rutimeyer, but to the so-called "Bronze dog." The horse-bones belong to a pony of an elegant race, which was probably domesticated. According to these remains the pile-builders lived principally by hunting and keeping cattle, in part also by fishing.

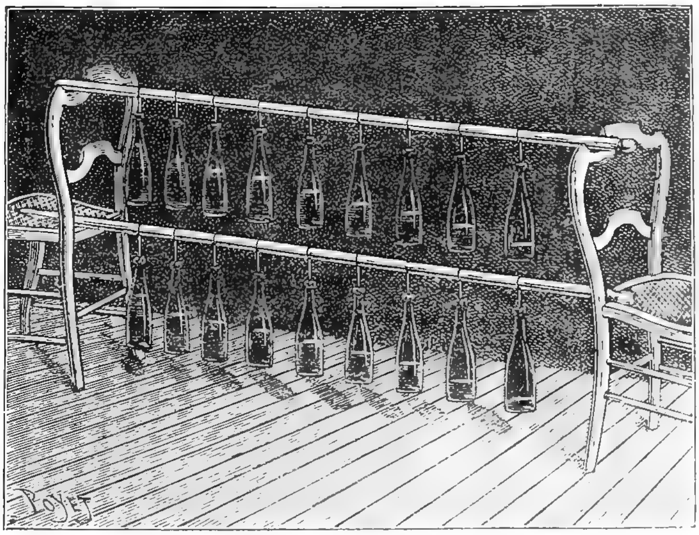
THE STATE OF OUR CEMETERIES.—Sir Spencer Wells in opening a discussion on "Cremation," in the large hall of Sion College, showed that our cemeteries are now little, if any, better than the old churchyards against which Dr. Thomas Walker waged such a long and arduous war. He said: "The present condition of many cemeteries is shocking and revolting—bodies festering in a slough of corruption, while others are covered only with a few inches of earth. The Brompton Cemetery, surrounded on every side by the dwellings of the living, was bought by the Government in 1853, ostensibly for the purpose of closing, but since then it has been receiving more than 5,000 bodies annually. The present state may be more easily imagined than described. In the Tower Hamlets Cemetery it is alleged that as many as 1,053 children's bodies have been packed in seventeen trenches, and in one instance sixty bodies in one trench, which remained open until it was over-filled. It has frequently been found necessary to bail out the liquid corruption; and owing to the foul stench the workmen engaged have been taken out of the trenches in a fainting condition. In the Wolverhampton Cemetery the common graves are kept open from day to day until quite filled. In the Ardwick Cemetery, Manchester, with a very small acreage, 70,000 bodies have been interred. The dead lie in what are practically wide trenches with about 18 inches of earth between each. In Glasgow the system of pit burial is generally adopted, and goes on, although it has been denounced by the medical officer of health as dangerous to the public, and a gross breach of decency."

THE PROTEST AGAINST EXAMINATIONISM IN EDUCATION.—The growing conviction that competitive examinations are a ruinous failure has found able and authoritative expression in the November issue of the *Nineteenth Century*. In that issue we find "the strong protest of the signers against the dangerous mental pressure and misdirection of energies and aims which are to be found alike in nearly all parts of our educational system. Alike in public elementary schools, in schools of all grades and for all classes, and at the universities, the same dangers are too often showing themselves under different forms. Children are treated by a public department, by managers and schoolmasters, as suitable instruments for earning Government grants; boys of the middle and richer class are often trained for scholarships with as little regard for the future as two-year-old horses are trained for races; and young men of real capability at the universities are led to believe that the main purpose of education is to enable them to win some great money prize or take some distinguished place in an examination. We protest most emphatically against such a misdirection of education, and against the evils which necessarily arise from it." This document has been signed by hundreds of the most thoughtful and influential persons in Britain—men widely differing, or even mutually hostile on perhaps every other subject, but here joining in a protest against a system which, if persisted in, must reduce us to intellectual ossification. Professor Max Müller, commenting on this document, admits that he was, forty years ago, an eager advocate of the system of Civil Service examinations. He now frankly owns his mistake, and admits that the fault has been, not with the application of the principle of examination, but with examination itself. Mr. Frederic Harrison thinks that "examination, having been called in to aid education, has grown and hardened into the master of education. Education is becoming the slave of its own creature and servant. Like all servants turned masters, it is now bullying, spoiling, and humiliating education."

THE LAST EXPLORATIONS OF M. DE BRETTES.—M. de Brettes, of whose early travels in the Grand Chaco to the south of the Rio Vermejo a brief account has already appeared in these columns, has just returned to Paris from a second expedition, with reference to which he furnishes some interesting particulars to the *Journal des Debats*. Having started from France in May, 1886, entrusted with a mission by the Minister of Public Instruction, he was detained by difficulties of one kind and another upon American soil for sixteen months, and prevented from penetrating into the Chaco. He did not, however, allow this time to be wasted, for he purchased a yacht, and, with the help of a French engineer, M. de Boisvier, he completed the hydrographical survey of the Lake Ypa-Carai which had been commenced twenty-seven years before by the English engineers Burrell and Valpy, but interrupted by the Paraguay war in 1864. At the instigation of the Consul of Bolivia, M. de Brettes then entered the Chaco for the second time (October 13th, 1887), starting from Apa, on the frontiers of Brazil, and making for Baranquerita (the Northern Chaco). His escort then consisted of fifty Guana Indians and a single native of Paraguay who had resolved to accompany him, and who was nicknamed accordingly by his compatriots "Guapo" (the brave man). But this brave man soon took fright, and fled back to Apa half dead with terror. M. de Brettes then travelled through the territory of the Guana Indians, who were then at war with their mortal enemies the Chamacocas, and he was himself attacked by this tribe and slightly wounded. He continued his march westwards for six days, suffering terribly from thirst, and he at last reached Bolivian territory, ten days' march from Pilcomoyo, having gone through the hitherto unexplored territories of the Guanas, the Kamananghas, the Baughis, the Neennsemahas, and the Aksseks. During the whole of this difficult march he did not fail to take note of all the important geographical positions, and thus, for instance, he followed for upwards of 70 miles a *senda* (Indian path) which leads from the Rio Parguay to Bolivia across the Chaco. This was the knotty point of the problem, and M. de Brettes further ascertained that this *senda* runs through a perfectly flat country, and that there would be no difficulty in clearing the road which Bolivia so much desires to make. He also came upon some very curious brick ruins to the right of this Indian tract in latitude 21° 48′ south, longitude 63° 07′ west meridian of Paris. The Indians who accompanied him said that beneath the round monuments like low towers, which M. de Brettes saw, were tombs, but he was unable to verify this, though he extracted from some of the cavities in the ground some fine specimens of pottery similar to those found in the tombs of the Aymaras of Bolivia, whence M. de Brettes concludes that the Incas' dominion must have extended far beyond the Andes. Among the pieces of pottery which he has brought back is a duplicate of what M. Jacquemart describes as the *chef d'œuvre* of American pottery, a vase which is now in the Louvre. In addition to the potteries of the Incas his collection comprises Guanas and Chamacocas vases of modern manufacture and a great number of Indian articles, such as violins, costumes made of feathers, necklaces of all kinds, and arms.

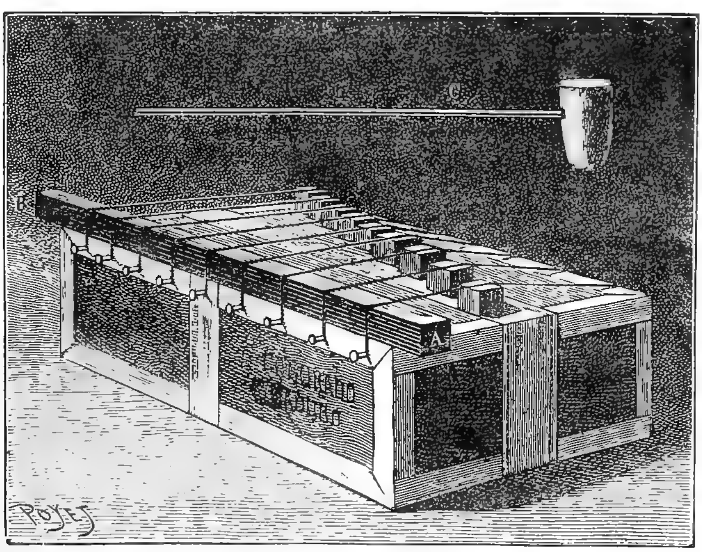
PREPARATION OF MUSICAL INSTRUMENTS.

M. L'ESPRIT has sent to *La Nature* descriptions and sketches of musical instruments which may be easily constructed of domestic materials.



MUSICAL INSTRUMENT MADE WITH WINE BOTTLES.

The first of these instruments is composed of glass bottles of any kind, filled with a certain quantity of water, the height of which varies according to the note to be obtained, as it is shown in the accompanying sketch.



MUSICAL INSTRUMENT MADE OUT OF A CIGAR-BOX.

After a few trials it will be found practicable to reproduce all the notes with their octaves, including the flats and sharps, for arranging which a musical ear is, of course, required. The bottles are suspended by their necks with double loops of string, hung over broomsticks, resting on two chairs. To produce the sound the performer uses two rods or the two sticks of a child's drum. Airs in two parts can be played on this instrument, or duets may be executed by two performers, one on each side.

The second instrument is a kind of harp. Take a flat box; a cigar box will serve, and drive into each side nails, shown in fig. 2. From the nails on opposite sides thin brass wires are stretched. Pass a square ruler under the wires from A to B (fig. 2). On the other side place small cubes, cut from a similar ruler, and find by trial the length of the cords to produce the notes required. As a matter of course, the strings must be stretched tight. To strike them when properly adjusted, a slip of whalebone (C) may be taken, to the end of which is fixed a cork.

SOME RECENTLY DISCOVERED FORMS OF MICROSCOPIC CRUSTACEA.

(*Part II., continued from p.* 622.)

Mecynocera clausi, I.C.T. Differs remarkably from every other known species in the extreme length of its anterior antennæ, by which it can be at once recognised. It is about $\frac{1}{25}$ inch in length. Its rostrum is bifid and very slender. The anterior antennæ are 23-jointed, alike in both sexes, and about twice the length of the entire animal (fig. 1); the 11th, 12th, and 13th joints of left antennæ only are edged with fine saw-teeth (fig. 2). The basal portions of both antennæ bear several short setæ and a few long ones, and at intervals, and especially at apex, are several long, whip-like setæ. The posterior antennæ are very muscular; the outer branch is 3-jointed, the inner 7-jointed, and terminated by spreading setæ. The maxillæ are well developed, with

Fig. 4. Abdomen and caudal segments of male ditto. × 400.

two spreading setiferous branches and broad rounded palp. The anterior foot-jaw is 3-jointed, and like the posterior, which is small, bears a large number of plumose setæ.

The swimming feet (fig. 3) have small hooked spines at ends of joints, but no terminal spines besides abdominal joint is divided longitudinally, the intervening space being filled with hyaline membrane. The caudal terminations in the female are divergent, in the male less so; both are terminated by four plumous setæ on each side. Colour reddish brown.

Males and females were both plentiful, and taken by

the strong spinous setæ. The fifth feet are wanting in both sexes. The abdomen of the male (fig. 4) is 4-jointed, that of the female is 3-jointed, the basal joint of the latter being somewhat heart-shaped. The third

surface tow-net at all the places visited. Indeed, this species seemed to be more widespread than any other.

Cymbasoma rigidum, I.C.T., plate vi. In the earlier portion of this paper a short description was given of the new British species *Cymbasoma Herdmani*, I.C.T. The form about to be described was, however, the earliest found, and the writer has since also found it in the Maltese seas. Its length is about $\frac{1}{8}$ inch. The first joint of the cephalothorax (fig. 1) is equal in length to the succeeding five, the last being much smaller than the others, and appearing as though part of the abdomen. The eyes are long and kidney-shaped, with a conspicuous brain below. The anterior antennæ (fig. 2) are about eight times as long as the broadest part, and terminated by two claw-like spines; the inner side of each antenna has five hooked spines (fig. 2). From two raised circumferences near the centre proceed long spinous setæ, and several smaller setæ are situated near the apical portion of the antennæ. The first four pairs of swimming feet (fig. 3) have strong muscular basal joints, from which proceed two 3-jointed branches, with thick terminal setæ. The fifth pair of feet are each composed of a long joint, at the apex of which are three strong spinous setæ. The abdomen is very muscular; the caudal setæ are short, broad, and divergent, and are each terminated by three strong setæ.

One specimen only, a female, was taken in the tow-net, at Orotava, Teneriffe.

The lower portion of the body is of a deep sepia colour. The animal is peculiarly rigid and muscular.

The illustrations accompanying the paper are taken from Mr. Thompson's drawings in the Transactions of the Liverpool Biological Society and the Linnæan Society of London.

THE GEOLOGICAL HISTORY OF SHARKS.

IN the Suffolk Crag great numbers of sharks' teeth occur, and among these are many of large size, which bear the name of *Carcharodon*. They are often upwards of four inches in length, triangular in outline, and armed along the cutting edges with close-set toothlets, such as are so often found upon the large knife-like teeth of carnivorous animals. The great sabre-toothed feline (*Machairodus*) of our late tertiary times, and the extinct carnivorous reptile *Dicynodon* of South Africa are well-known instances of the same thing. It is plain that a tooth so armed lacerates the flesh more extensively and completely, penetrates further, and is more easily withdrawn. A knife-blade passed into soft wood, or cheese, or flesh, soon jams, and can hardly be moved backwards or forwards; but if the edges are furnished with saw-teeth, the tool enlarges its cut, and will penetrate much deeper. Teeth of the Carcharodon occur also in the tertiary deposits of Florida and Carolina. In some places they are so plentiful that ship-loads are regularly sent to England for conversion into super-phosphates, the same process being, as our readers well know, applied to the fossil bones and teeth of the Suffolk Crag. Many of these fossil teeth were dredged up from the bottom of the Pacific during the expedition of the *Challenger*. A closely-allied species (*Carcharodon Rondeletii*) still survives in the seas of warm climates. It attains the great length of forty feet, but the tertiary shark of the same genus must have exceeded even this enormous bulk. The recent and fossil teeth hardly differ materially, but of course there may have been more conspicuous differences in the perishable parts of the body, with which we cannot hope to become fully acquainted.

Agassiz and other palæontologists have described many kinds of large crushing teeth borne upon the jaws of very ancient sharks. Some are known from the Devonian formation. A vast number of forms have been figured from the limestones of the Carboniferous period, and the succession lasts, with hardly diminished numbers, down to the Lias, after which there is a great falling off in the variety and frequency of these fossils. The key to the arrangement and use of such teeth has been found in the recent *Cestracion Philippi* of Port Jackson, a shark whose fore teeth are pointed and adapted to the seizing of prey, while the hind ones form a tessellated pavement, set with regular rows of large and powerful grinders, which are rendered intensely hard by the dense enamel which covers the exposed surface, and yet to some extent movable by reason of the membranous spaces between. This dentition is well suited to the crushing of crustacea and hard-shelled mollusks.

Among the oldest sharks are some whose teeth were subdivided into several long-pointed cusps, smaller ones sometimes intervening. These belong to the extinct genus *Cladodus*, which is first met with in Devonian rocks. Quite recently Garman has described a very peculiar deep-sea shark from Japan, to which he gives the rather repellent name of *Chlamydoselachus anguineus*. It has an unusually long but nevertheless shark-like body, a wide mouth opening quite at the fore end of the head, as in most fishes, and not beneath, as is usually the case with sharks. The gill-openings are extremely wide in comparison with any other shark. The teeth closely resemble some of those attributed to *Cladodus*, and good naturalists could be named who maintain that the old Devonian fish still survives in the Japan seas. Others believe that the form of the teeth in sharks cannot possibly justify a confident assertion of identity, but there can be little doubt as to the near affinity at least of the creatures separated by so vast an interval of time.

The oldest known sharks are also among the oldest known vertebrates. They are represented by teeth, scales, and possibly spines found in the bone-bed of the Ludlow formation (Upper Silurian). Some long extinct fishes (*Pteraspis*) claim an equal antiquity, but no surviving form of vertebrate life can be traced back anything like so far as the family of sharks.

Upon this remarkable persistence of an extremely ancient type we have to make two remarks. Firstly, that it is in singular conflict with the general course of life upon the earth. In seas, as in wide continental areas, there is a profusion of competing forms; new races appear frequently, and spread fast; ancient types are suppressed, or driven out into secluded regions. We find that the truly ancient families among animals are now to be sought chiefly in ponds and lakes and rivers, even such as once could hold their own in the broad ocean. But the tide of time has not exterminated the sharks, nor even compelled them to take refuge in corners. They are still numerous, varied and widespread—truly a dominant race, notwithstanding the lapse of uncounted ages.

In the second place it is not a little startling to find in sharks rudiments and embryonic structures, not serviceable to the animals themselves, though immensely interesting to the naturalist, who learns thereby something about their yet more primitive pre-Silurian and invertebrate progenitors. The external gills, which never serve to aerate the blood, and the early stages of the development of the kidneys will remind comparative anatomists of the details of structure to which we point. We should have expected that natural selection, working through untold ages, would by this time have simplified the course of development, finding out short cuts to avoid waste of tissue and waste of time in the assumption step by step of the permanent organisation of the body. But purposeless embryonic arrangements, which point to Annelid ancestors, are still preserved, to the conspicuous advantage, we must gratefully acknowledge, of the biologist, who thus finds some of the most difficult channels of phylogeny buoyed for his guidance. The succession of life on the earth follows no law of capricious change. The English constitution has been said to owe its remarkable character to the circumstance that Englishmen have never changed their institutions, except to remove a practical grievance, and only to just such an extent as the grievance required. It seems to be a somewhat analogous law of nature that anomalies and vestiges of an antiquated state of things are tolerated and preserved so long as they do not cost time or substance which can ill be spared. But to the student who has some hazy idea of what geological time means, the mention of structures inherited by existing sharks from pre-Silurian invertebrate ancestors loses none of its strangeness by reflection; and it is only the sheer impossibility of finding a less difficult solution which forces him to accept such an explanation of the recorded facts.

THE SOLAR ECLIPSE OF JANUARY 1.

THE total solar eclipse, which will occur on January 1, 1889, although it will not be seen in our hemisphere, will be an event of great astronomical importance. It will be fully visible in the Pacific States of the Western Continent, and the Americans are preparing to observe it. It is extremely rare for a year to open with a total eclipse. It has not occurred since 1682 (new style), and will not occur again till 2161. The coincidence has also happened in 1162, 660, and 641 B.C. and 865 and 1405 A.D., the two latter dates being of the Julian calendar. The path of totality, or complete obscurity, will cross Nevada and California over an area favourable for observation. The best places for observation in California are Point Arena, Ukiah, Bartlett Springs, Willows, Chico, Quincy, Loyalton, Oneida, Long Valley, Milford, etc. All places on or near the centre of the path will be in darkness for about two minutes of the time. At the central line, near Oroville, the totality will be 114 seconds; at Point Arena, it will be 120 seconds. It will last from 108 to 120 seconds—longer nearer the coast than in the interior. In Nevada the shadow of the moon will cross the western line at the town of Verdi, and its breadth is so great that from Verdi north along the boundary for a distance of about 100 miles there will be total darkness of the eclipse. The central point of the moon's shadow will cross the Western Nevada line at a point 32 rods north of the 124th milepost. The south edge of the moon's shadow will pass about halfway between Reno and the highest point of Peavine Mountain. Thus Reno will be just outside the shadow. The centre of the path will be about six miles north of Winnemucca, and 29½ miles north of Tuscarora. The south edge of the path will pass north of Wadsworth and south of Pyramid, Lovelocks, and Humboldt House. The north edge of the path will pass north of Buffalo Meadows, Willow Point, Paradise Valley, Spring City, Willow Creek, Cornucopia and White Rock, and will pass ten miles south of Fort McDermit.

The eclipse, from beginning to end, will be very long. For instance, at Point Arena the beginning of the eclipse will be 1 hour and 10 minutes before the beginning of totality, and the end will be 1 hour and 16 minutes after the ending of totality, the whole lasting over two hours and a half. It begins at that place at 0h. 15min. 11sec. mean time. For standard Pacific time, 14 minutes 58 seconds should be added to that. In San Francisco the eclipse will not be total, but very nearly so. About eleven-twelfths of the sun will be obscured. There it will begin at 23 minutes 7 seconds past 12 o'clock, and end at 9 minutes 6 seconds past two o'clock. The time of greatest obscurity is at 48 minutes 43 seconds past 1 o'clock. It is greatly to be hoped that there will be clear weather, though January is an unfortunate time of the year for astronomical work in that part of the world, since it falls in the middle of the wet season. The Royal Astronomical Society has published a letter of Professor E. S. Holden, of the Lick Observatory, giving the probable meteorological conditions. He gives the records of cloudiness at various Californian stations for the last fifteen days of December and the first fifteen days of January, but prefers not to express any definite opinion on a subject so uncertain as Californian weather in January. He simply presents the data. Time signals from the Lick Observatory are received daily (at Pacific standard noon) at nearly every railway station in California. On the days immediately preceding and following the eclipse they will be automatically transmitted from the standard clock, and special pains will be taken to make them useful to observing parties in the field. The observing party from the Lick Observatory intend going to Bartlett Springs with their instruments, which will include a spectroscope. Mr. Burckhalter (Chalot Observatory) and party will go somewhere between Cloverdale and Ukiah. Mr. Blinn (Blinn Observatory) will go to Winnemuca Peaks, Nevada. Professor Davidson (Davidson Observatory) will probably go to some point in Nevada, in the hope of getting good weather. It is expected that a number of eclipse expeditions will be formed in the east and go to California, and some observers are expected from Europe. Photographers will accompany all these parties. Members of the Pacific Coast Amateur Photographic Association are making preparations for the event, and will occupy different points along the line of totality.—*Iron.*

SCIENTIFIC AIMS.

PEOPLE who occupy themselves with heat and light and electricity, or with plants and animals, or who mix solutions in test-tubes and see what colours are produced, or who take daily readings of the thermometer and barometer, all claim some kind of place in the world of science. These and other employments of the same kind are for many purposes conveniently distinguished from purely literary, and also from purely practical pursuits. But no definition of science can hold water which takes account merely of the sort of object concerned. It is possible to play with scientific instruments, to buy and sell them, to use them ignorantly, to treat them as charms, works of art, or means for the gratification of the senses. If we mean to use language carefully, we must look for the essential character of a man of science, not so much in the things with which he is concerned, as in his aim and method. Whoever strives diligently and successfully to attain to knowledge of the laws of nature by the observation and interpretation of the phenomena of nature, may claim to be a man of science. So possibly may others too. Our definition does not pretend to be complete. It excludes the student of arithmetic and algebra, whom most people take to be occupied with science. But any definition of science which includes these, includes logic too, and becomes so wide and abstract as to have little or no practical value. Let us keep to our confessedly incomplete definition, which is right and definite as to what it includes, though probably not as to what it excludes.

Is it merely a question of words which we are raising? Not if we are engaged in clearing up our notions as to the characteristics of a particular sort of productive workers, and of the way in which they become productive. Let us give that turn to our discussion. Have any men signally promoted the increase of natural knowledge in any other way than by combined observation and interpretation of natural phenomena? Some of us will be inclined to say, Yes. We shall think of men who have heaped up stores of information for the use of others, men like Schwabe, with his fifty years' observation of sun-spots, or Flamsteed, with his catalogue of of 2884 stars. We cannot refuse such men a place among productive scientific workers. They worked with scientific tools and for scientific ends, even if they only collected information for other men to use. Well, then, what about the meteorological observer, who daily, at 9 and 3, or 10 or 4, sets down the readings of the thermometer and barometer? Is he a man of science too? We must concede that he is in intention, at least. Whether he is in fact will depend upon the use to which his observations are put. If they accumulate and fill portfolios, until improved methods drive them out of notice without leading to a single generalisation or prediction, we must refuse to confer upon the observer a place among productive workers for science. He has merely piled up observations which nobody has been able to use.

We have entered upon this discussion because we have reason to believe that thousands of patient observers are busy in the name of science with toilsome work of this kind, work which is and will remain unproductive, because unstimulated by any questions of interest to science. In many a quiet parsonage and country-house recorders have been long at work with a patience which only requires the inspiration of a clear and definite object to make it highly respectable. They hoped, and still hope, that they are collecting data useful to scientific meteorology, but, alas! the meteorological discoverers of the century, Redfield and Buys Ballot, and Buchan, have put and answered the great questions without their help.

Will it be so with the thousands of diligent naturalists who are preparing county lists? They believe themselves to be storing up valuable facts for the use of future generations. Have they any definite ground for their belief that the discoverers of some future age will care for their tables and lists of species? Hitherto the scientific study of distribution has led men like Wallace and Huxley to merge the British Isles with Europe and North Africa and most of Asia, and perhaps with North America, in one vast northern province. The smallest scientific subdivision of that natural history region includes ten times the area of the British Isles. Will the naturalist of the future ever treat scientifically units so small as 100 square miles of British land, defined by no natural barriers, and without characteristic species? If this is extensively done, there may be hope for the list-compiling naturalist, but it may be doubted whether there is any room for so encouraging a supposition. We shall perhaps be told that scientific questions continually arise which require the collection of hosts of minute facts, and the assertion is justified by the whole history of science. But would it not be better to put the questions first and collect the information actually wanted to answer them? Life is too short to prepare elaborate answers to questions which have never been, and perhaps never will be raised. The local naturalist who works with definite questions in his mind will work to profit. Without such questions he will probably beat the air. How great and desirable a change would come over our field-clubs if we ceased to record occurrences of species in small areas of arbitrary definition, and began to inquire why particular species are limited to certain spots. Why does a particular alga or dipterous larva haunt one stream only in the neighbourhood? Will it bear transportation? Is it a matter of food, or purity of water, or of enemies? What tempts the wall-rue fern to occupy the crevices of an old wall? Is it because of the lime in the crumbling mortar, or because of the nitrates, or because of a special exposure, or because of right conditions of moisture? In attempting to answer such questions the student will be tempted to observe and compare his experiences. He will work to purpose, with a definite object and with his attention well awake. How unlike the paralysing occupation of setting down a list of species with localities, studying the features of every capture merely so far as is necessary to apply the long Latin or Greek name without error, and trusting to a long-distant morrow for the recompense of labour which hitherto profits no one, and may never benefit a single student of nature. "To place stuffed birds and beasts in glass cases, to arrange insects in cabinets, and dried plants in drawers," says Sir John Lubbock, "is merely the drudgery and preliminary of study." May we not speak even more coldly of the cataloguing of names and localities? He goes on to say that "to watch their habits, to understand their relations to one another, to study their instincts and intelligence, to ascertain their adaptations and their relations to the forces of nature, to realise what the world appears to them—these constitute, as it seems to me at least, the true interest of natural history." It is such wise words as these which we would impress upon the young naturalist who has not yet finally chosen his path. We would entreat him to inquire whether the pedantry of natural history has not proved just as barren of results as the pedantry of classical scholarship, and whether what is most fascinating in natural history, namely, the attempt to solve questions of real human interest, is not at the same time the truly scientific side of the subject.

INSECT ARTILLERY.

SOMETIMES, when one is wandering along a river bank, and turning over such large stones as may lie near the edge of the water, a very remarkable sight may be witnessed. Out rushes a handsome little blue beetle with a red thorax and red legs, evidently in a violent hurry, and makes for the nearest place of concealment; and as it hurries along a puff of bluish-white smoke proceeds from its body, probably succeeded by another, and that again, perhaps, by a third; and each is followed by a slight but perfectly audible report. If the insect be interfered with, the process is repeated, it may be, ten or a dozen times in rapid succession, and one is irresistibly reminded of a war-vessel in full retreat, whose stern guns nevertheless keep up a constant fire upon her pursuer.

This curious little beetle is popularly known as the Bombardier, and scientifically as *Brachinus crepitans*, and may be considered as a typical example of the tolerably large genus to which it belongs. It is plentiful enough in some places, but correspondingly rare in others, and is usually found, if at all, in the neighbourhood of water, and particularly on or near the banks of running streams. And it affords us an excellent example of one of the very strangest methods of defence to be met with in the whole of the animal kingdom. Its discharges are, without hyperbole, those of insect artillery. They are due to a highly volatile liquid, secreted for its special function by special glands lying in the region of the tail, which passes into vapour immediately upon coming into contact with the air. They are intended for defensive purposes in combating various foes, and more especially in warding off the attacks of the larger *Geodephaga*. And they have even something of the missile nature, inasmuch as the explosive fluid itself is highly irritant in character, and will even leave a dark stain upon the human skin, which cannot be removed even by frequent ablutions.

For our knowledge concerning both this fluid and the organs which distil and discharge it we are chiefly indebted to the researches of M. Léon Dufour, who devoted special care and attention to their examination. And from him we learn that the apparatus in question is double, one division lying along either side of the abdomen, and each consisting of two parts, the one secretory, and the other conservatory. The first of these assumes the form of a delicate thread, and is, in fact, a gland in what may be termed its primitive or lowest condition; the other is a kind of reservoir, in which the fluid is stored up until required for use. And the former opens into the latter just as the secreting-glands of the bee and the wasp open into the bag which contains the poison.

In appearance the secretory portion of this gland varies very considerably, according to its degree of expansion or contraction. When fully distended it is oblong, semi-transparent, and nearly filled with air, and occupies nearly the full length of the abdomen. When contracted, however, it becomes merely a soft, opaque, whitish body lying in the terminal abdominal segments, and scarcely recognisable for the same organ. The reservoir does not change its form in like manner, but is always a globular, reddish-brown object, situated in the anal segment, and provided with special muscles to ensure its due contraction when a portion of the contents is to be expelled.

By turning the abdomen from side to side, the *Brachinus* can direct its discharge with some little accuracy, and seldom fails to check a pursuer, provided that it be at tolerably close quarters. In this manner, in its Continental habitats, it frequently contrives to repel the giant *Calosoma sycophanta*, one of the largest of the predacious "ground" beetles, and a terrible enemy to insects smaller than itself. One well-aimed discharge and the *Calosoma* relinquishes the chase, evidently suffering very considerably from the pungent nature of the volatile fluid which has been employed against it. And in our own country several of the larger *Carabi*, and such fierce and insatiable creatures as the shore-loving *Broscus cephalotes*, are frequently repulsed in like manner.

The exact nature of the explosive fluid seems rather doubtful. It is readily soluble either in water or alcohol, and leaves a slight dust behind it after discharge. And the interior of the reservoir, if that organ be emptied and examined, is seen to be covered with a deposit of the same character. It is strongly irritant, as has already been stated, and, should it enter the eyes, will cause pain and inflammation fully as severe as would an equal quantity of the strongest vinegar. And it will stain any part of the skin upon which it may happen to fall, and that so deeply that its traces will remain uneffaced for several days to follow.

Still more potent is the same fluid in the larger exotic species, some of which can scarcely be held in the naked hand, so severely do they burn the flesh. If the discharge of our common British example is similar in its effects to strong vinegar, that of its tropical relations approaches very nearly to nitric acid. And both Lacordaire and Burchell, the African traveller, tell us that they have often been obliged to release specimens which they had captured, merely because the pain caused by their discharges was so intense.

By slightly compressing the abdomen the explosions can be produced even after death, provided, of course, that sufficient time has not elapsed for the tissues to harden, and the fluid in the reservoirs to dry up. If they be directed upon a sheet of white paper, a reddish spot is left, which afterwards changes to brown. And, after the explosive liquid itself is exhausted, "a black, grainy liquid" is discharged in its place, which does not pass into vapour. In *Brachinus displosor* a similar liquid, but of a yellow or brownish colour, is emitted after the explosive discharges have ceased.

The quantity of liquid secreted, or at any rate the amount expelled at each discharge, varies very considerably in different species; and thus we find that, while our own British Bombardier can produce eighteen or twenty explosions in rapid succession—although each is perceptibly more feeble than its predecessor—*B. displosor* is limited to twelve or so, and other species to fewer still. But it is difficult to ascertain these facts with any degree of accuracy, for the simple reason that it is impossible to tell whether the beetles selected for experiment have not lately made use of their strange capabilities, and so partially exhausted the contents of their reservoirs.

Besides *Brachinus*, there are one or two other genera of beetles which possess similar powers, and among these may be mentioned *Paussus*, resident principally in the Moluccas, and certain species of *Cerapterus* and *Oxœna* But in none are they so strikingly pronounced as in the true Bombardiers.

Now what are the analogies of this fluid? Is it connected with, or a modification of, the sexual secretions? Or is it a special provision, restricted to the comparatively few insects in which it appears?

Scarcely the former, one would think, for it is present both in male and female, and it is scarcely possible that any part of the generative system should be so modified as to produce precisely the same secretion in opposite sexes. Nor, on investigation, does any part of the generative apparatus appear to be wanting. Clearly, theory the first is not correct.

Theory the second, although nearer to the truth, is also open to fatal objection, for in no animal do we find organs or members which are not present, although very likely in a greatly modified form, in thousands of other species. Thus to hold that the explosive apparatus of these remarkable beetles is absolutely unique is probably true only insomuch as it does not appear to be present in other insects *in precisely the same form.* And we know that great numbers of insects do possess an apparatus which at least is somewhat similar in character. Thus most of the *Geodephaga* emit when handled a volatile and evil-scented fluid, not only from the mouth, but also from two small glands situated near the tail—just the region, it will be noted, in which lie the secretory organs of the *Brachini.* And some of these can eject the liquid in question to a distance of several inches. The well-known Musk Beetle (*Cerambyx moschatus*) has under exceptional conditions been known to do the same. Ants, again, expel formic acid when annoyed, and cause considerable pain and irritation if the face be held near to a disturbed nest; and some of the *Hemiptera* possess a somewhat similar power. Thus it would seem that the explosive nature of the Bombardier's discharge is merely due to the fact that the liquid which it secretes is of a more volatile character than usual, passing at once into vapour when expelled instead of evaporating by degrees. And so we have the key to the mystery.

FLINTS.*

PROFESSOR JUDD said that on that evening he proposed to speak to them concerning the uses to which flints could be put. It must be confessed at the outset that the uses to which flint could be put at the present day were greatly restricted as compared with those to which it had been put in the past. At the present day they sometimes employed flint as a road-metal, and for this purpose, though it answered fairly well, yet it was generally inferior to many of the hard igneous rocks like the well-known dhu-stone employed in the London streets. Flints were sometimes ground and reduced to powder, the powder being employed in the manufacture of glass and porcelain. There were a few gentlemen of dandified manners and conservative instincts—he did not mean politically—who preferred to use a flint and steel mounted in silver rather than the ordinary wax vestas and fusees employed in lighting pipes and cigars; and, lastly, muskets with flint locks are still prepared for somewhat unsophisticated savages, though the most unsophisticated savages of all were supplied, it is said, with muskets without touch-holes. Among savage nations flint was still largely employed for many purposes. But in nations where the arts had become known, the use of metals had to a very large extent displaced the use of flint and other stones. Among savage nations, however, flint and similar materials were constantly employed either for obtaining fire or for making tools and weapons.

Now, let them inquire for one moment what were the properties of flint which enabled it to be used in that particular way. These properties, which he had already referred to in a former lecture, were, first, hardness, which enabled it, when struck with pyrites or steel, or any hard substance, or even with another piece of flint, to emit sparks, and also enabled sharp flints to be used for cutting purposes; but with this hardness was combined a certain amount of toughness, so that it preserved a sharp edge much longer than a piece of glass or similar material, which was sometimes employed for the same purpose. Most remarkable of all was the conchoidal fracture to which he had called attention, which enabled fragments to be struck off, having the remarkable form of flakes. They would recollect what he said about flakes, with their bulb of percussion, and which enabled them to be trimmed so as to form weapons and tools of very definite form. Then there were two other properties which had some influence upon flint. First, the porosity; the porosity of flint allowed water to be absorbed and to be driven off by the ordinary drying process; so that flints were sometimes moist throughout and sometimes dry, and their other properties changed with the quantity of water they contained. Lastly, they had this important property, that flints, although, geologically speaking, they withered away, yet, spoken of historically, they were among the most unchangeable of things; so that, whereas weapons of iron and bronze, and even gold and silver, had perished, articles made of flint were almost imperishable, though even many of these worked flints could be seen on the exposed surface to be undergoing the first stages of decay, such as the flint exhibited, which had been covered in one position, where the original black surface was preserved, and on the other side there was a thin white coating, due to disintegration. Now, perhaps he ought to mention that different examples of flint exhibit very great variations in the degree to which they possess these several properties. Some flints differed greatly from others in their uniformity and fineness of grain. There were some flints which were wonderfully uniform in texture throughout their mass. These lent themselves to being fashioned in the most beautiful forms, whereas there were others which showed great irregularities in grain. In one part the structure was fine and in another part it was coarse, and thus they did not lend themselves to be fashioned with the wonderful beauty that they would see that certain flints were susceptible of acquiring. Now let them inquire what were the methods of making and using objects of flint and other similar stones; and the methods employed both in making and using flint weapons could only be judged of by studying similar weapons used by savage tribes at the present day. In many countries the use of stone was still common. In Australia, among savages there, and in the South Sea Islands, the use of metals is unknown—the art of extracting metals from the ores is quite unknown, and if they used metals at all, it was only metal which had been derived from the white man. As a rule their weapons and tools were all fashioned from stone. They had, however, sometimes an opportunity of understanding how the ancient weapons and tools were used by the early people who made them, for occasionally, as in peat mosses and similar situations, they might find the handles or the attachments of the tools actually preserved, and they might study the manner in which they were used.

Let them examine first the methods which must have been employed by the ancient workmen in fashioning the tools and weapons which they employed. With regard to those weapons and tools, he might mention that they sometimes used ordinary flint-pebbles, masses of flint which had been washed out of the chalk and rolled into pebbles. These were generally of a brownish, reddish,

* Sixth Lecture to Working Men at the Royal School of Mines.

or yellowish tint, while the tools which were made from the chalk were black or grey. Here, for example, was a most beautiful specimen of flint, where they could see a pebble had been taken and by a few dexterous blows had been made into a weapon. This came from Herne Bay, and they would see by a drawing on the wall, that the instrument probably was somewhat more pointed originally—that the point had been broken off, and that the instrument was then thrown away. They sometimes found clear indications that after an instrument of that kind had been blunted a fresh point had been given to it by chipping, but in time that wore out, and then the instrument was thrown away and a new one made. Such instruments as these were reduced to the form which they now bore by a few dexterous and smart blows, which, administered in a proper direction, would take off flake after flake, reducing the flint to the particular form exhibited. Much depended upon the skill with which the work of taking off the flakes was done, and doubtless, as at the present day, there were skilful workmen and unskilful workmen; some of the instruments made being of a very rude character, while others were very beautifully fashioned. In other cases a good black flint was selected—a flint taken from the chalk. They might sometimes see a part of the white coating which characterised flint in chalk still adhering to a part of the flint, as in the specimen from Herne Bay, and in the instrument found in London, which was preserved in the British Museum. At other times they found that masses of flint which had received a somewhat definite form by a few sharp blows taking off flakes, had been worked up in the most beautiful manner by further treatment. Here, for example, was a flint-knife, or scraper, which had been first roughly shaped by a number of blows. That specimen was from Denmark. It had been made into its present form, and teeth had been produced along the edge of the mass. The way in which those teeth had been produced was not by percussion, as the general outline of the flint had been produced, but, judging from the way in which flints arrows and similar objects were made by the Exquimaux and Indians of the present day, a somewhat different mode was adopted. If the flint was fashioned by hard blows and then a hard substance was pressed against it, little flakes might be made to fly off, and a number of delicate flakes might be taken off by pressure, and thus a perfect form be produced, especially the beautiful serrated edges which characterised some of the weapons. A diagram of one of the flint flakers used by the Esquimaux was shown, and the handle of this flaker consisted of a piece of very dark-coloured ivory, which was largely found in the Northern Hemisphere; while the tool itself consisted of a piece of the horn of a reindeer, which was used on account of its extreme hardness. This was fastened very securely by a sinew to the piece of ivory which served as a handle, and then the sinew contracted and held the piece of reindeer-horn firmly. With that weapon the Esquimaux could be seen to take a flake off a flint and work off little flakes from the edges until they produced the beautiful serrations which characterised some of the well fashioned articles in flint like the arrow-heads. How beautiful those objects could be made by this method of flaking could be seen from diagrams and specimens show. Lastly, when the very best flints were required, mines were opened in the chalk strata. Very rude mines they were, of course; they were really great conical holes which were made into the chalk leading down into a particularly good bed of flint, and carefully selected beds of flints were capable of being worked with very great care, first by chipping, and then by flaking, until most exquisitely beautiful articles, such as those exhibited, were produced. There was a wonderful variety of fashions in the different types of these instruments used in different places. On a diagram was shown a curved knife; also various forms of spear and javelin-heads; also a few of the variety of types of arrow-heads, which were made by those methods. With regard to the determination of the methods employed, they depended upon watching savages like the Esquimaux and the Indians at work; and travellers who had spent much time amongst these people had given them an account and showed clearly how any such work was being done now; and doubtless the work done in the past was effected by very similar men. Some persons by studying these various objects had learnt to make flint implements. His friend, Dr. John Evans, the well-known antiquary, who had devoted a great deal of time to the subject, and had, perhaps, the finest collection in the world, became a dexterous worker in making flint-instruments; and he remembered how the late Sir Charles Lyell was much interested in the making of the instruments and in all questions bearing on the antiquity of man. Dr. Evans sat beside a workman who was making one of these objects, and carried away every fragment of the flint in his pocket for the purpose of study. Others had worked pieces of flint for less worthy objects, like the celebrated Flint Jack and other forgers in France, who had worked in the same way as the old workmen; instead of using old stone hammers, they used hammers of steel, however, and they managed to make flint instruments in this way. It had sometimes been suggested that perhaps all the instruments were forgeries, but that was as unlikely as that all coins should be bad ones. If there had been no true coins, he did not suppose that makers of base coin would have arisen; but as a matter of fact there was generally no difficulty in distinguishing the spurious from the real article. The real articles had a peculiar lustre and feel which those who had studied the implements got to know perfectly, and they often had peculiarities which no forger, however cunning, could impart to them; and moreover, these flint implements had been found again and again by persons whose testimony was unimpeachable. There was not the slightest doubt there were many of these genuine flint implements. What he had with him were genuine, though there were forged ones, just as there were base half-crowns and sovereigns.

Let him now say a word about using those flint instruments. To a certain extent the mode in which those implements were employed in ancient times was conjectural, but it was not wholly so, for they found in modern savages so many implements of like forms that they could not doubt that they were similarly employed in the past. Among the oldest flint implements which had the greatest interest for them, they had several well-marked types. There was first the long pointed type, of which there were drawings of three specimens on the wall. They were of large size, and in regard to the way in which they were used there might be some doubt. It had been snggested that in many cases they were employed as ice chisels. He would point out to them that the climate of this country was formerly much colder than it was at present, when these people lived here, and that they probably lived by fishing, as the Esquimaux did in the present day. In that case implements of this kind would be very useful for chopping holes in the ice, in order to let down a line to get at the fish. Such instruments might easily escape from the grasp of the person and drop to the bottom of the water, and that might account for the fact that that type of instrument was especially common in gravels, where they had sometimes been found in considerable numbers. But in some cases there could be little doubt that these implements were fixed in handles and served as hatchets or weapons, and skulls and other bones of animals had been found actually perforated with those implements, the implements sticking in portions of the skull. Another use to which an implement of that kind could be put was splitting open bone and taking out the marrow, and in many cases great heaps of those bones, all carefully split by sharp instruments of that kind could be found. Then they had another type, which was found with these types — the ovoid type. They were generally much smaller than the others. The use to which these were put was also problematical, but it had been suggested, with great show of reason, that in many cases they were used for scraping skins, and that such scrapers were constantly employed at the present day with or without handles. There were many examples. Here was a specimen of the scraper fixed into a wooden handle, and it was used for dressing skins. The same sort of implement was largely used by the Esquimaux and many other people. Lastly, they might have simple flakes more or less dexterously struck off, which were employed for cutting pieces of wood, or bone, or other articles, for which purpose they were very effective. Passing from those rude and simple types, they found knives, either straight or curved, often with their edges dressed in the most beautiful manner. They found spear-heads, and javelin-heads. Then they had the wonderful variety of beautiful objects known as arrow-heads. From those types they passed to the forms which were very ornamental. Sometimes after an instrument was made, it was beautifully ornamented. Here was one ornamented with grooves, and another ornamented by very careful and elaborate chipping. It might be surmised that many of these were made more for show than for use; they were emblematical rather than useful weapons. They were like the maces and swords of state which were borne before Royal people and Lord Mayors, and such great folk, which were not employed for knocking people down or stabbing them. Next to chipping an ornamental surface to the objects, they found that the grinding and polishing of implements by sand and similar materials was practised by the use of sand and water and rudely chipped implements. Then they might have grooves cut through their crown, so as to allow the handle to be fitted more firmly; and in other cases holes were drilled right through the tools. In these cases the hole was probably produced with very great labour by means of a pointed stick used with plenty of sand and water, and worked after the fashion of a centre-bit; in that way a hole could be driven through the hardest stone. This, of course, would take a long time, but savages generally had plenty of leisure. Now a great number of other weapons and instruments might be mentioned as being made of flint or similar material. There were pieces of flint chipped so as to serve best for striking lights, and these strike-a-lights were made in the earliest times, as they were made quite down to within the memory of some of those present. Strike-a-lights were most probably used first with iron pyrites or other pieces of flint, and till quite recent times they were employed with the steel and tinder box. Besides this, flint and other materials were used to make hammers. Here were some of the hammers which were actually employed. By successive blows flakes had been dexterously struck off, and then the core was thrown on one side when a sufficient number of flakes had been taken from it. Stones were found slightly rounded by a few blows so as to serve probably as sling stones, others as heads of clubs sometimes, and sometimes for attaching to nets to sink them to the bottom; sometimes the flakes were set in great masses on blocks of wood so as to form threshing instruments. In Asia Minor at the present day sets of flint flakes could be purchased. Then there were pestles and mortars, a large stone with a curved surface and rubbers, by means of which grain could be rubbed down to the condition of flour; and lastly, there was no doubt that the earliest surgical instruments were made of these flints. Long after flints and similar materials had ceased to be employed for other purposes they were used for certain delicate surgical operations, and one could easily see that a beautifully clean piece of flint was very preferable to instruments made of bronze such as were employed by Eastern surgeons at the present day. Lastly, he might mention that some of the more delicately struck-off flakes were employed for cutting out needles, harpoons, and other articles, and in the use of delicate fragments of flint they saw the origin of art. The drawings and sculptures which had come down to them in ivory were worked by sharp fragments of flint, or else carried out in the manner illustrated. Here they saw the origin of art.

Now with regard to the mode of fastening these implements to their handles. Sometimes the implements were clearly inserted in a hole in a piece of wood that served as a handle; a hole was made into the handle, and the flint driven into it, and every blow served to fix it more firmly. In other instances, as the wood would wear away, the stone instrument was fitted into a socket of bone and the bone fixed in the weapon handle. Sometimes bone only was employed. From these simple cases they had others where a stone implement was tied into the bone or weapon handle either by means of a thong made of vegetable fibre or the skin of an animal, as they could be wetted and dried, and in drying they often held the mass very firmly in its place. In other instances, as in Western Australia, masses of gum or resin were employed and melted round the natural flint or other stone. In a diagram was shown a handle fastened to a scraper by means of resin, and sometimes both cords and resin were employed. In other cases there was a groove cut and the handle pressed forcibly into it, or sometimes the handle was twisted round and fastened to a straight handle, the whole being bound strongly together; and, last, they came to a case where holes were drilled to hold the handle. In some cases they had actually found the workshops where the flint implements had been made. They occasionally found, sometimes in an old pit where quantities of gravel or other materials had been dug out, and sometimes in other places where these remarkable tools were formed, the flakes which had been struck off in fashioning the instrument, and they found the cores from which large flakes had been struck, and sometimes long flakes which could be fashioned into delicate instruments. Then they found great blocks of stone, generally with a depression in them, on which these masses were rested while the blows were being struck which separated the flakes; and in one case a very ingenious worker, Mr. Spurrell, had contrived by picking up pieces of flakes at a certain spot and fitting them together to reconstruct a rough chalk flint out of which a spear-head had been made. In the centre was a cavity, evidently the place where the tool was originally, the flakes which were lying about on the floor were actually the flakes which were struck off in making the implement. The implement, of course, had not been found, but enough of the flakes had been found to show the general character of the rough flint out of which the implement was originally made.

Now, the study of these flint instruments had led them into very interesting results with respect to the history of the human race. It was certain that the age of man in Britain and in other countries went back very far indeed beyond the period covered by history, or even by tradition. Flint implements which had undoubtedly been made by man had been found in situations and with surroundings which left no possible doubt that they were of enormous antiquity, an antiquity of many many, thousands of years, though they could not give their actual date in years. These implements were found sometimes in the gravel of rivers, like the gravel of the Thames Valley, not only the gravel in the present river, but at a greater elevation than the present river—50 and 60 and 70 feet above—where the river formerly worked before it cut down its bed to the present level. They found such instruments in the old caves which were sometimes inhabited by these men, and they also found the remains of animals which had either been washed in or had been carried in by men who had killed them for their prey, and with some of those skeletons of animals not living now in this country were found these remarkable flint instruments, the whole being covered up by a layer of stalagmite, and it was possible for an investigator to break open these stalagmites, and find concealed below, the bones of these animals, mingled with weapons of men who lived at the period when the caves were inhabited. Besides these proofs they had raised beaches—that was sea beds, which by the movements of the land were now far above the sea level—they found in those remarkable refuse heaps, or *kitchen middens*, as they were sometimes called, or shell mounds, many of the relics, and tools, and weapons made of stone employed by these ancient people who lived almost entirely upon shell-fish, with such game as they were able to kill with their rude weapons. Now in the remarkable lake dwellings of western and other countries, of which they had examples in Central Africa and New Guinea, at the present day, in peat mosses and other situations, there were many deposits containing these remarkable flint instruments.

And now he must point out to them what were proofs of the antiquity of these objects. The proofs of antiquity were of two kinds. First of all it was clear that in many cases great physical changes had taken place since these objects were deposited in the situations where they now found them. In many cases, as he had already pointed out, the rivers which had flowed at these spots, had worn down their beds 20, 30, 40, 50, and 60 feet below the level at which they must have flowed when these instruments were deposited in the midst of the gravel. In other cases, as, for example, the flint instruments which had been found along the shores of the Solent and in the Isle of Wight, they had evidence that when these men lived, and used implements of that kind, the Isle of Wight was joined to the mainland, and then all the wearing away which first took place by the river which ran there, and then by the sea which effected the separation of the Isle of Wight from the mainland, all this action had gone on since those implements were lost in the bed of that ancient river. Moreover they had clear proof that the climate had changed, he would not say for the better, but it was somewhat warmer now than when these men lived there. The second proof of the antiquity of these objects was found in the fact that they were associated in such a way with the remains of various animals, some of which were actually extinct, and had died out altogether in the world, and others no longer existed in this country, but in distant countries, such as the hairy mammoth, which does not live at the present day. These, with reindeer and many other animals with curious shells, which were found in the rivers at that period, though not living in this country now, and various forms of vegetation—all these associations indicated that man was living contemporaneously with these curious forms of life. That the antiquity of these objects was very great could not be for one moment doubted, though it was quite impossible to assign the age of each object in years. It must be measured by many, many thousands of years.

Let him just recall to their recollection some of the results of these interesting studies, carried on concerning these wonderful flint instruments. He would not waste time by insisting upon the fact that these objects were really of artificial origin. He might as well try to argue that his watch got into his pocket by chance, and that it was not made by a watchmaker, as that these beautiful objects were not made by men with a definite object. The study of these interesting objects showed that there was a regular succession amongst them; that many of the oldest objects contained proofs of antiquity which were most striking. Thus associated with the remains of animals of a kind which were quite extinct, they had very rude and primitive types, and as they came down to more recent times—in which the evidences of the change of climate, in the inhabitants of England, the wild beasts living in England, and they approached nearer to our own time, they found other types employed. The oldest and simplest types were those which were classed as older palæolithic, and these older palæolithic were the types which were employed by men who lived here in very remote times. In that variety the implements had generally long spear-headed and rounded forms, and simple flakes, which were employed for various purposes, also occurred. Of the men who fashioned these instruments they knew very little. The instruments were so simple in kind, and were so seldom found associated with other objects which would throw light upon the nature of the avocations of the users of these instruments, that all they could infer was that they were hunters and fishers; probably, by their superior numbers and cunning, they waged successful warfare with some strange animals that lived in the country, including the curious woolly elephant, the hippopotamus, the lion, the bear, and other animals. That they fished in the river was exceedingly probable, and it was also certain that the climate was colder, and what would perhaps strike them as improbable, even wetter than at present. The next or reindeer period was characterised by the fact that people made weapons of much more delicate and varied types. At this period the reindeer lived abundantly in this country, though now it had emigrated far to the north. The climate, as they might well imagine, was probably colder then than at present, and they found that the men of that period exhibited greater skill in the making of weapons. They made stone implements which were very carefully and often delicately fashioned, and were of a much more varied type. Amongst the instruments made there was a much greater variety of type than in the older palæolithic time. They found that with flakes of flint they carved various articles like needles and harpoons out of pieces of bone, and they even attempted art, for ornaments and drawings were actually found in some cases which were made by these people. But, nevertheless, they were very primitive people indeed, for it was very clear that amongst them pottery was quite unknown, and they seemed to have had no dogs or other domestic animals. In their mode of burial, evidence was obtained that superstition, the mother of religion, as it had been called, existed, and, as they found with the bones of early people who had been buried, the axes, and treasures that belonged to them, they might infer that they had some idea of the future life in which those objects would be of use to them. There was also an indication that human sacrifices were offered in these periods, for in many cases the number of bodies laid round a central one, would seem to indicate that slaves and attendants were slaughtered to serve as attendants to them in another world, as was the case with savages in the present day. Most of them were hunters, and they were probably more skilful men than those of the palæolithic time, and there was evidence that they were not cannibals. Even a greater time seemed to separate these palæolithic men from the neolithic men, and a great advance seemed to have been made in some forms of civilisation in the interval between palæolithic and the neolithic periods. The implements employed in the neolithic time were of the most beautiful and exquisite workmanship. They were fashioned by the process he had endeavoured to describe that evening, and in addition to that it was found they were even rounded to a smooth surface, and those surfaces were sometimes beautifully polished. They were sometimes perforated so as to be attached to handles, and sometimes they had most striking ornamentation worked on the surface. There were indications that for the purpose of obtaining the best materials, for making these stone implements, mining operations were carried on, sometimes with a fair amount of skill, and that something like commerce was carried on for highly-prized materials were carried to enormous distances—half across a continent—in order that the much-coveted materials might come into the hands of persons who had articles to exchange for them. In this neolithic period there was evidence that a very rude kind of pottery was employed; that the dog and other domestic animals had been tamed and brought into use, and here was a primitive but useful kind of agriculture carried on. In this period the bodies were generally buried in a crouching position, and he was sorry to say that there was evidence that was a going backward in one respect, for cannibalism was certainly prevalent, though they might hope that it was occasional rather than habitual. The people of that period seemed to have been short in stature, with oval skulls and black hair. It was even possible that ancient people, known as Baskes, which were found in Spain and in the mountain regions of Northern Africa—that these people were descendants of some of these northern men. It was possible, seeing the similarity and habits of many of the Esquimaux tribes in Greenland and British North America were so similar to the habits of the men of the newer palæolithic period, that the Esquimaux were the direct descendants of the newer palæolithic men. But since metals were invented the use of stone rapidly declined, though they must recollect that in many parts of the world people had not got beyond the stone-age. They still used the rough or sometimes more carefully prepared weapons made of stone. First, perhaps, iron which was found as a meteoric production and was employed for implements. Then copper, which was found native, was used. Next, man learned to make an alloy of copper and tin, and then they had an age of bronze, which was succeeded by the period when iron came to be very generally employed, which was the iron-age, and he supposed that now they lived in the steel-age. But even now, in this steel age they had the modern survival of the use of flint. Some present could recollect the use of the old tinder-box with strike-a-light, and in mines not very long ago a steel wheel working against a piece of flint was made to emit sparks, was all the light the colliers had to work by in very fiery mines. Flint locks, and guns, and pistols were employed down to recent times, and they were still made at Brandon in Suffolk, where the trade of flint knapping was carried on at the present day. They might find in the museum many illustrations of how flints were worked up from the cores at Brandon, and fashioned into various kinds of flints for muskets. It might be that these old workmen at Brandon must be regarded as lineal descendants of the old neolithic, and even of palæolithic workers of flint. They had seen that night how the study of these artificially-worked flints carried them back beyond—very, very far beyond—the periods covered by all histories—even the histories of Egypt and China. But what of the study of the flint itself? As they stood on the sea-shore, the meanest pebble that they picked up and carelessly flung into the water, might reveal to them a story which, if they had really read it aright, must send their thoughts in ever-widening circles outward across the ocean of knowledge towards that mysterious horizon which divided science from the unknowable.

Reviews.

Transactions of the County of Middlesex Natural History and Science Society. Session 1887-88. (London: Mitchell and Hughes.)

These transactions contain no small amount of interesting matter in a paper on "The Chemistry of London Clay." Mr. W. Mattieu Williams points out that the peculiar character of clays is that they contain not merely silica and alumina, more or less pure, but combined water, as distinguished from moisture. If such combined water is once driven off by heat the clay loses its plasticity, which cannot be restored by mechanical admixture with water.

Mr. Sydney T. Klein, F.L.S., F.L.S., gives an interesting paper on *Ephestia Kühniella*, a lepidopterous larva, which recently appeared at the East End of London, and destroyed or spoiled many hundred pounds' worth of flour.

After fumigations had been tried in vain, and after poultry became over-satiated with gorging, the pest was overcome by the appearance of a swarm of tiny ichneumons.

Professor Flower, F.R.S., in a paper on "Horns and Antlers," points out the difference between the deciduous antlers of deer and the true, permanent horns of oxen and sheep.

There are further papers on the "Position and Prospects of Electric Lighting in London," by W. L. Carpenter, B.Sc.; "Fossils of the Flint," by Mr. G. Barraclough, M.R.C.S.; and the "Water-supply of Middlesex and the Metropolis," by M. H. Hughes, C.E. In this paper the author attempts to defend the prevailing and inequitable system of charging for the water-supply not in accordance with the quantity consumed, but with the assumed ratable value of the premises occupied by the consumer. We do not object to the rating principle as regards the incidence of other local burdens, but in such cases no other way is possible. It must be remembered that wherever water is furnished by a company, with rare exceptions, the supply is intermittent, and where it is in the hands of a local authority it is constant.

Mr. C. Rousselet gives a paper on "Some Methods of Collecting and Keeping Pond Life for the Microscope," and Mr. T. Blashill contributes a memoir on "Miniature Earth Pyramids in the Clay at Hampstead."

First Yearly Report of the Meteorological Observations on the Sonnblick.

The Sonnblick Observatory is situated in 47·3° N. lat. and in 12·87° E. long., and at the altitude of approximately 10,000 feet above the sea level. The Director of the Observatory, Dr. J. Hann, has issued a complete conspectus of the observations made at this lofty station from October, 1886, to September, 1887. The results merit attention, not only because the Sonnblick is the most elevated meteorological station in Europe which is completely equipped, but because the observations at other stations are in general desultory and imperfect.

The highest meteorological station in the earth is that of Pike's Peak, in Colorado (about 14,000 feet), but as yet it has furnished merely a few mean determinations of atmospheric pressure and temperature. The same must be said of the station on Mount Washington, though these two observatories have been instituted respectively in 1872 and 1873. The observations at the French stations on the Puy de Dôme (4,890 feet) and on the Pic du Midi (about 9,000 feet) have not hitherto been used for deducing general conclusions.

The mean values of the atmospheric pressure for the whole year are 520·42 millimetres at 7 a.m., 520·85 at 2 p.m., 520·95 at 9 p.m., or a mean of 520·74. The temperature is at 7 a.m. −7·4°, at 2 p.m. −6·1, and at 9 p.m. −6·9°, or a mean of −6·8°. The absolute moisture is 2·8, and the relative is 93. The yearly mean of the extreme atmospheric pressures shows a maximum of 531·7 and a minimum of 501·1. The greatest barometric variation on the Sonnblick is 30·6, as against 36·8 millimetres at Salzburg. The extremes of temperature are 8·0 and −29·2°, the range being 37·2°, whilst at Salzburg the corresponding values are +30·4 and −16.5°, with a range of 46·9°.

The progress of the decrease of temperature with increasing elevation, and which will, to a certain extent, hold good for the entire Alpine region, is—

	Elevation.	Temperature.
Sonnblick	3095	−6·8°
Säntes	2465	1·8
Obir	2040	0·3
Schmittenbache	1940	1·1
Schatberg	1776	1·8
Wendelstein	1730	1·9
Hohmsalzberg	1490	3·8
Gastein	1020	5·3
Rauris	940	4·9
Niederkirchen	850	5·7
Zell	750	5·6
Ischl	467	7·6
Salzburg	428	8·7

The Sonnblick Observatory affords an opportunity of observing the decrease of atmospheric warmth on ascending, as in the neighbourhood there are numerous stations at different heights above the sea-level. The decrease of temperature with increasing height takes place in a sinple arithmetical series only in summer. In other parts of the year it decreases in an accelerated proportion. The change is most irregular in winter, when there even occurs a rise of temperature on proceeding from the bottom of the valleys of Pinzgau to a certain relative height. A very striking instance of this phenomenon was recorded in January, 1887. The temperature increased up to an altitude of 840 metres above the valley (1690 metres above the sea). At this height it became stationary, and then decreased, so that at 2,520 metres above the sea-level the same temperature as at the bottom of the valley.

The observations on the Schmittenbache and at Obir, if collated with those taken on the Sonnblick, give the following values for the decrease of temperature for each 100 metres of elevation in the atmospheric strata between the elevations of 2,000 and 3,000 metres: in winter 0·58, in spring 0·66, in summer 0·77, in autumn 0·72, and in the entire year 0·68.

If the differences of the mean monthly temperatures on the Sonnblick and at Säntes, Schmittenbache, and Obir are used for calculating the mean normal temperature, we find for the Sonnblick −6·8, whilst at Säntes it is −1·8. The mean normal temperature on the Sonnblick, as calculated, is very probably in winter −13·5; in spring −8·6, in summer −0·1, and in autumn −5·4. These points will be better realised if we remember that the mean yearly temperature on the Sonnblick corresponds to the isotherm on the earth's surface, passing through the middle of Spitzbergen, the southmost of Novaj Sembla, and in Asia from Obdorsk to Ochosk. The mean winter cold on the Sonnblick is as great as in Orenburg; the pring resembles January in Central Russia; the tumn is like the same month at Wilna. But the sum er has a mean temperature lower than has ever been r gistered at the same season in the northern hemisphere, and such as may, perhaps, prevail only in the higher southern latitudes. The mean variability of temperature from day to day on the Sonnblick is smaller than it might be expected. Great changes do not occur; the greatest fluctuation amounted to 11 degrees, and took place between February 6th and 7th, whilst at Rauris there was a change of 14·8° from January 8th to 9th, and of 11·7° from January 4th to 5th. Comparison with a number of other stations proves that the progress of these changes of temperature is entirely different at different stations. Thus the magnitude and the frequency of the rises and falls of temperature must rank among local phenomena. The lowest mean variations of temperature on the Sonnblick is in January and May, whilst at the same time great fluctuations occur at Rauris and Ischl.

In winter and autumn the cloudiness is greater in the low grounds than at the high Alpine stations. In spring and summer the summits are more overcast. In spring, summer, and autumn the frequency of sunshine on the Sonnblick falls earlier in the day than in the lower grounds. At this elevation in summer the greatest frequency of sunshine occurs between 8 and 10 a.m., and then rapidly decreases. This is evidently due to the influence of the ascending air current, which forms clouds and mists on the summits as soon as the valleys become heated. On the heights the afternoon sun is therefore a cause of cloudiness, whilst in the low grounds it dissolves the clouds.

On the Sonnblick the predominating winds are the south-west and the north, whilst in the valleys the west and north-east predominate. Calms are very rare. In the valleys calms occurred in thirty-five per cent. of the observations, but on the Sonnblick only two per cent.

RATIONALITY IN THE LOWER ANIMALS.

We often hear discussions on the question whether or not the lower animals possess any share of reason, or, in other words, whether they differ from us in degree or in nature? The affirmative side is taken chiefly by working naturalists; those who make actual observations on our "poor relations" in the woods, the fields, or in default in menageries. The negative view is upheld for the most part by metaphysicians, who convince themselves on *à priori* grounds that "brutes" cannot reason, and who wave aside every appeal to facts as an impertinence.

We think that a novel argument may be drawn from facts which are admitted without dispute, but the bearing of which has not been fully recognised.

It may at the first sight appear extremely paradoxical if we adduce superstitious fears, in man or beast, as a paradox, since most persons would at once pronounce superstitions as a proof, more or less complete, of irrationality. But yet we shall see, on close examination, that in the entire absence of reason superstition could not exist.

Let us suppose Giles the ploughboy, or any other similarly uncultured individual, is plodding his weary way homewards after his daily toil. He sees a field-mouse hurry across the path, or a crow stalking along the newly turned-up furrows. He will feel no surprise and will take no more notice of either animal than, perhaps, to fling a stone at it. Wherefore? Because the fact that living animals are capable of voluntary movement is part and parcel of his own daily experience, and because he has always heard them spoken of as capable of such movement. But what if he should see an old bone, a stick, or a stone, in short, any lifeless object moving regularly and continuously along a level piece of ground, and suppose he should be unable on looking more closely to detect any agency by which it was pushed or drawn? His curiosity would be unpleasantly roused; he would feel uneasy, and if he saw no chance of trickery he would suspect the interference of some supernatural, or at least extra-natural agency. But why should he thus feel disturbed in mind? Because he has in his mind a rough notion of a certain order of nature, any departure from which strikes him at once as uncanny. His life experience and the traditional experience of his parents, neighbours, and associates tell him that *only* living animals are capable of spontaneous movement. If, then, he sees such movements on the part of a portion of lifeless matter he feels that the boundaries of his experience are transcended, and that he is in presence of unknown forces. His idea of an order of nature is the key to his feeling of mystery and awe, or, if we prefer the expression, to his superstitions. Were he incapable of forming such a concept all phenomena would seem to him equally matters of course, and he would be incapable of the feeling of mystery.

Now, this very power on the part of man of conceiving of an order of Nature, of a normal course of things, has always been accepted as evidence of human rationality. It presupposes not merely the power of observation, but of generalising from the facts observed. If, therefore, we find in the lower animals instances of superstition, of uneasiness apart from the feeling of danger, we are driven to the conclusion that they, too, conceive of a normal order of things, that they recognise any departure from such order, and are, therefore, in so far rational.

Some of the most striking instances of brute superstition have been observed in dogs. We were once witness to an instance of this kind. A dyer in a northern town had a very white fleecy poodle, and from some freak he dyed the animal a rich, full shade of magenta. As he was going along the street of his village, attended by the poodle, a notoriously pugnacious terrier ran up to accost the stranger, perhaps in peace or perhaps in war. But as soon as he came near enough fully to recognise the un-dog-like hue of the poodle, he stood to gaze a moment and then fled as fast as his legs could carry him. His notions of the fitness of things had received a rude shock.

We once knew of a dog named Tab, by no means deficient in intelligence, who was always greatly alarmed at a thunder-storm, so much as to be rendered positively ill. It is difficult to ascribe this fright to the dread of bodily injury.

Much more striking instances of this kind are on record. A very vicious terrier was once just on the point of attacking a performing monkey, when the latter took off his cocked hat and saluted him very gracefully. The dog at once bolted under some shrubs and would not reappear until the monkey and its owner had left the premises. Such facts which have been collected and recorded by Dr. G. J. Romanes are utterly inexplicable unless we admit that the dogs have deduced from their experience some rude idea of an order of Nature, of which the instances given are violations. In all probability such cases show that brutes are able to sum up their observations in the form of general propositions.

The First Appearance of Germanic Tribes in Europe.—According to Montelius (*Archiv. fur Anthropologie*) the immigration of these tribes took place towards the end of the Stone epoch, about 4,000 years before our era. He supposes that they came along the cost of the Black Sea, and penetrated into Gothland by way of Denmark.

THE UTILITY OF BEES.

(*Concluded from p.* 597.)

EDMUND AGASSIZ, a bee-owner of Switzerland, writes thus to *La Nature* :—

'ith us no one questions the utility of bees for en- , the fecundation, and in consequence the pro- eness, of fruit-trees in general. As for the grain I have never remarked that the bees visit the t, at least in our country. At the time when the is in bloom other flowers supply an abundant sion for the bees, which always visit by preference plants which secrete most nectar. It is the same the vine. With us the bees do not visit it, or when the fruit is very ripe. Still, I have seen them nally visiting the vines, but finding little, they one elsewhere.

me years ago I read in a small agricultural journal r from a person who complained of having no n his trees, and foolishly ascribed this defect to the which he thought exhausted the trees by sucking uices. Now, the spring of that year was exceed- unpropitious; the blossoming of the trees had uined by cold, wind, and rain. The bees had not able to fly about, in consequence of the bad er, so that they could not fairly be blamed for the ef. Fertilisation had failed, not only because the not been able to visit the drenched and im- ded blossoms, and the wind which, in a assists in the work, though in a hap- could not convey the clotted and ne pollen from one flower to another. No one e trouble to reply to this correspondent.

any case the culture of bees cannot be too much aged. Here in Switzerland agriculture is carried to t height, especially rational apiculture with im- hives. We have many societies, lectures, and ions. I shall at the season make further observa- s to the visits of the bees to the wheat when in "

following passage from the *Australian Times* es consideration :—

over rarely produces fertile seeds in New Zealand, e the humble-bees necessary to its fecundation t found there. Mr. Douglas, of Motiti, has just ed a nest of humble-bees in the hope that these may prove a remedy for the situation. Darwin ed the following striking proposition: If we o gather fertile seeds of clover and of pansies, ist have cats!" In fact, humble-bees are necessary e fecundation of these plants, and as field-mice are ond of honey and destroy them, we must protect wls and the cats which kill the field-mice. Mr. A. llace, in his grand work "The Geographical Dis- ion of Animals," informs us that the entomological y of New Zealand corresponds to its botanical y. An analogous fact is observed in the Gallapagos s, which are still poorer.

h reference to the remarks of M. Edmond Agassix, l above, that bees do not visit the vines, at least in erland, M. Jobard, of Dijon, writes that in the Côte the facts are very different. This is shown by the llowing letters, Mr. Henri Maitre, of Chassagne, in ôte d'Or, writes, "Another proprietor and mysel assagne, are the only persons here who keep bees. he arbours and walls of our gardens are each year d with splendid clusters. They are indubitably the finest in the village, and our common friend M. Monniot can tell you if I exaggerate."

M. Furgeot, of Mersault, in the same department, writes, "I know a neighbour who has a fine hive, and his trees are generally envied for their fine fruits. The vine in his court produces large grapes, though it is considered to be of a small-fruited variety."

M. Froissard, an eminent agriculturist of Anney, writes, "I am perfectly convinced that M. Jobard is right. It is with plants as with ourselves. Their reproduction by consanguinity, if I may thus express myself, ultimately reduces every organic species to rachitism. The crossing of the pollen prevents this degeneration, and the bees effect such crossing as they gather pollen from flower to flower. I have earned, by way of amusement, 1,000 francs yearly by my eighteen hives, rationally managed. If persons of influence would take up this question they would confer a wonderful service on our peasantry."

By way of hearing all sides of the question we quote the following remarks from a work entitled "Cameos from the Silver Land," by E. W. White, F.Z.S. (London: Van Voorst): "The people of Rioja have a great horror of bees, and allow no hives within leagues of their city, asserting that they destroy both fruit and flowers, especially of the grapes and oranges." Mr. White called this "an ordinance based upon ignorance," an opinion with which we should be disposed to agree. But we should like to know the origin of this strange notion, and upon what facts, real or imaginary, it is founded.

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents, nor can he take notice of anonymous communications. All letters must be accompanied by the name and address of the writer, not necessarily for publication, but as a guarantee of good faith.

COLOUR OF THE WINGS OF *CATOCALA SPONSA.*

I have heard that at a recent meeting of the Entomological Society there was exhibited a specimen of a *Catocala*—believe *sponsa*—in which the hinder wings, instead of the ordinary red, were of a rich purple colour. Can any of your entomological readers say whether this was an anomaly, or whether the specimen produced was a female, which, I am told, is very rarely to be met with? G. G.

THE UTILITY OF BEES.

I have read with much interest this article, which appeared in the SCIENTIFIC NEWS for December 14th, 1888, but cannot agree with it as regards the fertilisation of cereals, especially wheat. Mr. A. S. Wilson, after careful experiments and observations, came to the conclusion that self-fertilisation is the rule among cereals.

Cross-fertilisation, no doubt, does occasionally take place, being generally effected by means of the wind. I never yet saw a bee in a wheat-field, and I should like to know what reward they get for fertilising the wheat. E. B.

Great Malvern.

[They could certainly find pollen.—ED. *S. N.*]

ANSWERS TO CORRESPONDENTS.

L. B. B.—The experiments of Ludwig and his pupils show that a supply of oxygen is necessary to the activity of the cardiac nerve-centres. *In vacuo* or in CO_2 the heart soon ceases to beat.

DIARY FOR NEXT WEEK.

Tuesday, Jan. 1.—Royal Institution, Albemarle Street, at 3 p.m.—*Clouds and Cloudland*, by Professor Dewar, F.R.S.

Wednesday, Jan. 2.—Society of Arts, John Street, Adelphi, at 7 p.m.—*How Chemists Work—an example to Boys and Girls*, by Professor Armstrong F.R.S.

Thursday, Jan. 3.—Royal Institution, Albemarle Street, at 3 p.m.—*Clouds and Cloudland*, by Professor Dewar, F.R.S.

Saturday, Jan. 5.—Royal Institution, Albemarle Street, at 3 p.m.—*Clouds and Cloudland*, by Professor Dewar, F.R.S.

SELECTED BOOKS.

Astronomy with an Opera Glass. Popular Introduction to the Study of the Starry Heavens with the simplest of Optical Instruments. With maps and directions to facilitate the recognition of the constellations and the principal stars visible to the naked eye. By G. P. Serviss. London: Sampson and Son. Price 7s. 6d.

A Text-Book of Elementary Metallurgy, for the use of Students. By A. H. Hiorns. London: Macmillan and Co. Price 4s.

A Sketch of the First Principles of Physiography. With Maps and numerous Illustrations. By J. Douglas. London: Chapman and Co. Price 3s. 6d.

The World's Inhabitants; or, Mankind, Animals, and Plants. Being a Popular Account of the Races and Nations of Mankind, Past and Present, and the Animals and Plants inhabiting the great Continents and Principal Islands. With about 900 Illustrations, representing all the Types of Mankind, their Home and their Public Life, together with many of the Principal Types of Animals and Plants. By G. T. Bettany. London: Ward and Lock. Price 7s. 6d.

Seas and Skies in many Latitudes; or, Wanderings in Search of Weather. Maps and Illustrations. By R. Abercromby. London: Stanford. Price 18s.

A Short History of Natural Science. Fourth edition. With Corrections and Additions. By Arabella B. Buckley. London: Stanford. Price 8s. 6d.

Electric Bells, and all about them. A Practical Book for Practical Men. With more than 100 Illustrations. By S. R. Bottone. London: Whittaker. Price 3s.

On the Senses, Instincts, and Intelligences of Animals. With Special Reference to Insects. By Sir John Lubbock, Bart., M.P. With 100 illustrations. London: Kegan Paul, Trench, and Co. Price 5s.

Elementary Commercial Geography. A Sketch of the Commodities and Countries of the World. By H. R. Mills, F.R.S.E., Lecturer on Commercial Geography in the Heriot Watt College, Edinburgh. London: C. J. Clay and Sons. Price 1s.

NOTICES.

Binding Cases, Title Page and Index for this volume will be prepared, and will be obtainable in due course from the Publisher, 3, Great Queen Street, Westminster, S.W.

The price of the Title Page and Index will be 6d.

The price of the Binding Case for Vol. II. will be 2s. 6d.

Vol. I., bound in cloth, with Title Page and Index, 9s. 6d.—by post 10s.

Back Numbers of SCIENTIFIC NEWS can be obtained from all Booksellers and Newsagents, or direct from the Publisher, 3, Great Queen Street, Westminster. Vol. I. price 6d. each, or by post 6½d.; Vol. II. price 3d. each, or by post 3½d.

METEOROLOGICAL RETURNS

For the ten weeks ending on Monday, Dec. 17th, 1888. Specially prepared for SCIENTIFIC NEWS from official reports.
